The Miners' Federation at first proposed to leave the care of the sick to the Friendly Societies, but has now changed its attitude and advises its districts to work the Act in their own interests; some have acted on this advice, and it is expected that eventually the Federation—some 600,000 strong—will make themselves into an "approved society." In the Chesterfield district there are very large collieries and some of the pledges to resign were made on conditions regarding them. Negotiations are going on. The Commissioners have been called upon to decide whether various ships' officers come under the Act. They have decided some cases and reserved others for further consideration—another illustration of the haste with which the Act was forced through Parliament. Traveling expenses are to be allowed to county insurance committees on a declaration that the amount has actually been paid by the member applying for it, who must apply personally—conditions which are exciting no little resentment.

As to the dispute with the profession rumors of a coming compromise have been floating about all the week. Many newspapers have given currency to a statement on the authority of the Press Association, that the Cabinet on Monday had practically agreed to increase the payment of the medical men on the panel to 7s. 6d. But this could only be a mere *ballon d'essai;* for the Chancellor, as I told you, had distinctly stated that he would not bring the matter before his colleagues until next week and then he would make known their decision.

Guy's Hospital new laboratories are well worth inspection by any one interested in the progress of research and the means of study. The lecture theater, which accommodates sixty students, is in the basement, where also are hot and cold rooms, a dark room for micrographic work, the store room, and the high-power electric centrifuge. On the ground floor lavatories and store rooms are located; above these the practical pathological and bacteriological laboratory. The floor above that is for general microscopical work, in which half a dozen research students are provided with places and the Gall student of pathology has a private room. Here the examinations of the clinical material for the wards are carried on. The third floor has a room for the lecturer on pathology and a large research laboratory. The fourth floor contains general laboratory, operating theater, and accommodation for animals being kept under close observation. Above this, on the roof of the building, is provision for other animals.

Sir Almroth Wright gave an address yesterday at the opening of the *x*-ray and bacteriological department of St. John's Hospital, Lewisham, erected as a memorial to King Edward.

The Lord Mayor (Sir T. Crosby, M.D.) yester-

day issued an appeal on behalf of the Hospital Saturday Fund, which he spoke of as well managed and doing excellent work.

Deputy Surgeon General T. J. Crowley died on October 5. He entered the naval service in 1883 and was rapidly promoted for exceptional ability, in every step receiving the greatest respect of his confrères.

Dr. E. M. Light, who held a conspicuous position in the insurance world, died on October 1 at the age of 52. He graduated at Cambridge in arts and medicine in 1887-8.

OUR BERLIN LETTER.

(From Our Regular Correspondent)

CHEMOTHERAPY OF SEPTIC CONDITIONS—ARGATOXYL—SANATORIA IN GERMANY—TUBERCULOSIS AMONG THE MIDDLE CLASSES—ISOLATION IN THE HOME—BACILLUS CARRIERS.

BERLIN, August 15, 1912.

THE chemotherapy of septic conditions was the subject of a paper read before the Society of Internal Medicine and Pediatrics by P. Rosenstein. The preparation used by the author is an acid compound of atoxyl and silver. This salt is dissolved only with great difficulty. Its action is a selective one. For this reason it is supposed to have very slight toxicity. Particularly good results were obtained in septic conditions in which other methods of treatment had failed. The above remedy was employed in cases of carbuncle, abscess, peritonitis, septic scarlet fever, puerperal septicemia, otitis media, and muscular rheumatism. There are three different modes of action: The fever may suddenly subside; it may fall gradually; or an abscess may be formed. The remedy may be injected intravenously or intramuscularly. In the discussion Zülzer reported that he had employed the remedy in twelve cases of sepsis, in four of which the result could not be attributed to the argatoxyl. In four other cases, however, the good and rapid outcome could undoubtedly be ascribed to the use of this drug.

A large number of interesting papers were presented before the sixteenth general meeting of the Central Committee for the Campaign Against Tuberculosis. According to the business report there are at present in Germany 138 sanatoria with provision for 14,079 beds. Regarding three months as the average period of treatment, as many as 56,000 patients can be provided for annually. In addition there are 21 children's sanatoria with 1,352 beds and also 100 institutions with 8,644 beds for scrofulous cases, and those suspected of having tuberculosis. There are as yet insufficient accommodations for the care of advanced cases.

The campaign against tuberculosis among the middle classes was the subject of a discourse by Dietz of Darmstadt. The Red Cross Society has established a special division, a sanatorium for persons of moderate means, in the maintenance of which the Central Committee has cooperated. The speaker included among the middle classes all those persons who are not subject to compulsory insurance and who have not the means to enter private sanatoria. There are, therefore, included merchants, officials, farmers, university men, and artisans with a moderate income. For artisans there are systems of private insurance, but these are not sufficiently utilized, so that compulsory insurance has been proposed for these individuals. In the German public sanatoria, according to the estimation of the speaker, there have been treated during 1911 as many as 6,600 of the middle class. It is now possible to decide the question whether it is desirable to treat in the same institution individuals belonging to the laboring and to the middle classes. The answer is, no. Diverging political and personal inclinations make this association irksome to both classes. There should be separate divisions in the same institution, or still better, separate institutions. At the present time more than ever the middle classes are availing themselves of the advantages of voluntary insurance and funds are being set aside for the establishing of beds for those of moderate means.

The isolation of the tuberculous individual in the home was the subject of an important paper by Ranke of Munich. The ideal solution of this problem would be the sanatorium treatment of all cases. Since this is impossible the next best step is efficient isolation in the home. But this is frequently not feasible, for there are 40,000 families in Berlin that each live in one room. If the tuberculous patient occupies his own room, but if he still mingles with the rest of the family, periodical disinfection of the dwelling should be carried out. Close scrutiny should be kept of all cases belonging to vocations, such as those of school teachers and those that are concerned in the handling of food. Of greatest importance are the training of children in habits of cleanliness, the establishment of compulsory notification of tuberculosis, and finally the unremitting campaign of education.

Bacteria carriers was the subject of a closely related theme discussed July 4 before the Medical Society by Sobernheim. That infectious agents are carried about by the healthy as well as by the sick is a fact that has been known for a long time. It might be concluded that this is of no great significance since the bacteria are so widespread. This attitude is a false one and leads to serious errors of omission. In Berlin there have been found among healthy children 7.6 per cent. of diphtheria bacillus carriers. Inoculation experiments on animals have shown that the organisms in the bacteria carrier are just as virulent as those present in the sick individual. Under suitable treatment the organisms in the former should disappear in from one to four weeks. The bacteriological rather than the clinical cure should be the aim both in private and in institutional practice.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

THE MODE OF DISSEMINATION OF AMEBIC DYSENTERY—THE RAT-CATCHING CAMPAIGN—THE PLAGUE.

MANILA, P. I., September 14, 1912.

THE regular monthly meeting of the Manila Medical Society was held in the amphitheater of the College of Medicine and Surgery, University of the Philippines, at 8:30 P.M., September 2, 1912. The first paper read was entitled: "An Experimental Investigation of the Parasitism and Pathogenicity of Species of Ameba and Entameba," by Dr. E. L. Walker. The author of this paper has been almost exclusively engaged in working upon this problem in Manila, for several years, and his conclusions are of the greatest importance in throwing additional light upon the pathogenicity of amebas in tropical countries. Dr. Walker stated that there are distinct biological differences between the

pathogenic and non-pathogenic amebas, especially in their size and the number and arrangement of their nucleoli. It will be remembered that all surface waters in the Philippine Islands that have been examined up to the present time, that are not thermal or strongly chemical, have been positive for amebas. In all of Dr. Walker's work, however, he did not find any pathogenic amebas in any of the waters which he examined. He is of the opinion that the disease is ordinarily transmitted through food handled by servants and others who have amebic dysentery and who work in kitchens, and perhaps, also, by the indirect method of using the stools of those who are sick with dysentery to fertilize vegetables, or, as is so frequent in the tropics, of using fecal matter as an insecticide. In the use of vegetables, like lettuce and cabbage, it will be apparent that if these are sprinkled from time to time with ameba-infected fecal matter, and such vegetables are eaten raw, there is considerable danger of conveying the disease. He thinks that the chronic cases, or perhaps they may be regarded as carriers, are also largely responsible in harboring the infection and distributing it to others by ways that will readily suggest themselves. He believes that the ordinary amebas in the water supplies of the Philippines may be safely disregarded. In the discussion which followed, Major Ashburn, of the Tropical Board, and Dr. Heiser, the Director of Health, requested the opinion of Dr. Walker as to whether his conception of the method of transmitting the disease would lead him to recommend any changes in the hygiene and prophylaxis in connection with drinking water, or the ordinary rules with regard to the eating of vegetables in the raw state. Dr. Walker replied that he could not recommend any change in the general public health measures. He thought, however, that considerable advance had been made in the study of this disease, and facts had been produced to enable the health officer to take steps to prevent the spread of dysentery.

The campaign of rat-catching which has been so persistently carried out by the Bureau of Health since the first case of human plague occurred, on June 17, has finally been rewarded by the detection of plague among rats. On August 31 the first plague infected rat was found at No. 351 Calle San Sebastian. This is in the same block in which the three cases in human beings occurred. On September 7 an infected rat was found at No. 104 Calle Santa Rosa, and another at No. 215 Calle Echague. These addresses are in adjoining blocks to the infected block mentioned above. All rat-catching efforts have now been concentrated upon this infected area. During the first week no general cleaning-up measures were undertaken; trapping and poisoning, and other methods of catching rats were alone carried out. This was done with the idea of not causing the infected rats to scatter to other portions of the city. Work has now been commenced at the outer borders of the infected territory and block after block is being cleansed. As soon as the cleaning measures at a given premise are completed, the owner is required to install the necessary metal garbage cans and to carry out such rat-proofing measures as may be deemed advisable by the sanitary engineer. This work is gradually proceeding inward toward the infected block, so that rats are literally being driven before the sanitary force, and when all of the workers meet at the center, the result should be a rat-clean district. It is also suspected that many of the rats are harbored in the closed storm-water drains, and efforts are now being made to fumigate these with sulphur.

The whole plan of campaign is now being based upon removing all available sources of food supply, so that the rats will be driven to the traps and to eat the poisoned bait which is set for them. This plan is very much handicapped by the fact that the infected area is in one of the large retail districts of Manila, and enormous quantities of food, such as corn, rice, potatoes, sugar, and other things of this kind are kept in baskets, and during the night hours rats have access to it.

There have been no cases of plague among human beings since August 22, and the total number of cases and deaths in Manila to date have been seven.

At Iloilo there have also been seven cases and seven deaths, the majority of which have occurred, at different times, in one house—this in spite of the fact that the house was thoroughly disinfected and sprayed with petroleum each time that a human case had occurred. The campaign against the plague is proceeding along the same lines at Iloilo as in Manila. So far, no plague infected rats have been found. The work is considerably handicapped by the lack of proper municipal ordinances to enforce sanitary measures, and the reluctance of the municipal council to grant the necessary legal authority.

In order to meet the requirements of the Philippines, enormous quantities of foodstuffs are imported from China and Japan. These consist largely of potatoes, onions, in open crates, and eggs, garlic, and foodstuffs peculiar to Chinese and Japanese, in baskets. Such cargo arrives in steamers almost daily from China and Japan, and as much of it is shipped from plague infected centers, the opportunity for plague infected rats to be introduced therewith is almost unlimited. On account of the great dependence of the Islands for their food supply upon these sources, it is, of course, impracticable to prohibit its importation, and in view of the enormous quantities of such cargo, it is impracticable to unpack it in order to free it from rats before it is introduced into the country, so that, in spite of the constant vigilance which is exercised, it is apparent that importations of plague rats in cargo may occur from time to time. It is indeed remarkable that the Philippines should have remained entirely free from plague for a period of over six years when the disease is present in epidemic form within a comparatively few days' steaming distance of the Islands. So far as known, no human cases have passed the maritime quarantine inspection at the ports of entry.

3. Midwives in Massachusetts. J. L. Huntington.
4. Chronic Invagination of the Ileum, Secondary to a Lipoma of the Intestinal Wall. H. W. Goodall.

2. Treatment of Enlarged Cervical Glands.—J. S. Stone emphasizes the following points: Cervical adenitis is always a secondary complication. Prompt removal of the primary cause, if this is possible, is by far the best method of cure of the adenitis. In those cases in which

the glands themselves have broken down hygienic and medical treatment cannot alter pathological facts. Surgical treatment determined by the existing conditions is of the utmost importance, while hygienic and medical treatment are useful aids which should not be neglected, but which should not assume undue importance.

4. Chronic Invagination of the Ileum.—H. W. Goodall notes that lipomata of the intestinal wall are rare. The clinical signs and symptoms arising therefrom are those of chronic invagination of the intestine. Dewis in 1906 reviewed the literature of intestinal lipomata and found but 44 cases reported. The situation of the tumors was recorded as follows: duodenum 6, jejunum 4, ileum 7, cecum and colon 5, sigmoid 5, rectum 6, small intestine 2, intestines 1, unknown 6. The rarity of intestinal lipomata was, however, of secondary importance in the case reported by the author as the symptoms were those of chronic invagination, the recognition of which led to the proper treatment and the final cure. It is of interest to note that 16 of these reported cases of lipomata caused an invagination of the intestine; whether or not the remaining cases presented symptoms of invagination one is unable to say. The author has brought out the following facts: A chronic intussusception may be (a) primary or (b) secondary to malignant or non-malignant disease. The clinical course regardless of the cause is often suggestive of malignant disease. The diagnosis is rarely made before operation or death, owing to the unfamiliarity with the clinical history and findings. The clinical history in the majority of cases is alone sufficient evidence for making a diagnosis. The history combined with typical tumor findings allows a positive diagnosis to be made. Resection of the bowel offers a cure and should be attended with a low mortality.

1. The Treatment of Cancer on Biological Principles.—J. Ewing states that in attempting to build up a rational therapeutics of cancer, it is highly important to realize that the factors concerned with the incidence, growth, and constitutional effects of one type of cancer may be widely different from those concerned with other forms of the disease. Therefore, it is a common experience to find that one type of cancer responds to a serum or vaccine with encouraging results, while another behaves in exactly the opposite manner. Even in the same stages of the same variety of cancer, different individuals, as remarked by Vidal, seem to react in a different manner to the same agent. Hence there is need of much more comprehensive study of the effects of the disease before an efficient serum therapy can be properly controlled. Furthermore, the widely different etiology of many carcinomas, and the complex altruistic relations of the different tissues concerned, foreshadow serious obstacles in the way of a paninmune serum or a vaccine. If chorioma depends for its growth upon irregularities in lutein secretion (Pick), the proper point of attack is not the tumor itself but the lutein cell. There are interrelations between the sexual organs which may eventually demand attention in the attempt to control aberrant growths in these organs. The regeneration of squamous epithelium is markedly related to the activity of the thyroid gland, and several organs and tissues respond notably to variations in the activity of the hypophysis. Perhaps the study of internal secretions may open new avenues of approach for serum therapy in cancer. Thus, from a general survey of present conditions, the complexity of the problems seems to bar the hope that a specific treatment of cancer will shortly become of practical importance. Meantime, it may not be amiss to suggest that the combination of several methods, each ineffective alone, may increase the palliative effects and even lead in occasional instances to a virtual cure of inoperable cancer.

4. Constipation and Anemia.—Beverley Robinson asks, how may cases of anemia and constipation be cured? First, it is essential for the patient to go to the closet every day at a fixed time; usually, soon after breakfast is best. Again, it is necessary for the patient to have the diet properly regulated, not to overeat, to avoid foods that are known to be constipating, for a while or until immunity is established; to avoid excess of sweets and uncooked fruits or vegetables. Proper daily exercise in the open air, particularly walking, is obligatory. No fashionable observances or unwise advice should be permitted to interfere with the above régime. Of drugs, aloin in minute or small doses, given as granules or tablets, at dinner or at bedtime, is the most useful and least objectionable. Frequently it may be combined advantageously with belladonna, strychnine, and ipecac. When the daily evacuation has been delayed or prevented from some accidental cause, one or two glycerine suppositories will give a sufficient movement in a few minutes, and are preferable to other local means. Without strict attention being paid to the preceding instructions, it is frequently almost useless to insist upon iron or arsenic in any form, or combined.

8. Early Diagnosis of Laryngeal Tuberculosis.—W. Lamberson states that every tuberculous patient should have a laryngeal examination made when first seen, and frequently during treatment. Tuberculous involvement of the larynx is not proportionate to the extent of the disease in the lungs. Many cases of serious tuberculous laryngitis may be aborted by recognizing the importance of, and treating a slight or intermittent huskiness of voice at the proper time. One should not wait for the typical, pear-shaped swelling or anemia before making a diagnosis of laryngeal tuberculosis. The majority of cases start with hyperemia rather than anemia.

9. Refraction without Cycloplegia.—N. J. Weill notes that in competent hands under absolute cycloplegia skiascopy is mathematically more exact for refractive measurements than is the ophthalmoscope in equally competent hands, assisted with the ophthalmometer to estimate the corneal astigmatism and the trial lenses for the check subjective test. For practical, satisfactory results, for the patient, the latter method, without cycloplegia, is generally applicable, equally trustworthy, and preferable for the reason that the patient is not incapacitated, inconvenienced, or alarmed.

1. Sterility and Impotence in the Male.—T. Belfield

points out that the essential value of the testis is shown by many observations not to be spermatogenesis only, but the transformation of overgrowth into energy. When spermatogenesis is prevented the testes invariably present one striking feature, namely, a pronounced increase in the number and size of the interstitial cells. There is a close relationship between the ductless glands and the testes. In a case of so-called "retrograde puberty," the administration of adrenal substance relieved the symptoms. The recognition of the excretory function of the testis throws light on its frequent invasion by mumps, typhoid fever, etc., and the infections of the epididymis, which is the modified kidney of cold-blooded vertebrates, may also frequently occur through the blood.

2. **Prolapse of Uterus and Vagina.**—W. J. Mayo classifies prolapse cases into three groups: First, those occurring during the child-bearing period, in which there is usually supervaginal hypertrophy of the cervix which may amount to from 4 to 7 inches. The resulting cystocele and rectocele are seldom extreme. In these cases the author has found that high amputation of the cervix, not closer than ½ inch to the internal os, in connection with the external Alexander operation on the round ligaments, will cure at least 96 per cent. of these cases, and with the elongated cervix, the anterior vaginal wall, carrying with it the bladder, can be transplanted upward several inches in the amputation, and occasionally the uterosacral ligaments have been shortened at the same time. The author objects to any general indiscriminate use of the Alexander operation, but it is valuable in these cases. As to the effect on future pregnancies, he says that round ligaments undergo hypertrophy and involution like the uterus, and he has not observed any bad influence in these cases. The second group of prolapse cases occur in middle-aged patients, and the operation used at Rochester in cases with marked cystocele and non-atrophic uterus is the Watkins-Wertheim operation, and this has been done more satisfactorily since they have used the Frankenthal technique. In the treatment of prolapse in elderly women they have found an operation that they have used for eighteen years, and which they call the "vagino-pelvic fixation operation," the most satisfactory. Its principles are simple: the vaginal wall with its attachments to the cervix lies outside the body. By removal of the uterus, and usually of the ovaries and tubes, the round and broad ligaments can be secured high in the pelvic cavity and that part of the vaginal wall which was attached to the cervix outside the body is fixed to the round and broad ligament stumps inside the pelvis.

3. **Hygiene of Swimming Pools.**—N. P. Ravenel states that it must be admitted that contagious diseases can be spread by means of artificial swimming-pools, and that if the water contains the germs of typhoid fever they can be taken into the body. With ordinary waters and with a pool of good capacity, the change once a week keeps the water in fairly good condition. The addition of hypochlorite of lime is a simple and cheap procedure which insures absolute safety.

7. **Chloroma.**—By W. L. Bierring. (See MEDICAL RECORD, Vol. 81, page 1115.)

8. **Reconstruction of Ball and Socket Joints.**—P. W. Roberts reports a case of tuberculous hip-joint disease in which the half-destroyed head of the femur was bound down by strong adhesions and was freed and removed, being sawed off in the middle of the neck. An ivory pin 1 inch long and three-sixteenths of an inch in diameter, threaded its whole length, was then screwed into the stump of the neck, and after the removal of a part of the body of the astragalus the remaining portion was screwed down hard on to the cut end of the femur, and, secured in this way, the parts held firmly. The newly formed head was replaced in the acetabulum, the wound was closed and the leg was put up in a long plaster spica. The subsequent history was uneventful. At the end of ten weeks the graft was found united with about 30 degrees of voluntary motion. The author believes that the same method might be employed in disease of the shoulder-joint, and that one may look for possibly a great reduction in the length of time of treatment of tuberculous hip-joint disease by the use of this method.

1. Ventral Hernia. W. H. Battle.
2. A Case of Septic Thrombosis of the Left Sigmoid, Left Cavernous, and Left Inferior Petrosal Sinuses, with a Suggestion for Treatment in Future Cases. C. A. Ballance.
3. The Prevention and Cure of Beriberi. H. Fraser and A. T. Stanton.
4. Temporary Partial Heart-block Occurring as a Sequel to Acute Pneumonia. A. L. Dykes.
5. Spinal Analgesia. Report on 400 Operations at the Military Hospital, Aldershot. J. W. H. Houghton.
6. Ovariotomy about Forty Years After a Discharge of Fetal Bones Through the Rectum; Recovery. Death a Year Later at the Age of 78 from Strictures of the Small Intestine and of the Common Bile-duct. J. D. Malcolm.
7. The Life Cycle of the Organism of Syphilis. J. E. R. McDonagh.

2. **Septic Thrombosis of the Sigmoid, Cavernous, and Petrosal Sinuses.**—C. A. Ballance reports a case of this condition occurring on the left side in a boy aged 12 years. In spite of prompt surgical intervention death occurred. Thrombosis of the cavernous sinus may occur from frontal sinus or sphenoidal sinus infection, from cellulitis of the face, carbuncle of the neck, meningitis, sarcoma of the base of the skull, marasmus, and traumatism, as well as from extension of septic processes from the sigmoid sinus or petrous bone. The following symptoms may appear: (1) *Those due to venous obstruction*, (a) Proptosis; (b) edema of eyelids and chemosis of the conjunctiva when the thrombosis extends into the ophthalmic vein; (c) edema of the face when the facial vein is thrombosed; (d) enlargement of the frontal veins, due to diversion of the circulation through the orbito-facial anastomosis; (e) venous hyperemia of the retina and choked disc are not symptoms of thrombosis of the sinus; such congestion depends upon the obstruction involving the ophthalmic and retinal veins. (2) *Symptoms due to interference with nerves.* (a) Supraorbital neuralgia, due to irritation of the first division of the fifth nerve. This division of the fifth nerve is generally the first to suffer. (b) More or less paralysis of the muscles of the eye, which may amount to complete ophthalmoplegia, due to affection of the third, fourth, and sixth nerves. The completeness of the ophthalmoplegia indicates a change in the wall of the sinus as well as in its contents—i.e., phlebitis as well as thrombosis.

3. **Prevention and Cure of Beriberi.**—H. Fraser and A. T. Stanton have noted beneficial effects produced in animals suffering from polyneuritis by the administration of extracts from rice polishings, and all the evidence has shown that the production of beriberi in man and of polyneuritis in fowls was not to be explained by any gross nutritive defect in the ordinary sense of the term, but rather by a deficiency of some substance of whose nature and action one was ignorant. Believing in the clinical and pathological identity of beriberi and polyneuritis gallinarum, it was decided by the authors, in the first instance, to test the value of the remedial agent on fowls suffering from polyneuritis. Experiments previously recorded have shown that the active substance is soluble in water and in 91 per cent. alcohol. In alcoholic solution it retains its activity unimpaired for months, and the first test was carried out with an alcoholic extract. Cases of polyneuritis were obtained in the ordinary way by feeding fowls on polished rice, and as soon as an animal showed distinct evidence of the disease it received the remedial agent; throughout the treatment the fowls were fed on the rice the consumption of which had given rise

to the disease. A cure resulted in most of the cases thus treated. The administration of the extract was also of prophylactic value. The remedy has not yet been tried in human cases of beriberi.

2. The Length of Life of the Rat-flea Apart from Its Host. W. Nicoll.

2. The Rat-Flea Apart from Its Host.—W. Nicoll concludes from his investigation, that material infected with fleas and larvae may remain infected for as long as a year. This appears to be due to the fact that the larval and pupal stages in the development are greatly prolonged under the adverse conditions. Dampness, however, rapidly kills off both fleas and larvae. No direct evidence was obtained that the fleas bred under these conditions; but the appearance of larvae towards the end of some of the experiments suggests that they did breed to some extent. Fleas derived from the infected material readily attacked rats, and proceeded to multiply in the course of a short time.

Berliner klinische Wochenschrift.

September 30, *and October* 7, 1912.

Granuloma Telangiectaticum.—Hudda reports a case of this paradoxic lesion. The patient was a lad of 17, admitted to the clinic for a small ulcer on the palm of the hand. This had succeeded upon a traumatism two months before. A fold of skin had been pinched in a cleft in a wooden slab. A bluish red ecchymosis persisted for some days—in fact, it had not all vanished when a month later a tumor was evident *in situ* which gradually attained the size of a walnut, and bled freely when struck or squeezed. A physician applied a ligature to it, whereupon it fell off, but soon formed anew. The dressings could not be changed without the supervention of free hemorrhage. Patient had not come in contact with animals. When first inspected by Hudda the growth was dark red, the size of a large bean, and painless. The neighborhood was not infiltrated. A pedicle was hidden by the fungus-like character of the mass, which appeared on superficial inspection to be sessile. The entire surface was somewhat raw and covered by a deposit which was in part blackish and in part yellowish, the former hue due to dried blood and the latter to the natural discharge, which was of a penetrating fetid odor. The growth was radically extirpated, and the microscopic examination showed a connective tissue cell structure supporting numerous strongly dilated capillaries. There were but few of the conglomerations of cocci, once believed to be the active cause, but the Schridde formations were readily brought out by staining. Our knowledge has not been advanced by the report beyond the fact that cumulation of evidence continues to show conclusively that botryomyces are not responsible for these lesions.

Relationship Between the Nose and the Generative Organs.—Koblanck and Roeder have sought to extend our knowledge of this autogenetic relationship by experiments on immature female animals. If the nasal organ should be wholly or in part removed there should in theory be some influence exerted on the developing genitals. In the earliest experiments the intervention proved to be too severe, disturbing the course of the experiment. In dogs the inferior turbinal was removed. Those animals which did not react too strongly to the operation were followed up past the period of sexual development, then killed, and other genitals studied. It was found that loss of the turbinals had exerted no influence of any serious nature on the general development, but there was a remarkable arrest of development in the ovaries, uterus, and vagina, especially in the horns of the uterus. Sexual desire was also extinguished. The more probable explanation of this phenomenon is an original connection between the nasal organ and the hypophysis, as a result of which injury to the former reacts upon the latter inhibiting its normal influence on sexual development.

Atropine Poisoning.—Wolter, in reporting two cases of atropine poisoning, one fatal, quotes figures to show that a certain number of cases regularly occurs, illustrating the dependence of the incidence on fixed conditions, as is the case with many other poisons. The mortality is about 11 per cent. In the fatal case, aside from the ordinary symptoms of atropinism so commonly seen the patient had convulsions and trismus and was unconscious. The cat's eye was fully used as a biological test of the urine, vomited matter and the poisoned cordial which the patient had drunk. The temperature was high, pulse very rapid. The treatment was mostly directed to efforts at elimination. Morphine was used for the various motor symptoms which developed. Attempts were made to nourish with the sound, which made it necessary to overcome the trismus. Death which was evident from the first was preceded by cyanosis. In the second—recovered—case, the picture was similar but less severe. The various motor phenomena were controlled by chloroform inhalation. A good vitality enabled the patient to throw off the intoxication. The treatment was eliminative chiefly. The chloroform was used primarily because of the exisiting delirium.

Hemoglobinuria.—Miller writes exhaustively on this condition from the causal viewpoint. It can originate from the respiratory, digestive or cutaneous areas, from the uterus, from wound surfaces and from the blood itself. It may be due to burns, cold, overexertion, poisons, hemorrhage, pregnancy, and infections. The elimination of hemoglobin is effected by the convoluted tubes, not by the glomeruli. The lesions which appear in the kidneys are purely degenerative, not inflammatory. The jaundice which accompanies hemoglobinuria is an absorption-icterus. There is no hematogenous icterus.

Significance of Hemolytic and Anhemolytic Streptococci for the Pathology of the Tonsils.—Henke and Reiter state that the tonsils of perfectly healthy subjects may harbor both of these forms. They show the untenability of the view that anhemolytic cocci are not pathogenic. Both sorts occur alike in mild and fatal anginas. The authors seek to refute the view that anhemolytic and saprophytic cocci become hemolytic and pathogenic when raw surfaces are produced. Quinsy socalled is chiefly a streptococcus disease, and there is no difference whatever in its type as based upon the quality of the streptococci.

Postvariolous Osteomyelitis.—Batzdorff states that this lesion was first described by Chiari in 1892. Since that period remarkably few cases have been reported. It is therefore the more singular that two cases have been recorded within a few years at Breslau. The first was a symmetrical osteomyelitis of the acromion. The second was limited to one humerus, and developed very early in the course of the smallpox, in fact, rather as a complication than a sequela. The radiogram showed the presence of a large sequestrum by the seventh week of the infection. Of interest was the fact that seven years earlier the patient had had typhoid. While no Eberth's bacilli were found in the pus it is possible that the variola activated a latent typhoid osteomyelitis.

Arthritis Statica.—Strauss states that before the Röntgen era but little was known of non-inflammatory deforming affections of the joints. They were variously attributed to injury, senile or arteriosclerotic changes, trophic and metabolic anomalies, etc. Much credit is due to Preiser for light thrown upon this obscure subject. He has described some 2,000 cases of socalled static arthritis and elaborated a successful management for the

same. These cases are commonly mistaken for rheumatism, gout or sciatica. The term "static" signifies that the joint is imperfectly weighted, or, as might be said, its bearings are not right. This results from several different factors—improper balancing of the body, anomalous muscular pull, etc. Whatever the mechanism, a train of secondary phenomena is set up. The joints form an element of lessened resistance. They are readily injured, and also readily attacked in infectious processes like tuberculosis and gonorrhea. Preiser apparently ignores a dystrophic element due to anomalies of internal secretion. His management is purely orthopedic.

Deutsche medizinische Wochenschrift.

October 3 and 10, 1912.

Treatment of Circulatory Failure Especially in Acute Infectious Diseases.—Hoffmann states that this very aspect of therapeutics well indicates the progress medical science has undergone in recent years through improvements in diagnosis and experimental pharmacology. Once purely empirical the management of this condition has now developed into a true functional therapy. We have complete insight into the special action of individual remedies, and can sharply determine the indications. The introduction into therapeutics of hormones has brought about a notable transformation. We exert a favorable influence upon the circulation with adrenalin in infections, even if we cannot prove that the latter diminish the natural production of the substance. The therapeutic use of substances native to the body is surely a step in the evolution of a rational therapy. The symptoms of an acute failure of the circulation differ notably in respect to the particular source—whether the heart or blood vessels. The former is naturally expressed by dyspnea—cardiac asthma—followed by cyanosis and edema of the lungs. These attacks as a rule supervene after unusual exertion or the taking of a hearty meal. In most cases the patients survive the first attack. If the failure is vascular, we see a different train of symptoms—tachycardia, pallor, cold sweats, delirium, and unconsciousness. Ordinary swoon, on the other hand, represents a failure of the vagus nerve, especially its splanchnic branches, which recovers under posture only. In primary cardiac failure as described above we make free use of mustard paste and hot hand and foot baths or cut out the circulation temporarily from one of the lower extremities, this act replacing the ancient venesection which, however, is coming more and more into use. The aim of treatment is necessarily to unburden the weak heart. Various cardiac roborants are thrown directly into a vein, notably of late years digalen and strophanthin. When, on the other hand, the failure is peripheral caffein is rationally indicated, and especially in recent years adrenalin and pituitrin.

Potentia Generandi in Double Tuberculous Epididymitis.—Bull sums up a case as follows: The patient despite this affection is the father of three children. All the evidence upholds the genuineness of the paternity. At the same time there are some circumstances which serve to obscure the status of the case. The spermatozoids are motionless. The semen has no characteristic odor and Florence's reaction is negative, indicating a relative absence of prostatic secretion. The patient has also tuberculosis of this organ. This defect of prostatic fluid is believed in many quarters to anagonize procreation. The patient's wife shows no evidence of infection and the children react negatively to the von Pirquet test.

Renal Diabetes of Pregnancy.—Novak and two others consider the frequency of glycosuria and carbohydrate intolerance in pregnancy. The condition is not in any way dependent on the diet, and herein it is sharply differentiated from true diabetes. The question of carbohydrate tolerance is also one apart from *renal* glycosuria, which at first sight impresses us as a leakage phenomenon due to transitory permeability of the excretory mechanism. This socalled renal diabetes is said to be rare outside of pregnancy. The question now suggests itself, "has this condition any definite relationship with the autotoxic state of pregnancy?" There is no increase, but often a decrease in the sugar of the gravid blood, and, as already stated, the glycosuria is not aggravated by a carbohydrate diet. But certain gravidæ who do not present renal diabetes show a remarkable carbohydrate intolerance, as shown by the occurrence of induced alimentary glycosuria. The two facts taken side by side appear to show that either the kidneys or liver—the organs most vulnerable in gravidity toxicosis—may exhibit functional inefficiency as shown in anomalies of carbohydrate metabolism.

Chemotherapy of Sepsis.—Rosenstein refers to the use of a synthetic containing both arsenic and silver which was introduced by Blumenthal into the therapy of puerperal sepsis. He has tested its action in sepsis of various kinds and notes a quasi specific effect due perhaps to the coöperation of several factors. The disease process was checked, and a gradual improvement set in, in a certain number of cases. In other instances a marked local reaction occurred. An aseptic abscess may form at the site of the injection puncture. Another termination was the localization of a general process and the healing of the local lesion. The author believes that the drug is bactericidal, and also strongly promotes leucocytosis. Both the silver and the arsenic are believed to act by chemotherapy, *i. e.* bacteriotropic. The author has not yet ventured the intravenous method.

Sterilization by Means of Vasectomy.—Kappis covers this subject in one of the first papers published in Berlin, for, as is well known, this intervention is American, and with the exception of Switzerland, practically unknown on the Continent as a social measure. The author first takes up the work of Sharp of Indiana, who first began to vasectomize prisoners in 1899. Having learned of his results through a personal witness he decided to vasectomize a young man on the simple indication of excessive onanism which had had severe consequences, both physical and psychical. There seems to have been no direct sociologic element in the intervention. The patient was even anxious to be castrated. The author did the vasectomy without much expectation of a satisfactory result, but was agreeably disappointed. The habit was suddenly discontinued, then resumed for a brief period, but only to a slight extent, after which he has been permanently cured (eight months to date) and has recovered his health. But the author evidently regards the rationale of the cure as largely suggestive.

Röntgen Study of the Larynx and Trachea.—Réthi writes briefly on this topic. He has for a long time sought to get better negatives, using all the different angles for posing, and found the antero-dorsal very well adapted for the purpose, because it cuts out the vertebral column and also brings out the structures below the larynx. However, it is by no means easy to interpret the radiograms offhand, and the author reproduces from Sobotta's Anatomy a median lateral section of the larynx and trachea to serve as a key. The plates themselves are so sensitive that according to the author even an object like a fishbone in the larynx would be readily visible.

Opinion of Sanity or Insanity from Appearance for Experts Alone.—In a murder case a question was asked of a non-expert witness, "When you observed him (the defendant) was his appearance that of a sane or insane man?" This question was held properly excluded. The apparent condition of the mental system as to sanity or insanity is not a matter of fact merely, and involves essentially the inference and opinion of the witness. It is a matter for experts and not for ordinary witnesses.—Odom v. State, Alabama Supreme Court, 56 So., 913.

Insurance Medicine.

Disease in Relation to Accident.—Douglas Knocker says that he has long been impressed with the need for careful study, observation, and record of the above subject. He has likewise been much surprised at the divergence of views upon it, at the lack of authoritative opinion, and at the tendency of medical men to depend upon old observations rather than to study the subject anew. Knocker's paper deals primarily with disease and secondarily with the causative accident; it does not deal with accidental injury, or injury caused by accident apart from disease. The subject may be treated under four separate headings: (1) The disease is an accident. (2) The disease appears subsequently to the accident and in consequence thereof. (3) The disease existed before the accident, which causes it to get worse. (4) The disease accentuates the effect of accident.

1. Under the first heading are included processes of the same nature as that indicated by the initial accident, as, for example, infection with anthrax. Many insurance policies exclude liability for such condition, as they frequently contain a clause reading: "Injury due solely to external, violent, accidental, and visible means." On the other hand, such accidents come under the usual provisions of Workmen's Compensation Laws. Physicians must remember, too, that what to them is not an "accident" but a foreseen occurrence may in law still be determined as an accident. Thus a man suffering from arteriosclerosis and a detachment of one retina was told by a competent ophthalmologist that he would surely have a similar occurrence in the other eye if he underwent any sudden strain, lifted heavy weights, etc. The man did precisely what he was warned against, and the expected happened. In law, however, he obtained the usual indemnity from the insurance company which insured him against "accidents."

2. Diseases which are consequences of the accident may be subdivided into three sub-groups: (*a*) infection through the seat of injury by accident; (*b*) nervous diseases resulting from accident; (*c*) diseases resulting from the treatment itself. The first sub-group includes accidents with subsequent infection, and includes septicemia, pyemia, erysipelas, tetanus, e.c. In law, infection in a wound is *prima facie* part of the wounding. Only rarely it may be proved that the infection is a subsequent occurrence, not due to the acciden, at all. Nervous diseases have been the usual claims of workmen for compensation when no physical disability could be brought in reference, to an alleged accident. Numerous cases of malingering have been, of course, brought up before the courts, but since medical referees have been sitting with the judges, such diseases as "neurasthenia" due to accident have become much rarer. Under the sub-group "cure causes disease" must be considered such deformities as scars due to burns, contractures, paralysis following injury to nerves in a fracture, flat-foot following injury to bones of the foot, etc. Knocker quotes numerous legal cases illustrative of the conditions named above. Thus, an insurance company was held liable for a death from pneumonia following a fall into a damp spot in the hunting field. Such conditions as typhoid fever, "ptomaine poisoning," etc., have been used successfully as claims for damage against dairies, hotels, etc. A signalman obtained a verdict on the basis of a nervous condition resulting from fear of having an accident occur, which, however, he successfully prevented. A woman recovered damages from a man whose "practical joke" consisted in telling this woman that her husband met with a bad accident, this lie making her very ill. "Disease following processes of cure" has led to many interesting legal questions. Thus a small exostosis appeared on a workman's hand following an injury, and he was awarded annual indemnity for it, though an operation would probably have removed this "consequence of cure." His physician, however, stated that there is a definite risk of sepsis in every operation, and the court sustained his views.

3. Under "diseases existing before accident but aggravated by it" are included numerous conditions that have frequently led to fraudulent claims. Hernia and pain in the back are the worst offenders in this respect. Hernia may be very rarely due to a sudden strain, but the legal claims make it appear that this is the most frequent etiology of the condition. Tumors have been claimed to arise after some accidental injury, but the courts have usually ruled otherwise. An attack of gout in a thumb following an accident to the thumb was, however, held to be an accident, though the workman did not deny that he was suffering from constitutional gout. Cases of locomotor ataxia and of aneurysm have been held to be accelerated by accident and suitable indemnity awarded.

4. Frequently a pre-existing disease aggravates the consequences of an accident. Occasionally the granting of an indemnity in such cases appears quite unfair to a lay mind. Thus indemnity has been granted because an aneurysm that was on the verge of rupture finally ruptured after an accident; because a rheumatically weak joint has been dislocated by strain of work; because an unsupported rupture was aggravated by strain. Insurance companies protect themselves by clauses excluding pre-existing diseases and the effects of injury upon them. In an action based on negligence the weak health of the plaintiff, even if he had reached the last few hours of his life when injured or killed, is no defense to the defendant, though a reasonable jury might reduce the damages accordingly. The English Workmen's Compensation Act likewise leaves little defense to the employers in this connection; thus, rupture of an advanced aneurysm because of strain in turning a spanner was held to be an accident. Injuries following an epileptic fit, *e.g.* fall into a ship's hold, have been held accidents under this act.

Suggestions and Ideas.—Knocker reiterates the need of research in the question of accident in relation to disease. The data of such research may go far to oppose the questionable value of "expert" testimony from doctors under the guide of the lawyers employing them or the strain of cross examination. Thus the relationship of injury to the development of tumors needs careful investigation. Complete examinations of men claiming to suffer from the consequences of accident must be performed. The urine should always be examined, for headache may be due to nephritis and not to a head injury, for example. A written account of everything observed should be made on the spot and the original paper should never be destroyed, for the originals can be used in court. Diagnoses, comments, etc., should be written out separately, so as to be excluded at trial if necessary. "A medical witness is a bombshell that may blow up on either side, and in consequence should never be used except in case

of necessity." The witness that weighs most with the court is the hospital surgeon who attended the injured man, and the side that gets him will usually win. It is useless to argue that medical witnesses are impartial. They may go into the witness box intending to be fair, but a cross-examination casting doubt upon their integrity or professional skill drives them often into defence, if not defiance. A medical referee, sitting with the judge, renders great assistance, for he helps out the judge in medical matters and also curbs the imaginative medical witness. Knocker thinks that fraudulent cases have diminished very considerably since medical referees have been introduced in England.—*Meeting of the Life Assurance Medical Officers' Association.*

Relation of the Medical Examiner to the Contract.—The relation of the medical examiner for a life insurance company to the contract, is, according to Mr. Guilford A. Deitch, General Counsel, Reserve Loan Life, Indianapolis, a most important one, for upon the manner in which he performs his duties depends in a very large measure the success or failure of the company. The relationship existing between a life insurance company, in law as in fact, is that of principal and agent. In the performance of the duties entrusted to him, the medical examiner stands in the place of the company, and his acts within the scope of the powers vested in him are the acts of the company itself, and his knowledge from discovery while acting for the company is likewise the knowledge of the company. By no contractual stipulation can the company make its medical examiner the representative of the applicant. Having derived his authority to act from the company, being obliged to act in conformity to its instructions, looking to it for compensation, and acting for it in a professional capacity to gain facts for its use, the law constitutes the medical examiner agent of the company irrespective of any stipulation to the contrary in the application.

In a few of the States, among which are Indiana, Maryland, Michigan, Ohio, and Pennsylvania, the companies are shielded against fraudulent conduct on the part of the examining physician in preparing the application. In each of these States the making of fraudulent statements in an application for life insurance is made a misdemeanor, punishable by fine or imprisonment.

The ideal medical examiner, in addition to proficiency in professional skill, must be possessed of a goodly knowledge of human nature, must be endowed with ability to use such tact as will enable him to elicit from the applicant all information that would in any way bear upon the assumption of the risk, and must above all be possessed of a sense of moral duty to the company that cannot be changed by any prospect of personal profit.

In making the examination, the examiner's duty is to obtain the facts relating to the physical condition, family history, environment, habits, and morals of the applicant, that the medical director when the report is received, may have a full history of every phase of the applicant's life that would in any way affect his insurability. To obtain these facts and to fulfill the purpose of his appointment, the examiner should not limit his inquiries to those set out in the examination blank furnished him, but should take the questions there given as suggestive of the facts sought and should augment the examination by pursuing these questions in detail in order that the report to the company may bring before it a picture of the risk as full and complete as the nature of the case will admit. The trained examiner looks not alone to the responses made by the applicant as a basis for making report of his examination. From the moment his eyes fall upon the applicant he is reading in the latter's speech, facial expression, general appearance and surroundings, facts that put him on inquiry as to the existence or nonexistence of conditions that would render the risk undesirable. As between the medical examiner and the medical director, it is the duty of the former to report facts affecting the longevity of the applicant rather than opinions as to his insurability. In the doing of this, he should ever have the safety of the company in mind, and he should always give it the benefit of any doubt as to the effect of existing conditions, no matter how insignificant, which might in his opinion tend to lessen the applicant's life expectancy. The examiner should not conclude that the rejection of a risk which he has recommended as first-class, in any way reflects upon his ability or indicates a disbelief in his honesty. He must consider that the company has other sources of information which may show the existence of facts warranting a rejection, notwithstanding that the examination on its face showed the applicant to be an acceptable risk. Furthermore the examiner should not plant his belief based on knowledge of the individual case, that a certain defect in the health record of an applicant does not tend to shorten his expectancy against the experience of the medical director. The conclusion of the examiner in such a case is but a belief, while the director can prove by tables of experience that a class of risks similarly affected will show an actual loss exceeding the expected loss on approved risks. Statistics show that a greater number of the rejections by the home office of the company have previously been recommended by local examiners as acceptable risks. Although the examiner owes a first duty to his company to make the examination so careful and complete as to bring before the director all facts that would in any particular bear upon the applicant's insurability, he also owes a duty to both applicant and soliciting agent to make a full and conscientious report of the result of his examination so as to give to the applicant the benefit of all conditions favorable to him and that all mitigating circumstances may be known to the director. *Second Mid-Year Meeting of the Medical Section of the American Life Convention.*

Construction of Life Tables for the Population of the United States.—At the recent Congress on Hygiene and Demography, Mr. Miles M. Dawson, in a paper with this title, said there are no valuable mortality tables based on data obtained in the United States. It was not until the census of 1900 that anything at all worth while was done in the matter of deriving a population mortality table. That census had the advantage that several of the States and many cities in other States had adopted effective means of registration of deaths and that returns from the death registrations had been made directly to Washington. Consequently at ages other than infantile it was possible to compute the death rates in a proper manner for these registration periods and accordingly this was done. At the present time, as a direct result of the establishment of a permanent Bureau of the Census, the number of States and cities in which there is uniform and effective registration of deaths is greatly increased until now more than half the population is covered by such States and cities.

Book Reviews.

A System of Treatment. By Many Writers. Edited by Arthur Latham, M.A., M.D. (Oxon.), F.R.C.P. (Lond.), Physician and Lecturer on Medicine, St. George's Hospital; and T. Crisp English, M.B., B.S. (Lond.), F.R.C.S. (Eng.), Senior Assistant Surgeon and Lecturer on Practical Surgery, St. George's Hospital. Volume I, General Medicine and Surgery; Volume II, General Medicine and Surgery; Volume III, Special Subjects; Volume IV, Obstetrics and Gynecology. Price $24 net for four volumes. New York: The Macmillan Company, 1912.

The four volumes comprising this system consist, exclusive of the index, of a total of 4,764 pages. Each volume contains 133 pages of the complete index to the entire set. The work covers the entire ground of medicine, surgery, gynecology, and obstetrics, and is fairly complete. The large number of writers who have contributed to its pages consist of many of the best known clinicians of England, men whose eminence impresses the stamp of authority upon this product of their joint authorship. The editors have admirably acquitted the task of coordinating the enormous amount of material that enters into this work. To the American practitioners this system of treatment is valuable chiefly as a means of gleaning the modern methods of treatment as practised by their British colleagues.

Volume I includes the general subjects such as the principles of treatment, surgical technique, etc.; the infective diseases; the constitutional diseases; intoxications; general injuries; the diseases of bones and joints, of the head, spine, chest, lungs, and bronchi, and of the mediastinum, pericardium, heart, arteries, veins, and lymphatic glands and vessels. It will suffice to mention only a few of the names composing the authorship of this volume in order to indicate its strictly representative character. These names are Dr. Mitchell Bruce, Dr. Eustace Smith, Mr. Lockhart Mummery, Mr. Maynard Smith, Dr. T. J. Horder, Dr. Hale White, Mr. Ernest Lane, Lieut.-Col. Reid Roberts, Sir Thomas Oliver, Dr. E. I. Spriggs, Sir Havelock Charles, Dr. Purves Stewart, Mr. Arbuthnot-Lane, Mr. H. S. Pendleburg, Dr. Hector Mackenzie, Dr. Cyril Ogle, Dr. J. Mackenzie, Sir William H. Bennett, and Mr. Arthur Connell. It is difficult to pick out any one article for commendation, so well do they all seem to cover the ground of their individual themes. Mr. Arbuthnot-Lane presents a complete account of the operative treatment of fractures. In the ample provision of sixty pages James Mackenzie discusses in his clear style the treatment of diseases of the heart. Dr. Spriggs's article on diabetes is particularly valuable for its details in the management of the individual case. In the chapters on the treatment of pulmonary tuberculosis one notes the ample description of the methods of sanatorium treatment. A special chapter is devoted to the subject of the treatment of pulmonary tuberculosis by means of the induction of an artificial pneumothorax.

In the second volume Dr. Herbert French contributes the articles on pernicious anemia, on the other forms of anemia, and on hemophilia and aplastic anemia. Professor George R. Murray writes on leucemia and on purpura. In the treatment of the latter disease no mention is made of the recent use of human blood serum. Dr. James Torrens writes on pseudoleucemia. The article on Addison's disease is written by Dr. Otto Grünbaum. Dr. Leonard Williams contributes the articles on the administration of thyroid extract, congestion and inflammation of the thyroid gland, infantilism, myxedema and cretinism, nocturnal enuresis, and thyroid inadequacy. The articles on the surgical treatment of inflammatory affections of the thyroid gland and of exophthalmic goiter, and the article on goiter are written by Mr. T. P. Legg, while Dr. W. Hale White contributes the article on exophthalmic goiter. Mr. Arthur Connell writes on injuries of the spleen and the surgical treatment of diseases of the spleen, and Professor George R. Murray writes on splenomegaly and chronic polycythemia with cyanosis and enlarged spleen. The articles on affections of the lips are written by Mr. James Berry and those on diseases of the jaws by Mr. E. W. Hey Groves. Stomatitis and other affections of the mouth are discussed by Dr. Arthur J. Hall, and the diseases and affections of the tongue by Mr. Jonathan Hutchinson. Mr. James Berry writes on cleft palate and Mr. C. H. S. Frankau on other affections of the palate. Mr. T. P. Legg contributes the articles on diseases of the salivary glands, of the neck, and of the esophagus. The principles of dietetics and infant feeding are discussed by Dr. E. S. Spriggs. Dr. Eustace Smith writes on food fever. Mr. Edred M. Corner on abdominal injuries, Mr. T. Crisp English on the preparation of patients for abdominal operations and the treatment of patients after abdominal operations, and Mr. E. W. Hey Groves writes on affections of the umbilicus. Mr. A. W. Mayo-Robson and Dr. W. Soltau Fenwick discuss respectively the surgical and medical treatment of the diseases and affections of the stomach and duodenum in an important array of articles. Among these articles may be mentioned those on atrophy of the stomach, hour-glass stomach, perigastritis, parasites and concretions of the stomach, seasickness, and volvulus of the stomach. The article on hypertrophic stenosis of the stomach is written by Dr. Edmund Cautley. Among the writers on the diseases and affections of the intestines may be mentioned Mr. T. Crisp English, Dr. James Torrens, Dr. G. A. Sutherland, Dr. Arthur F. Hertz, Dr. Robert Saundby, Mr. Ernest W. Hey Groves, Mr. G. R. Turner, Mr. C. T. Dent and Mr. Harold Stiles. The articles on diseases and affections of the colon, and on the operative treatment of chronic constipation are contributed by Mr. P. Lockhart Mummery, with the exception of the article on colitis, which is written by Dr. W. Hale White. To Sir Frederick Wallis have been assigned the articles on the diseases and affections of the rectum and anus. Dr. H. D. Rolleston writes on ascites and on various diseases of the liver; Mr. Edred M. Corner on acute peritonitis and subphrenic abscess; Dr. Arthur Latham on tuberculous peritonitis; and Mr. James Cantlie on abscess of the liver. Mr. T. Crisp English contributes the article on hydatid cysts of the liver and Dr. G. C. Law that on tropical liver. Mr. H. D. Rolleston discusses the medical aspects of cholelithiasis and Mr. A. W. Mayo-Robson discusses the surgery of the gall-bladder and of the pancreas. Dr. A. E. Garrod writes on urinary disorders and Dr. Arthur Latham on bacilluria. Mr. J. W. Thomson Walker discusses the surgical diseases of the kidney and ureter and Dr. W. P. Hennigham writes on the medical diseases of the kidney. To Mr. Sidney G. MacDonald have been assigned the articles on the diseases of the bladder; to Mr. Ivor Black those on the penis, urethra, and testicles, and to Mr. C. H. S. Frankau the article on chronic urethritis. Mr. John Pardoe contributes the articles on the diseases of the prostate and Mr. T. Crisp English those on diseases of the breast. Among the large number of authors who contribute articles on the diseases of the nervous system may be mentioned the following: Dr. T. Grainger Stewart, Dr. Alfred M. Gossage, Dr. William Aldren Turner, Mr. C. H. S. Frankau, Dr. H. Campbell Thomson, Dr. Maurice Craig, Dr. E. D. Macnamara, Dr. Purves Stewart, Dr. James Collier, Dr. James Taylor, Dr. Wilfred Harris, Dr. S. A. Kinnier Wilson, Dr. Judson S. Bury, Mr. James Sherren, Dr. E. Farquhar Buzzard, Dr. Gordon Holmes, Dr. J. S. Risien Russell, Mr. Robert Jones, Mr. D. McCrae Aitken, Mr. Donald Armour, and Dr. Herbert French.

The third volume deals with special subjects. It opens with articles on such subjects as anesthetics, ionic medication, massage, mechanical vibration, etc., and a full description of vaccine therapy. Among the contributors to this section may be mentioned Dr. J. Blumfeld, Mr. Herbert F. Waterhouse, Dr. R. Fortescue Fox, Dr. A. C. Inman, Dr. Harold Spitta and Dr. Gustav Hamel. Professor W. J. Simpson writes on tropical diseases, Dr. C. W. Daniels on tropical fevers, and other articles on tropical diseases are contributed by Dr. G. C. Low, Dr. W. Carnegie Brown, and Dr. J. M. H. Macleod. Among the contributors of articles on diseases of the eyes may be mentioned Mr. Ernest Clarke, Mr. R. W. Doyne, Mr. Harold B. Grunsdale, Mr. Arthur Lawson, and Mr. E. E. Maddox. Among the writers on the diseases of the nose we note the name of Dr. Chevalier Jackson. Mr. William Milligan contributes a number of articles on diseases of the ear. The diseases of the skin are exhaustively covered by Dr. J. M. H. Macleod, Dr. F. Gardiner, and Dr. Wilfred S. Fox. The subject of dental surgery is presented by Mr. Norman G. Bennett.

The fourth and concluding volume of this work is devoted to the subjects of obstetrics and gynecology. The opening article on the general management of pregnancy is from the pen of Dr. J. W. Ballantyne. The complications and abnormalities of pregnancy are discussed by Dr. A. Lionel Smith, Dr. W. R. Dakin, Dr. C. E. Purslow, Dr. Herbert French, Dr. Thos. G. Stevens, and Mr. John Bland-Sutton. Dr. E. Hastings Tweedy deals with the management of normal labor and the management of labor in special presentations. Among the writers contributing articles on the complications of labor may be mentioned Dr. Cuthbert Lockyer, Dr. C. F. Darwall Smith and Dr. C. E. Purslow. Dr. J. R. Freeland writes on the management of the newborn child. The obstetric operations are

discussed by Dr. Comyns Berkeley, Dr. Llewelyn Powell, Professor J. M. Munro Kerr, and Dr. C. Hubert Robert. In the chapters on gynecology the following contributors appear: Mr. Victor Bonney, Dr. J. W. Ballantyne, Professor J. B. Hellier, Dr. W. E. Fothergill, Dr. Septimus Sunderland, Dr. H. Russell Andrews, Mr. John Bland-Sutton, Professor Walter Carless Swayne, Dr. R. H. Gibbons, Dr. W. Blair Bell, and Dr. G. Bellingham Smith.

In concluding this review it can be stated without reserve that this work represents a valuable contribution to modern medical literature in gathering together the latest methods of treatment. With its exceptionally complete index it cannot fail to be of service to the busy practitioner as a work of reference.

A Text-Book of Human Physiology, Including a Section on Physiology Apparatus. By Albert P. Brubaker, A. M., M.D., Professor of Physiology and Medical Jurisprudence in the Jefferson Medical College; formerly Professor of Physiology in the Pennsylvania College of Dental Surgery; Lecturer on Physiology and Hygiene in the Drexel Institute of Art, Science, and Industry. Fourth edition. Revised and enlarged. Price $3.00. Philadelphia: P. Blakiston's Son & Co., 1912.

One of the most important functions of any text-book is so to guide the mind of the student that he will be induced to think for himself and to reason out his own conclusions. The mere collection of a mass of facts, no matter how great their intrinsic value, will never result in the production of an able physician. It is in the performance of this function that this particular text-book is at fault. There is too little discussion of the reasons for the acceptance or rejection of theories, not a single reference is given in the entire volume, and there is almost complete absence of that stimulus to independent thought which should characterize the ideal text-book.

This fourth edition has been rather extensively revised and brought up to date. The illustrations, especially the tracings, are excellent. The omission of detailed description of apparatus from the text is very commendable. The book is well made but the text is seriously marred by numerous typographical errors.

A Manual of Clinical Chemistry, Microscopy, and Bacteriology. By Dr. M. Klopstock and Dr. A. Kowarsky of Berlin. In their "Institut fur Medizinische Diagnostik," in Berlin. Only authorized translation from the last German edition, thoroughly revised and enlarged. Illustrated with forty-three textual figures and sixteen colored plates. Price $3.00. New York: Rebman Company.

This work contains chapters on the examination of secretions of the mouth and pharynx, nasal secretions, conjunctival secretion, sputum, gastric contents, feces, urine, prostatic secretion, blood, on diseases of the skin, and a final chapter on various methods of staining, etc. It will be seen that with regard to its contents this book is similar in scope to numbers of other works. Unfortunately, however, the present volume is handicapped by being a translation, and the translator's acquaintance with the English language is not always equal to his knowledge of German. Among the words and expressions which have a foreign look we have noted the following: Kongo-paper, renin and reninogen, kryoskop, Gutceit's detection of arsenic, Essbach's reagent, brenzkatechin, natrium, thiosulphate, natrii fluorat, peptone sicc., sykosis, ovarial cysts, the tip of a knife of aloin, and many others. On page 147 we find sodium chloride and sodium chlorid within a few lines of each other; the solutions at the bottom of page 185 have a curious appearance; on page 204, kalium iodid and kalium iodide both appear, and on the same page KOI is erroneously given as the formula of "kalium iodid." Naturally, many of the methods described are those in use in Germany rather than in this country.

The Prevention and Treatment of Disease in the Tropics. A handbook for officials and travelers compiled chiefly for the use of officials in the Sudan. By Edward S. Crispin, M.R.C.S., L.R.C.P., Fellow of the Royal Geographical Society, Fellow of the Society of Tropical Medicine and Hygiene, Assistant Director of the Sudan Medical Department. London: Charles Griffin & Company, Limited; Philadelphia: J. B. Lippincott Co., 1912.

This little book, scarcely more than a mere pamphlet, has been compiled for the benefit of those traveling in out-of-the-way parts of the world. It gives useful information both in the way of avoiding diseases and also in the line of such treatment as an unprofessional person may be able to afford. The author has done his work very well indeed, and we can strongly recommend the book to travelers in the tropics; it will take up but little room, and it may prove of great value.

Dental Anesthetics. A Text-book for Students and Practitioners. With a Contribution on Analgesia. By John Bolam, L.D.S. (Edin.), Honorary Assistant Dental Surgeon, Newcastle-upon-Tyne Dental Hospital; Lecturer on Dental Materia Medica and Therapeutics, Newcastle-upon-Tyne Dental School. By Wilfred E. Alderson, M.D. (Durham), M.S., B.Hy., D.P.H., Honorary Physician, Newcastle-upon-Tyne Dispensary; Senior Honorary Anesthetist, Newcastle-upon-Tyne Dental Hospital; Lecturer on Dental Anesthetics, Newcastle-upon-Tyne Dental School. Price $1.25. New York: William Wood & Company, 1911.

This is one of the most recent volumes in the well known "Students Aids Series." Dental students and practitioners will find this a useful little book; and it is refreshing to see the way the author points out the dangers of chloroform. Though brief, the book seems to be thorough; and the tone of the book inspires confidence in the authors.

The Hospital Corps Quiz Compend. A manual for the Hospital Corps, U. S. Army Hospital Corps, National Guard Red Cross Association, and for Students and Practitioners. By Frank C. Griffis, M.D., Medical Reserve Corps, U. S. Army. Price $1.00. Columbus, Ohio: The Edward T. Miller Company, 1912.

This little book seems calculated to be useful to soldiers in the Hospital Corps of the United States Army. It is written in simple language, and is about as concise as is compatible with usefulness. It should also prove serviceable as a First-Aid manual.

Aids to Histology. By Alexander Goodall, M.D., F.R.C.P., Edin., Lecturer on Physiology, School of Medicine of the Royal Colleges; Examiner in Physiology to the Royal College of Physicians, Edinburgh. Price $1.00. New York: William Wood & Company, 1912.

This handy little volume fills a gap in this useful series. It has evidently been compiled with care, and will prove of service to the beginner and also to the more advanced student for purposes of revision. The author is well aware that histology can only be learned with the aid of the microscope, but the present book may often aid a beginner where the larger text-books would only bewilder and confuse him.

Gynecological Nursing. By Arthur E. Giles, M.D., B.Sc. F.R.C.S., M.R.C.P., Surgeon to the Chelsea Hospital for Women; Gynecologist to the Prince of Wales' General Hospital, Tottenham. With 41 illustrations. Price $1.50. New York: William Wood and Company, 1912.

This is the latest addition to the literature on nursing, and it is one of the very best books for nurses that we have seen. The author is well known both as a gynecologist and as a writer. In addition to the purely technical matter, the book gives a sane presentation of many things pertaining to nursing in general. The volume begins with an introduction, which contains an unusually fine address to nurses; the author's ideal nurse is one that we do not often meet, but he assures us that the sketch is drawn from life. This chapter should be read by every nurse; it contains more common sense and kindly advice than we have ever heard or read in the addresses which are usually inflicted on the graduating classes of the training schools. In subject matter and style the volume is excellent, and it will prove of real value to nurses.

Collected Papers by the Staff of St. Mary's Hospital (Mayo Clinic), 1911. Octavo of 603 pages, illustrated. Cloth, $5.50 net. Philadelphia and London: W. B. Saunders Company, 1912.

The present volume includes the papers written by members of the staff of St. Mary's Hospital during the year 1911, which have also appeared in other journals. A review of its contents shows the enormous field of work and activity engaged in by the Doctors Mayo and their various collaborators. The present volume includes papers on the alimentary canal, the genitourinary organs, ductless glands, thorax, and extremities. There are also papers on technique and a few general articles on a variety of subjects. A brief chapter is inserted in commemoration of Dr. William Worrell Mayo, who was the father of the present Doctors Mayo, and prominent in the establishment of the Hospital at Rochester, which has been so ably carried on by his sons and followers. It was his satisfaction to live to the ripe age of ninety years, and to see firmly established one of the greatest surgical clinics in the world.

Society Reports.

PRACTITIONERS' SOCIETY OF NEW YORK.

247th Regular Meeting, Held April 5, 1912.

THE PRESIDENT, Dr. J. W. BRANNAN, IN THE CHAIR.

Case of Paget's Disease of the Bones of the Face.—Dr. ABBE showed a patient with unusual enlargement of the bones of the face. The case was especially interesting because the enlargement had become so great that it seemed to demand surgical interference. The patient had no illnesses until fifteen years ago, when he had an attack of grippe. In 1893 he had an attack of rheumatism which resulted in cardiac involvement. At this time the enlargement of the face and head became noticeable and has since progressed. Enlargement of his cranium compelled him to wear a hat two sizes larger than formerly. His right clavicle was abnormal and was four times the volume of the left and bowed forward. *X*-ray pictures showed that cranial vault was from 1 to 1¼ inches in thickness and showed very irregular hypertrophy with some rarefaction. The change in thickness was due to a deposit of bone under the periosteum on the outer surface of the skull. This was true of all reported cases. The cranial cavity was not diminished. Dr. Abbe said that a brother of the patient had the same enlargement of the flat cranial bones necessitating his wearing a hat of size 8½. This enlargement was mostly in the back half. In both patients the bone was 1¼ inches thick in places. The patient which Dr. Abbe showed had one very distressing feature. This was a great enlargement of the upper jaw. This had resulted in the formation of a solid ivory like mass of bone which completely filled the upper portion of the mouth from the level of the alveolar border and expanded both superior maxillæ with dense bone. This had resulted in lengthening the face very markedly. Both sides were symmetrical. The nasal cavity was not affected. The etiology of the condition was very obscure. Dr. Abbe said that the chief question in connection with this case was the possibility of and the manner in which the growth in the mouth could be removed.

Dr. BRYANT thought the case a most interesting one. He had seen two or three similar cases, but none as severe as the one shown by Dr. Abbe. He thought that the changes in the clavicle were of such a character as to suggest an inflammatory basis. In none of these cases seen by Dr. Bryant was an autopsy obtained. One case had involved the upper jaw primarily and the other after extension from malar bone. He knew of no new cause or method of treatment.

Dr. ABBE in closing said that a number of autopsies had been performed in similar cases. The condition had been confused with acromegaly. In the present case the normal small shape of the sella turcica and condition of the pituitary body as shown by the *X*-ray proved that this was not a case of acromegaly. Examination of the involved bones has shown that the process was a rarefying osteitis with some mucilaginous degeneration. There were always inflammatory changes. It is probable that a very carefully conducted surgical removal of all the superior maxillary hypertrophy will leave a flat roof to the mouth and vast improvement in general appearance.

The Falling Sickness.—Dr. C. L. DANA showed a patient illustrating what he said could be strictly called "a falling sickness." Falling sickness was the name usually given to epilepsy, but there was, the speaker stated, a form of falling sickness which was strictly entitled to be so called because the trouble was characterized by "falling" alone, with no other attendant symptoms. The persons who showed this symptom dropped to the ground and immediately got up again with usually no feeling of vertigo or faintness. There was a sudden giving way of the legs which crumpled up under the patient and he would drop to the knees or upon the buttocks. Attacks of this kind did very rarely occur as a form of *petit mal*. The speaker stated that such sudden falling also occurred in paralysis agitans, in locomotor ataxia, and in persons with bradycardia as part of the phenomenon of the Stokes-Adams symptoms. The patient presented to the society had the following history: William P., aged 8. The boy came of healthy parents and was a bright and intelligent child; went to school and kept up with the boys of his own age. Had been healthy as a baby and had begun to walk about the usual time; but from the very beginning of his walking life he had had at times attacks of falling, such as he still suffered from. In the attacks the legs suddenly gave way and he dropped rather forcibly to the ground, bruising his knees and often bruising his hands. He was not unconscious or clouded at all, though at times he said he was dizzy. He would pick himself up at once and walk along, then perhaps fall again. These falls occurred so frequently that some one had to accompany him when he went on the street and take him to school. The attacks occurred in the house when he was standing quietly as well as on the street. He had never any phenomena of this kind when lying down. The attacks occurred many times a day now, and the boy went to the office with bruised legs and bruised hands, owing to the falls. On examination he was seen to stand in a cerebellar attitude, the head bent a little to the left side, and the trunk slightly inclined to the right. He walked with a curious limp, carrying his right leg stiffly as though it were wood and he were afraid to bear his weight upon it. It was the right knee which he said gave way when he fell. He could run, but was liable to fall in doing so. He sometimes fell when standing quietly. He swayed somewhat when he closed his eyes and put his feet together. He could not stand on one leg with his eyes closed. He could not walk a straight line well. He was mentally bright. His cranial nerves, including the optic, were normal except that he had a slight lateral nystagmus. He had no headache or vomiting. There was very slight trouble with the sense of hearing and the caloric tests of the auditory nerve brought out a strong nystagmus. He had no actual weakness, no paralysis or atrophy, the knee and ankle jerks are present and equal. He had no hypotonia, no anesthesia, either cutaneous or deep, though he did have some ataxia of the legs, especially the right. Speech is normal. The blood is normal; Wassermann negative. Spinal fluid negative. He was well nourished and well developed. Intestinal carbohydrate fermentation was very excessive (12 per cent.). The right hand and arm were very distinctly larger than the left, the left leg a little larger than the right. The speaker interpreted these attacks as a form of "cerebellar fit" and thought that the boy had a lesion perhaps in the form of a sclerosis or congenital defect in the left lobe of the cerebellum. Dr. Dana also reported a case of what he termed "psychic" or what some would call "hysterical" falling sickness. Mrs. B. O., aged 33, no children, came of a healthy family and was healthy as a girl until she was seventeen. At that age, after finishing school and working very hard in teaching, she had what was called "nervous prostration" and had to give up her work for six weeks. She has been married for eight years. Has had no children. She had been in good health, though not strong. Three years ago she began to have sudden attacks of falling while walking along the street. Her knees would give way and she would drop suddenly to the ground without any feeling of dizziness, faintness or unconsciousness. She would get up at once but would perhaps at once fall again. At times the falls were repeated many times and she would be obliged to stop walking altogether for a time. The attacks were more likely to occur if she was excited or nervous and then she sometimes could not stand at all. On the other hand, she sometimes fell when getting out of bed in the morning under no excitement. After one or two miles when she got fatigued she was also apt to have the falls. During the last three years there had been a period of about three months when she went without the attacks. Her life was regular and quiet at home, but she had been under a strain from loss of members of the family. Her mind was clear. She slept well and had no hysterical seizures or stigmata. Physical examination showed nothing objective. The cranial nerves were normal, no nystagmus or labyrinthine changes. There were no changes in the reflexes. There was lack of steadiness in walking a line or standing with the eyes closed. In the attacks, as she described them, there was apparently giving way of the knees without any pain or any conscious sensory disturbance. The examination of the knees and limbs showed no defect of the articulations. Dr. Dana interpreted this as a kind of mental "tic" affecting the legs instead of the face, neck or hands.

Dr. KINNICUTT asked if there was not an atrophy of the muscles of the right leg, as on superficial examination it seemed distinctly smaller than the left.

Dr. DANA said there was a distinct difference in hands and arms, there was also some difference in the legs but less marked.

Still's Disease.—Dr. VIRGIL P. GIBNEY reported a case of this affection. (See page 93.)

Dr. BRYANT said that he had had no opportunity to observe cases as young as those referred to by Dr. Gibney. The *x*-ray pictures shown had not presented the characteristics of osteoarthritis.

Dr. MEARA asked how frequently cases of Still's disease were seen in New York City. During his five years' ser-

vice in the children's wards at Bellevue he had seen one typical case; in this there seemed to be a distinct reaction between the symptoms of arthritis and the lymphatic glands. During the exacerbations of the joint disturbance the glands were distinctly enlarged. They became smaller on the subsidence of the joint involvement. In this case the spleen and liver were enlarged. There was no tuberculin reaction. There was some blood reaction. Dr. Meara then described an adult patient at Bellevue who had a chronic process involving the small joints as well as wrists and knees. He had marked enlargement of cervical, epitrochlear, axillary and inguinal glands. He had a fairly continuous temperature of 101°. His Wassermann and tuberculin tests were negative. No focus of infection was found. Salicylates produced no results. Potassium iodide, however, gave prompt relief from pain and temperature dropped to normal. The glands continued enlarged. This case was cited because of the similarity to the symptom complex, called in a child Still's disease. He asked for the citation of similar cases of arthritis in adults with marked glandular involvement. No one present recalled such a case.

Dr. Roberts said that Still, in one of his communications, described cases which had improved after an attack of measles or pertussis.

Dr. Gibney said that glandular enlargement in his experience had not been a feature of osteoarthritis in adults. In children arthritis differed from the atrophic forms so common in adults. There were frequently two to five cases of multiple arthritis in the wards at the same time at Ruptured and Crippled Hospital. Most of these cases were of the inflammatory type, but some were not. The cause was obscure and metabolic studies should be done on them.

Dr. Kinnicutt said that he had seen several cases similar to that shown by Dr. Gibney and they should be regarded as instances of the disease described by Still. In none of them had there been improvement under treatment, in fact they had progressed from their inception, leading to permanent disablement. Thymus gland, however, had not been used. He agreed with Still's opinion that several distinct joint affections in children had been described under the name of rheumatoid arthritis, but that they permitted of differentiation by careful study. There was a class which practically corresponded with the rheumatoid arthritis of adults; a second, in which the lesions were similar to those of chronic rheumatic arthritis; and finally a group which could easily be differentiated from the two former ones. In this group there was a general enlargement of the lymph nodes, also of the spleen and a multiple enlargement of the joints. There might be a moderate effusion, but the lesion seemed to be largely pariarthritic and radiograms confirmed this impression. They showed the cartilage to be preserved, an absence of osteophytic changes and eburnation of bone. The recently reported improvement in some of these cases through the use of thymus gland suggests that the underlying cause may be metabolic rather than microbic in character.

The Prophylactic and Therapeutic Value of Fresh Air in Schools and Hospitals.—Dr. John W. Brannan read this paper. He said that the title of the paper did not fully express what he wished to talk about, for what he had in mind was not so much the air within the school and within the hospital as it was the absolutely pure fresh air to be found just outside their walls. Not all of our school children nor all of our patients can be taught or treated in the open air, but a very large proportion of those who need it most can enjoy this privilege, and it should be our duty as physicians and guardians of the public health to see that they get it to the largest possible extent. Those who must remain indoors should receive the maximum amount of fresh unaltered air that can be admitted through open windows and transoms. It was a long time after the discovery in 1882 of the bacillus of tuberculosis by Koch, before the outdoor treatment of pulmonary tuberculosis became thoroughly established. But many years before 1882 tuberculosis of the bones and joints and glands in children, known probably as scrofula, was treated in the open air. The hospital at Berck, on the coast of France, was established by the city of Paris in 1861, the French believing that this form of tuberculosis was favorably influenced by the air from the sea. Even long before this date, in 1797, a hospital was founded by two English physicians at Margate, on the coast of England for scrofulous disease in adults as well as in children. This was the only institution of the kind in England, but on the continent there were between 75 and 80 marine sanatoria, situated on the Baltic, the North Sea, the Atlantic Ocean, the Mediterranean and the Black Sea. The original municipal hospital at Berck had been followed by several large private institutions, so that there were now at Berck between two and three thousand beds for children with surgical tuberculosis, about half of them maintained by the city of Paris, the others supported by private endowment. In 1904 the Association for the Improvement of the Condition of the Poor of New York, impressed by the favorable results obtained at Berck, decided to establish a small hospital for children with surgical tuberculosis at Sea Breeze, the Summer Home at Coney Island, which had been maintained for many years by the Association for the children of the tenements of the city. The number of beds was restricted to forty-three, but now that the City had finally purchased a part of Rockaway Beach there was reason to expect that a new hospital, with one hundred and fifty beds, would be constructed and completed in the course of the next two years. What had been accomplished at Sea Breeze was probably known to all present, for though the hospital was modest in size, its light had not been hid under a bushel. What he had seen at Sea Breeze during the past eight years had led him to urge that not only our patients with pulmonary tuberculosis, or with surgical tuberculosis, should live in the open air, but that all of our patients, whatever their disease might be, and all of our school children, whether predisposed to tuberculosis or not, should be placed in an atmosphere approximately the same as that out of doors.

At Berck, as at other European seaside sanatoria, the children passed the day on the beach, or on balconies open to the air and sunshine. This régime was adopted at Sea Breeze, and in the eight years since the opening of the hospital there had not been a day, in all seasons and in all weathers, that the children had not been in the open air. This applied to bed cases and up cases alike. At night the windows of the wards were wide open throughout the year. In the warm season the sashes of the windows were entirely removed. From April to November about one-third of the children, as many as could be accommodated, slept on the open porch. Throughout the summer months the ambulant children bathed in the ocean every day, and the nurses had repeatedly called attention to the rapid closing of sinuses under the influence of the sea water. During school hours the children were in a room with open windows or in a tent open on all sides, a teacher and a kindergartner being supplied by the Board of Education. The good results obtained with the children at Sea Breeze were so uniform and so striking that it was decided to provide open balconies in all the hospitals then in process of construction in the department of Bellevue and Allied Hospitals. Every ward had at least one balcony attached to it, so that every patient, whatever his disease, might have the benefit of the outdoor air which in the past had been thought necessary only for tuberculous patients. In addition to the balconies there were large wide loggias at Bellevue and roof-gardens and roof-wards on all the hospitals. Gradually storm sashes and louver windows were being added to the balconies so that even in the winter the patients could be moved out of doors, one or more sides of the balconies being always open for the free entrance of the outer air. It was unnecessary to emphasize the stimulating effect of this treatment upon patients who under ordinary hospital conditions were confined to more or less poorly ventilated wards. It was not easy, however, to express this effect in figures or in percentages of recovery. In one disease, the acute pneumonia of children, an attempt had been made to reduce the results to figures. Previous to November, 1908, the children with pneumonia were cared for in a large sunny ward in the old building. The ward was fairly well ventilated, but there was no opportunity for outdoor treatment. After moving into the new building it became customary to place the children on the balconies for three or four hours a day, unless the weather was too stormy. The good effects of the fresh air were so noticeable that in January, 1910, it was decided to place the patients on the balcony as soon as the diagnosis of pneumonia was made, and to keep them there throughout the twenty-four hours, and this practice had continued up to the present time. It was noted that the patients, with rare exceptions, improved in all their symptoms, especially during the winter months, but no comparative study was made until a few weeks ago. The results of this study were as follows: From January, 1904, to November, 1908, 274 children (one year of age and over) were admitted to the hospital, and of these 69 died, a mortality of 25.2 per cent.; in the second period, from November, 1908, to April, 1912, 391 children (one year of age and over) were under treatment, of whom 42 died, a mortality of 10.7 per cent. No investigation had yet been made of the children under one year of age, nor of the adult patients in the hospital, but it was believed that the results were approximately the same.

The observations of Dr. John Howland, the attending physician in charge of the children's service, and his assistant, Dr. B. Raymond Hoobler, apparently showed that this remarkable result of the outdoor treatment was largely due to the increased blood pressure caused by the fresh cold air. As these studies had been published, the reader did not refer to them in detail, but simply stated that the rise of the blood pressure out of doors was attributed by these observers, to the reflex stimulation of the vasomotor centers by the action of the cold air on the skin of the face and the mucous membrane of the nose. Infants under one year of age were also placed in the open air as soon as the diagnosis of pneumonia was made, and adult patients were treated on the balconies or in a room with the windows open so that the temperature approximated that out of doors. These patients uniformly did well, but no statistical study had been made of the results. The effect of the cold air in quieting the restlessness and delirium of pneumonia, especially in alcoholic subjects, was very striking.

Maternity cases were removed to the balcony in from four to seven days after delivery; during the warmer months within 36 hours in some instances. The good effects were evident to all, and particularly to the women themselves. The nurse in charge reported that the patients slept better and called for less attention than when in the ward. A week or ten days (and nights) outing on a Bellevue balcony was not a bad substitute for Lakewood or Atlantic City.

Dr. Gregory, the hospital alienist, reported that the effect of open air upon the acute insane was very beneficial, especially in the excited and restless. It had a quieting influence and induced sleep. The same was true of the alcoholic patients, of whom there were thousands in the hospital annually. The fresh air and oxygen seemed to furnish the stimulation which they greatly needed, so that they ate and slept well. It had been Dr. Gregory's experience that if alcoholics were kept in the open air they would recover much sooner than if kept in the wards. The tremulousness and anorexia and mental depression disappeared very quickly. In functional nervous diseases the value of the open air treatment was generally recognized. It induced sleep, improved the appetite, and supplied the general stimulation which patients of that class required. Patients after severe operations gained rapidly when taken out of doors. In critical cases the stimulus of the fresh air often seemed to turn the tide. The patients themselves were prompt to show their gratification, especially the women, using the words "fine," "lovely," "splendid," and "very nice" in expressing their feelings.

Passing on to the consideration of the open-air schools, the reader said that they could be divided into three groups, first, those for children with pulmonary tuberculosis; second, those for children who are anemic, underweight, and illnourished, and hence considered to be especially predisposed to tuberculosis, and third, those for normal school children who are neither tuberculous nor predisposed to tuberculosis or any other disease. The open-air school movement began at Charlottenburg and was followed in 1907 by the outdoor school at Bostall Wood in the outskirts of London under the auspices of the London County Council. Other schools were soon established in various parts of England, of which those at Bradford and Sheffield are perhaps the best known. In January, 1908, the movement spread to the United States. In Germany and in England structures especially designed for the purpose were erected for the children. In this country we had been content as a rule to make use of buildings already in use, either by selecting a room facing the south and altering the windows, or by covering and partially enclosing a portion of the space on the roof. The first school in the United States, with the exception of the hospital school at Sea Breeze already referred to, was opened in Providence. This was followed closely by the Franklin Park School in Boston. The Providence school was in an abandoned schoolhouse from which a portion of the south wall was removed and replaced by windows which could be trussed up to the ceiling. The class in Boston was on the roof of a building built for a refectory in a public park. It was freely open on all sides; protection in stormy weather was secured by curtains which could be dropped as desired. The results obtained in these schools were so satisfactory that they were soon followed by the establishment of similar classes in Hartford, Chicago, New York, and other cities. These schools varied greatly in their construction and arrangement, but they all agreed in supplying fresh air in abundance to the pupils. In Hartford the class was held in a tent, in Chicago and in New York some of the classes were on the roofs of school or hospital buildings. In the Graham School in Chicago the fresh air was obtained simply by raising the windows of an ordinary school room. Two of the New York schools were of especial interest, being located on the upper deck of old municipal ferryboats. Most of these classes were for tuberculous children who had been excluded from the public schools. The régime was the same in all—life in the open air, nourishing food, rest in bed after dinner, and the systematic use of gentle exercises. The results also were practically the same in all—gain in weight, disappearance of the physical signs, and improvement in general condition, both physical and mental. As an instance of these good results, the teacher of the class on the Gouverneur ferryboat reported that of 37 children who had been in the class for periods varying from six months to a year, 30 had been readmitted to the public schools by the physicians of the Board of Education. It should be added that the pupils had not only regained their health, but had also kept pace in their studies with the other children.

Dr. Brannan then described the second group of open-air schools, the classes for anemic children established in the public schools by the Board of Education of New York. The children in these classes had no physical signs of disease, except enlarged glands in some cases, but they were anemic, underweight, and illnourished, and many of them from tuberculous families. The first class was opened in April, 1910, in public school No. 21, in Mott street, the center of the congested Italian quarter. Twenty such classes had been authorized by the Board of Education, and at the present time eight were in successful operation in various parts of the city. The same routine was followed as in the schools for tuberculous children. The food was provided by the committee on tuberculosis of the Charity Organization, a private society, all other expenses being met by the city, through the Department of Education.

The results in all the fresh air classes were excellent. During the first winter the children in the Mott street school gained on an average 6 pounds apiece, with a corresponding improvement in all other respects. The increase in hemoglobin was especially interesting; starting at an average for the class of 71 in the autumn, the figures reached 85 in the spring, whereas a control class of normal children in the same school declined from 87 to 81 during the same period of time. At the end of the school year the twenty-one children had so improved that they were returned to their former classes and a new group of anemic children took their places. Dr. Doty, the superintendent, reports that practically all the children in the school were anxious to join the fresh air class. As the cost of the extra food was considerable and seemed likely to limit the number of open air classes, it was decided to lessen the amount of food in the new classes and in some instances no extra feeding at all had been furnished, the children having only the usual dinner provided at home. As far as could be judged by a few months' trial, the children in these later classes were doing nearly as well as in the original class of school 21.

The third group of open-air schools, those for normal children in the public schools, was in some respects the most interesting and full of promise for the future. Having demonstrated that pure air fresh from outdoors could be given not only with safety but with great benefit to school children who were tuberculous or whose health was otherwise impaired, the next step was to give fresh air to all school children. One such school was established last autumn on the roof of the Horace Mann School and had been in operation throughout the past winter with eminently satisfactory results. Another class was opened a few weeks ago in public school No. 4 at the request of a number of parents of the children. With the permission of the Board of Education the room was cut off from the ventilating and heating system of the school building and the windows were kept open as in the anemic classes. The children received no extra food, as the parents were well able to provide for them at home. It was too early yet to expect results, but there could be no doubt that they would be the same as in other cases. The chief interest, however, attached to these last schools lay in the evidence they afford that the public, and parents in particular, were beginning to appreciate the value of fresh air for their children during school hours and were preparing to demand it of the school authorities. In Chicago and other cities the movement for fresh-air schools for normal children was spreading so that we might look forward to the day when all children would be taught in the open air.

In conclusion the speaker referred to Dr. Rollier's hospital at Leysin, Switzerland, where children with surgical tuberculosis are exposed absolutely naked to the sun throughout the year. As a result of this heliotherapy the

children became black and with the formation of pigment in the skin the cure progressed, so that at the end of a year the disease was arrested with complete restoration of function in the joints affected.

Dr. THOMPSON warmly seconded Dr. Brannan's efforts to get the school children and patients "back to Nature." He said there were two methods of estimating the fitness of air to breathe, namely the physical and the physiological. Of these the physiological is the true method, and he presented charts prepared by Dr. R. F. Hoobler in his wards to illustrate graphically the rate of metabolism in foul and fresh air respectively, and also the improvement in blood pressure which results from placing patients with pneumonia and other respiratory diseases in the outdoor air. The rate of metabolism improves about 20 to 30 per cent. in fresh air, and the blood pressure may rise 10 to 20 mm. or more. Dr. Thompson felt that a constant temperature in ward air usually means lack of air circulation, and that the modern humidity standards are absolutely fallacious as an index of the fitness of the air for breathing, and he deprecated the common practice of supplying schoolrooms and wards with superheated or "canned air."

Dr. MEARA said he was glad to testify to the value of the open-air treatment. Eight years ago there was no provision in Bellevue for such treatment. When the children were moved from the fifth floor in the new pavilion there were such facilities and the benefit had been marked. Dr. Meara had noticed the effect on blood pressure in the outer air and thought that it was due to the action of the cold air on the face and nasal mucous membrane, affecting the circulation reflexly. On the warmer days blood pressure did not show so much response. He thought Dr. Brannan's paper extremely interesting and instructive.

Dr. GIBSON said that the surgeons had long appreciated the therapeutic value of fresh air. He considered natural ventilation much superior to the elaborate inside systems. Dr. Gibson had been disappointed in the results obtained by fresh air in aggravated surgical cases of bone tuberculosis in adults. Especially had his patients failed to get much benefit from the Adirondacks.

Dr. GIBNEY felt that thanks were due Dr. Brannan for having brought the matter of fresh air before the Society in so thorough a manner. He was familiar with the great benefit which children with bone tuberculosis derived from fresh air seaside treatment.

Sir BERTRAM DAWSON said that a certain amount of this work had been done in England and that he could testify to its great benefits. In outdoor schools the common cold was no longer a feature of school life as it had been in the closed schoolroom. The children and the families as well seemed to improve not only in general health but in moral health. He regarded the open window as having unmistakable advantage over any inside system of ventilation. In a large convalescent home to which he was attached contagion had been spread by the ventilating system. The only ward which had escaped the epidemic had been one from which the artificial ventilation system had been cut off and the open window relied on for ventilation. The truth of the contention that artificial ventilation was harmful had been demonstrated by the vastly more luxurious growth on culture plates placed at inlets than those placed in other parts of the ward. He thought that partitions betweens different parts of the ward helped to limit the spread of disease.

Dr. KINNICUTT said that the charts of the cases of pneumonia in his service at the Presbyterian Hospital showed that the effect of dry cold air was to raise the blood pressure.

Dr. BRANNAN said that he was under the impression that someone had recorded results which showed that there was no marked rise of blood pressure when adult patients were exposed to fresh air.

Dr. ROPER said that the results of work done by Dr. Barringer at Hudson Street Hospital showed that in normal adults exposure of face to cold air produced but slight rise in blood pressure. This persisted for a variable time. In many cases it returned to normal during the exposure. This variation could not be considered very significant as it had been shown that the blood pressure of the same patients in the ward varied 10 to 15 mm. at regular periods from no discoverable cause. In twelve patients suffering from various infections but two had shown any decided increase in blood pressure on being exposed to cold air. There was no question as to the value of fresh, cold air in treatment of these cases but there was a question whether the blood pressure played an important part. It seemed more probable that the benefit was derived more from other sources, as, for instance, the increased ease with which metabolism was carried on, than from any direct effect on the circulation.

AMERICAN CLIMATOLOGICAL ASSOCIATION.

Twenty-ninth Annual Meeting, Held in Hartford, Conn., June 10-13, 1912.

(Special Report to the MEDICAL RECORD.)

THE PRESIDENT, DR. A. D. BLACKADER OF MONTREAL, IN THE CHAIR.

(*Concluded from page 785.*)

On Some Recurrent Febrile Attacks in Chronic Tuberculosis.—DR. CARROLL E. EDSON of Denver, Col., read this paper. He stated that his observations were purely clinical and that probably all had recognized the condition and could confirm his interpretation of it. To separate clearly and surely the symptoms and signs due to an intercurrent or nonrelated process from those due to the chronic and underlying tuberculosis was as important as it was difficult. Attacks of recurrent fever in tuberculous patients too frequently were not carefully studied or they would be found to have quite another cause than tuberculous reactivity. The picture was often not that of a lighting up of the old process. Often, especially where there was much scar tissue, the only change in the signs was that the formerly coarse, dry râles had become a little sticky. There were no fine râles, no new râles, no evidence of new infiltration or moisture along the border of the old area. This was most suggestive, for almost invariably new activity would show itself at the edge of the previously unaffected tissue. The tongue might be coated or remain clear and the bowels were only sluggish from confinement in bed. There might be some sweating at night. If treated as a simple tuberculous fever by rest in bed, the subsidence was slow and gradual, and it was from one to three weeks before the patient was out again. He had kept notes on this picture and had found that in each case there was a fairly regular periodicity in the attacks, the onsets being from four to six or eight weeks apart and the intervals varying with the severity and duration of the febrile periods, a mild attack being followed by a second a little sooner than a severe one. This similarity to migraine suggested the possibility that the fever was due to an eliminative and not to an inflammatory process. Acting on this theory he had found that by the use of oxidizing aids, salicylates, potash, and purgatives, the attack was shortened. Following out this clue an attempt was made to forestall the attack in one case by giving large doses of salicylate and a purge forty-eight and twenty-four hours before the return. This was partially successful. The recognition of these cases depended chiefly on two factors, the repetition of the attack without adequate cause in cases otherwise under improvement without correspondence of evidence of tissue change to the constitutional signs and upon the regularity of the periods of recurrence. The patient should keep a chart and mark each attack. It appeared that these attacks usually occurred in patients with rather extensive involvement of the pulmonary tissue such as would lead to generally lessened power of oxygenation, in patients who were careful to maintain their nutrition at a maximum and to avoid over exercise. The attacks were not characterized by true migraine and neither were they typical bilious attacks. They apparently were pulmonic in origin and due to accumulated unoxidized pyrogenous material, as was indicated by the prompt and often complete relief obtained when such an origin was made the point of therapeutic attack. During these attacks the patients were put to bed, given a scanty proteid and green vegetable diet, hyperabundance of water, some form of salicylate, and a mild purge. The best results had come from recognizing the nature and cause of the attack and following the indication for a greater amount of exercise in the intervals, and in anticipating each recurrence by proper medication.

Dr. DE LANCEY ROCHESTER of Buffalo, N. Y., said that he had had several cases of recurrent fever in tuberculous patients for which he had been unable to account In these cases, causes other than tuberculosis must be excluded before assigning tuberculosis as the cause. There were several cases of sinus disease periodical in occurrence, and it was only by the most careful examination that the cause of the trouble was found. In tuberculous patients discharged from sanatorium treatment the importance of elimination through the kidneys as well as through the skin and bowels should be emphasized. The alkaline diuretics were of value and tended to prevent the recurrence of these febrile attacks.

Dr. J. H. PRATT of Boston, Mass., asked the reader of the paper what evidence there was that this condition was due to suboxidation. The former teachings regarding suboxidation had been overthrown and, if he was not mistaken,

where there was fever and increased pulse rate, studies made with the respiratory apparatus showed that there was an increased oxidation.

Dr. Charles L. Minor of Asheville, N. C., said that there were no doubt a vast number of cases of recurrent fever attributed to tuberculosis which were due to the persistence of intestinal fermentation. An obstinate and exasperating temperature might be kept up by this fermentation which would only clear up under calomel and antiseptic treatment. They sometimes ran across febrile attacks which it seemed impossible to cure. The patients sometimes lay in bed for weeks or months without any effect on the temperature; when they got up the fever disappeared. More work should be done in attempting to find out the cause of these attacks.

Dr. Edward R. Baldwin of Saranac Lake, N. Y., thought that Dr. Edson's paper was a splendid one and showed careful clinical observation, but he would like to know what proof he had of these things. The mere fact that expectoration did not increase in some cases of tuberculosis with fever was not necessarily proof that there was no congestion in the focus of tuberculosis. In nearly all fevers which could not be accounted for in simple ways, the burden of proof rested upon the clinician; he must show that the fever was not due to autointoxication, or anaphylaxis, or hypersensitiveness. The laboratory explantation of the fever occurring during the active stages of tuberculosis would be a form of proteid intoxication which was called anaphylaxis. There was a great deal of proof to show the unstable condition of the patient afflicted with tuberculosis, and fever could be excited by very slight changes in the tuberculous foci.

Dr. Lawrason Brown of Saranac Lake, N. Y., said he had seen a number of these cases of recurrent febrile attacks in chronic tuberculosis cured by prolonged rest in bed; when the attacks came on one after another he sometimes kept the patients in bed two or three months. In studying the blood of patients afflicted with tuberculosis, he had found secondary organisms circulating in the blood stream in a number of instances. He had found the pneumococcus and streptococcus in 20 per cent. of the incipient cases, in 27 per cent. of the moderately advanced cases, and in 55 per cent. of the far advanced cases of pulmonary tuberculosis. Anaphylaxis might be due to the dissolution of these organisms. This was a factor they should take into consideration in their studies of these peculiar attacks of fever which occurred in tuberculosis with no increase in signs. In these cases of recurrent fever the patient should be kept at rest in bed for a period of time corresponding to that of the attack; if the attack lasted three or four days the patient should be kept in bed three or four days and then allowed to get up and about slowly. Whatever the cause of the recurrent fever, the focus of disease was easily disturbed. It was necessary to get the patient in a stable condition. During these attacks exercise should be withheld. When the patients had reached a stable condition they gradually improved and the attacks would soon cease if one gave the patient time.

Dr. Charles L. Minor of Asheville, N. C., said that some of the cases spoken of were distinct cases of tuberculous congestion. While there might be some cases of fever of non-tuberculous nature, there was no doubt in his mind but that many of them were due to the tuberculous process.

Dr. J. H. Elliott of Toronto, Canada, said there were two classes of these cases. In some there was practically no increase in expectoration and a careful examination of the chest would show slight changes in the adventitious sounds. These were almost closed cases. In cases where the expectoration was not increased the recurrent attacks of fever were lessened by the use of calomel or podophyllin or some purgative medicine. In cases where the expectoration was increased a satisfactory procedure had been the use of the autogenous vaccines; this method was especially useful in the almost closed cases where frequently the attacks were overcome by this means.

Dr. Carroll E. Edson of Denver, Colo., in closing the discussion, said, in answer to Dr. Rochester, that they must first assure themselves that there was no organic lesion elsewhere to account for these attacks; an unrecognized sinus condition would account for the concomitant symptoms. With regard to the question of suboxidation, that was a matter to be left to the laboratory worker, as the man who was practicing medicine had no time to deal with such an investigation. Increase in temperature and pulse rate was accompanied by an increased oxidation rather than a suboxidation. In regard to Dr. Baldwin's contention that the lack of expectoration was not necessarily concomitant with the tuberculous process, that was unanswerable. With regard to Dr. Brown's remarks, proteid retention was of course one of the theories and it was quite as likely to be correct as his own. With regard to the use of the vaccines, he did not think they were called for in this type of cases. Dr. Edson said he would yield to no man in urging on the patient the importance of prolonged rest, and rest in bed, when there was a tuberculous fever and inflammatory activity. He had kept patients in bed as long as eleven months at a stretch and had met with success. There was another type of cases due to a lack of secreting power and the burden of proof in these cases lay with the clinician. There would be a little flaring up and probably a protein anaphylactic phenomenon. Ninety-nine out of a hundred cases he believed to be of this nature. The assumption was that these cases were of a tuberculous nature. During the attacks these patients were not permitted to walk; they could do so, however, between the attacks when the temperature was normal or nearly so.

Report of Two Cases of Recurrent Laryngeal Nerve Paralysis Complicating Mitral Stenosis.—Dr. John D. Thomas of Washington, D. C., read this paper. He reviewed the very complete study of this condition made by Fetterolf and Norris last year, from whose conclusions it seemed evident that cases of recurrent nerve paralysis should be considered and classed, not necessarily as following or complicating mitral stenosis alone (though this was the lesion most often causing it), but should include any of the cardiac lesions which brought about the same pathological anatomical condition, excluding of course diseases of the vessels, as aneurysms. After reviewing some of the cases reported in the literature, he called attention to a condition which was present in both of his cases and which from a study of the cases reported was evidently present in several of these, that was, insufficiency of the pulmonary orifice. In the majority of these cases the insufficiency was what might be called relative, just as occurred at the tricuspid orifice in loss of compensation of the heart. This condition was a safety valve action just as was seen in the relative tricuspid insufficiency. In one of the writer's cases the very evident alleviation of symptoms became more and more noticeable as the lesion of the pulmonary valve became more and more marked, until at the present time, when the pulmonary lesion was the predominant note upon auscultation, the patient was in comparative ease. The same condition in insufficiency which he had noticed in two other cases of mitral stenosis also showed this same temporary alleviation of symptoms. This was a more common lesion than was supposed and if they were on the lookout for it they would find it oftener, particularly in the terminal stage of mitral stenosis as well as sometimes of insufficiency. The lesion with which this condition was most often confounded was aortic insufficiency, but a careful examination of the arterial system and other cardinal signs of aortic insufficiency would eliminate this lesion. Some of these cases which had come to autopsy had shown certain congenital defects which were not recognized clinically, and in others such defects were noticed before death. The points of great interest in these cases were: 1. The evident insufficiency of the pulmonary orifice. 2. The seeming temporary improvement of symptoms, particularly in one case, as this insufficiency developed. 3. The absolute absence of any signs of the only lesion with which it could be confused, namely, aortic insufficiency. 4. The systolic pulsation in the second left interspace.

The Influence of Carbonated Brine (Nauheim) Baths on Blood-Pressure.—Dr. John M. Swan of Rochester, N. Y., read this paper and concluded as follows: 1. Carbonated brine baths had no constant effect on the blood pressure of the human subject. 2. In the cases in which observations were made both before and after each bath the systolic pressure was raised more frequently than it was lowered; so that one might say that the tendency of the baths was to raise the blood pressure. 3. Although there were cases of high blood pressure in which a course of carbonated brine baths had been followed by a lower systolic pressure, there were other cases of high pressure in which the pressure has been higher at the end of the course of treatment than it was at the beginning; in one case 26 mm. higher. 4. Although there were cases of low blood pressure in which a course of carbonated brine baths had been followed by a higher systolic pressure, there were other cases of low pressure in which the pressure had been lower at the end of the course of treatment than it was at the beginning; in one case 20 mm. lower. 5. There was no method of determining in advance whether a given treatment would be followed by an elevation or by a fall of pressure. 6. In the series of eighty-one cases the systolic pressure was higher at the end of the course of treatment than at the beginning in thirty-nine; lower in thirty-four; unchanged in eight. 7. In cases of fibroid

myocarditis the pressure effect was inconstant. In this series of cases the systolic pressure was lowered more often than it was raised; but the pulse pressure was raised more often than it was lowered. It seemed to the writer a dangerous procedure to use a form of treatment in a case of cardiac fibrosis which might be followed by an increase of systolic pressure of 22 mm. or an increase of pulse pressure of 32 mm. 8. In cases of parenchymatous myocarditis the effect of the baths on blood pressure was usually to raise it, but in some cases baths were followed by a reduction of both the systolic and the pulse pressures. 9. In cases of dilation of the heart, cases of hypertrophy and dilation of the heart, cases of mitral regurgitation, cases of hypertrophy of the heart, cases of tachycardia and of aortic regurgitation, the same uncertainty of results was seen, except that in cases of mitral regurgitation the pulse pressure was reduced in every one of the five cases; and in cases of aortic regurgitation the diastolic pressure and the mean pressure were reduced in every one of three cases. 10. In a case of arteriosclerosis, an increase of 17 mm. in the systolic pressure and 23 mm. in pulse pressure might result disastrously. In a case of chronic parenchymatous nephritis, an increase of 9 mm. in systolic pressure and of 22 mm. in pulse pressure might or might not be negligible. In a case of interstitial nephritis, an increase of 50 mm. in systolic pressure could hardly be thought desirable. 11. The reduction of systolic pressure in a case of weak heart can scarcely be looked upon as a favorable circumstance. 12. The benefit in the subjective symptoms in cases of heart disease which followed a course of carbonated brine baths was not dependent on the influence of the treatment on the blood pressure. The conclusions were based on the study of the blood pressure in 81 cases in which courses of carbonated brine baths were administered. In five of the cases blood-pressure observations were made before and after each bath. The blood-pressure observations were made by the auscultatory method, in the recumbent posture. The Stanton sphygmomanometer was used.

The Negro and His Health Problems.—Dr. J. Madison Taylor of Philadelphia presented this communication. He said that the negro problem was one of anthropology, not one of ethics, religion, or variegated opinions. It did involve grave sub-problems of humanity, economics, and common sense. Under no circumstances should it be complicated by emotion. The whole race problem, in the final count, resolved itself into what was to become of the members of an alien people transported, by force and suddenly, to an unsuitable, a hostile environment. Members of this alien race deserved the same consideration as those of any other, no more, no less. They would get it, and all the more readily if partisanship, unreflecting zeal and politics could be kept upon a rational level. Prejudices for and against the negro neutralized each other. They only serve to obscure fundamental issues, producing no good, but only loss of vitality and moral tone in those who entertained them. The question for solution resolved itself into *whether members of a tropical race, evolved through thousands of years in hot countries, whose characteristics have gradually become adapted to local climatic conditions, were capable of flourishing or even surviving in a climate wholly at variance with the circumstances of their racial adaptations.* Another important anthropologic problem was whether a people practically in or near a state of savagery could be expected to become civilized or to conform to civilized standards within the short space of a few hundred years. This was not germane to the present inquiry. If the answer were in the affirmative, then was opened a host of doubts as to the validity of all experience, history, and findings of anthropological science; also complex questions arose as to what would become of the race till Time, the greatest solver of problems, should reveal the answer. If the query above proposed was answered in the negative, we should at once consider what could be done to effect a transference of the negroes to a suitable habitat. Two or more races brought into intimate contact socially and domestically evolved hybrids. All experience showed that hybrids, the product of sexual union of antithetic races such as the white and the black, were inferior to the original stock physically and morally. It was demonstrated by well attested facts that these hybrids of black and white were vastly more susceptible to certain infections; their moral as well as physical stamina was lower than that of either original race. Undoubtedly there were individual exceptions. Hybridism lowered normal defences to degenerative diseases, hence inhibition, the fundamental safeguard, was lessened and degenerative processes than continued with increasingly rapid strides as the alien blood weakened and the stronger prevailed. In America the supply of the original negro blood was limited; no new infusions were to be expected. Meanwhile pure streams of our Anglo-Saxon, Slavic, Celtic, and other blood, infused as they were in the United States with a different but not largely variant group of Latins, Hebrews, and others, were polluted by the negroid blood. However, those who felt alarm at this fact could take comfort from the reflection that it was contrary to all precedent for a tropical race (so entirely unfitted to subsist in a cold climate like ours) to survive more than ten, or at most fifteen, generations. Our subtropical summers might prolong survival more or less.

Election of Officers.—*President*, Dr. Charles L. Minor, Asheville, N. C.; *Vice-Presidents*, Dr. James M. Anders of Philadelphia, Pa., and Dr. C. D. Alton of Hartford, Conn.; *Secretary and Treasurer*, Dr. Guy Hinsdale of Hot Springs, Va.; *Delegates to the International Congress on Hygiene and Demography*, Dr. Thomas Darlington of New York and Dr. Schauffler of Lakewood, N. J. Next place of meeting, Washington, D. C.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Stated Meeting Held May 21, 1912.

The President, Dr. Elias H. Bartley, in the Chair.

On the Treatment of Cerebral Hemorrhage at the Time of the Occurrence.—Dr. Frederick Tilney read this paper. He said that the symptoms were usually manifestations of a systemic disease, especially in those cases not due to traumatism. The condition could be divided into three phases: (1) the period of preparation; (2) the period of insult, and (3) the period of paralysis. In the treatment of this condition it was important to arrive at the proper diagnosis, and differentiation had to be made between cerebral syphilis, cerebral abscess, and meningitis. By means of blood pressure examinations and the ophthalmoscope, differential diagnosis could be aided. It was also of importance to ascertain the presence or absence of hemiplegia. Regarding the treatment, if the attack took place elsewhere than in the patient's home, the latter should be allowed to remain in the place where he fell. Movement was absolutely forbidden, the head and shoulders were to be elevated, and the clothing, especially about the head and neck, was to be loosened. If the patient had to be removed to a hospital the greatest of care was to be observed in transportation. Phlebotomy was indicated in cases with a high blood pressure, especially when this was above 250 mm. of mercury. In cases with deep coma 10 to 12 ounces of blood might be removed. In these cases hot mustard foot baths or packs, a tourniquet about both legs, and an ice cap to the head could be applied. The action of the urinary bladder was to be watched and if necessary the patient was to be catheterized. The aim of medication was to reduce the blood pressure; since in the early stage the oral administration of drugs was dangerous, hypodermic medication had to be done. The writer than spoke of certain experiments he had performed a number of years ago, together with Dr. Robert O. Brockway, regarding the efficiency of certain drugs in reducing the blood pressures of hemiplegics. He found that the hypodermic injection of pure distilled water alone was sufficient to cause a rise in the pressure up to 25 mm. of mercury. Thus, he said, in the hypodermic administration of aqueous solutions of drugs in the above conditions, enough of the drug must be given to overcome the effects of the water. Aconitine 1/120 grain caused an initial rise of pressure lasting from five to thirty minutes followed by a drop. He regarded gelsemine hydrochlorate in doses of 1/15 grain as a reliable drug in causing an initial drop in the blood pressure. Aconitine was not to be relied upon. Hypodermic injections were to be continued in order to keep the pressure down, and the aqueous solutions were to be made as concentrated as possible. Nitroglycerin and the nitrites he considered inadvisable as they were evanescent in their action. Tincture of aconite in rather large doses, with the patient carefully watched for toxic symptoms could be administered per os. When the pressure finally reached a low point it could be so kept by careful administration of the tincture of aconite. Delirium and restlessness were to be controlled by bromides or hyoscine. Alcoholics were to be given alcohol in small doses. For persistent vomiting or hiccough, morphine and atropine were to be given, or even lavage was to be done. Sedatives to prevent any motion whatever were indicated. During the first 48 hours feeding was to be entirely fluid, and if necessary per rectum. For the first week he advised a purin free diet. The sick room was to be kept free from all disturbances; ventilation and temperature were to be agreeable. Bowel evacuations were to be encouraged by

cathartics if necessary. In patients with deep coma, bedsores could be prevented by keeping the skin dry and powdered, by applying pads of absorbent cotton to the external genitals, and by the use of air cushions or pads. The mouth and teeth should be thoroughly cleaned. The patients were to be kept in bed for at least three weeks. The paralyzed arm was to be placed in a splint while it was still in a flaccid condition and was to be powdered once daily. Hemorrhages in nephritics might be relieved by lumbar puncture and the removal of 25 to 30 c.cm. of cerebrospinal fluid. Surgery had not proved very successful in this condition.

Dr. WILLIAM BROWNING said that the result in the above condition depended on the skill of the man first called to treat the patient. In the prophylactic treatment for those in whom there was a possibility of cerebral hemorrhage, the coagulability of the blood should be increased by the feeding of gelatin. He said when the hemorrhage occurred there seemed at first to be a systemic shock. During this time there was apparently a cessation of the bleeding and the hemorrhage was reestablished by the patient becoming active again. This could be avoided by the enforcement of absolute quiet until there was a certainty of clot formation. The speaker strongly recommended the use of gelsemine by mouth. The breathing of these patients was to be relieved in order to prevent the occurrence of aspiration pneumonia. He said that patients should be allowed to get out of bed within a week or so, as there was a tendency for them to become bedridden.

Dr. ARTHUR C. BRUSH said that first one should be certain of the diagnosis as to whether the case was one of embolism or thrombosis. Then the patient was to be left alone in the correct position. The speaker believed in the reduction of the blood pressure by means of bleeding. Vomiting could best be restrained by morphine and atropine. It was all right to take the blood pressure and to perform lavage, but one did not always have the apparatus at hand and as everything had to be done rapidly, one had to get along with the material available.

Dr. TILNEY closed the discussion by remarking that the differential diagnosis had to be made within the first few hours. This was an important factor in the treatment. He said that he recommended gastric lavage only in those cases in which the vomiting was persistent.

On the Recent Epidemic of Sore Throat.—Dr. STEPHEN H. LUTZ reported 21 cases of various complications and sequelæ of sore throat that he had observed since November, 1911. His experience with vaccines in the cases of otitis and mastoiditis was very favorable. He believed that the source of the throat infections might have been due to the milk supply, as 12 of the cases which occurred at one time received their milk from the same dealer. He highly recommended the use in these conditions of urotropin in doses as high as 120 grains per day.

The Destruction of Vesical Papilloma by Means of High Frequency Cauterization.—Dr. BURTON HARRIS said that tumors of the bladder were more frequent than was supposed. He had seen in all 17 cases, 5 of which were observed in 1911. The diagnosis of papilloma of the bladder was easily made with the cystoscope. The growth appeared as a glistening white or brownish white mass, with long branching processes like seaweed. Virchow had termed them vascular papillofibroma. Although they were considered as benign growths, recurrence in the wound or at the original site of growth was invariable. The earliest symptom to be noted was hematuria. Later, frequency and urgency of urination, with pain, made their appearance. There might be periods of quiesence. In every case of unexplained hematuria the writer advised cystoscopy. Regarding treatment, the reader said that on account of the danger of self-transplantation supramubic operation was futile. The transurethral method of Nitze proved fairly successful in the originator's hands, but was a failure generally. The high frequency current, however, was used with success. This the speaker said was a painless method and the introduction of the electrodes into the tumor tissue was followed by blanching, disintegration and charring of the growth. The number of applications depended on the toleration of the patient and on the size of the growth. The duration of each application was about one minute. Anesthesia was contraindicated. In one case he had successfully checked a hemorrhage by inflating the bladder with air and then applying the current. The frequency of the sittings at first was every 7 to 14 days, the interval being made greater as the treatment progressed.

Dr. PAUL M. PILCHER remarked that he had seen several cases of papilloma of the bladder operated upon with bad results. He had used the method of fulguration treatment of papillomata with good results.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Aviation in Dreams.—In his new book entitled "The World of Dreams," Havoleck Ellis states "that the sensation of flying is one of the earliest to appear in the dreams of childhood. It is sometimes the last sensation at the moment of death. To rise, to fall, to glide away, has been the last conscious sensation recalled by those who seemed to be dying, but have afterwards been brought back to life. Those rescued from drowning, for instance, have sometimes found that the last conscious sensation was a beatific feeling of being borne upwards. Piéron has also noted this sensation at the moment of death from disease in a number of cases, usually accompanied by a sense of well-being. The cases he describes were mostly tuberculous, and included individuals of both sexes, and of atheistic as well as religious belief. In all the last sensation to which expression was given was one of flying, of moving upwards. In some death was peaceful, in others, painful. In one case a girl died clasping the iron bars of the bed, in horror of being borne upwards. Piéron, no doubt rightly, associates this sensation with the similar sensation of rising and floating common in dreams, and with the feeling of moving upwards and resting on the air experienced by persons in the ecstatic state. In all these cases alike life is being concentrated in the brain and central organs, while the outlying districts of the body are becoming numb and dead. In this way it comes about that out of dreams and of dream-like waking states, one of the most permanent of human spiritual conceptions has been evolved. To float, to rise into the air, to fly up to heaven, has always seemed to man to be the climax of spiritual activity. The angel is the most ethereal creature the human imagination can conceive. Browning's cry to his lyric love, half angel and half bird, pathetically crude as poetry, is sound as psychology. The prophets and divine heroes of the race have constantly seemed to their devout followers to disappear at last by floating up into the sky, like Elijah, who went up 'by a whirlwind into heaven.' St Peter once thought he saw his Master walking on the waves, and the last vision of Jesus in the Gospels reveals him rising into the air. For it is in the world of dreams that the human soul has its indestructible home, and in the attempt to realize these dreams lies a large part of our business in life."

Benjamin Rush on Medical Fees.—On February 7, 1789, Benjamin Rush delivered a lecture at the conclusion of his course before the students of the University of Pennsylvania. In this lecture the father of American medicine discussed the duties of the physician. Although the art of medicine has been completely revolutionized in the century and a quarter that have elapsed since Rush stood before his admiring students, the remarks that he made on that remote occasion are equally applicable at the present time. His opinions on the subject of the medical honorarium are practically identical with those entertained by most medical men of today. To H. J. Achard of Chicago one is indebted for a presentation of interesting selections from this address. "When we consider," said Dr. Rush, "the expense of a medical education, and the sacrifices a physician is obliged to make of ease, society, and even health, to his profession, and when we add to these the constant and painful anxiety which is connected with the important charge of the lives of our fellow creatures, and above all, the inestimable value of that blessing which is the object of his services, I hardly know how it is possible for a patient sufficiently and justly to reward his physician. But when we consider, on the other hand, that sickness deprives men of the means of acquiring money, that it increases all the expenses of living and that high charges often drive patients from regular-bred physicians to quacks, I say, when we attend to these considerations, we should make our charges as moderate as possible. Avoid measuring your services to your patients by scruples, drams, and ounces. It is an illiberal mode of charging. Let the number and time of your visits, the nature of your patient's disease, and his rank in his family or society, determine the figures in your accounts. It is certainly just to charge more for curing an apoplexy than an intermittent fever. It is equally just to demand more for risking your life by visiting a patient in a contagious fever, than for curing a pleurisy. You have likewise a right to be paid for your anxiety. Charge the same services, therefore, higher, to the master or mistress of a family, or to an only son or daughter, who call forth all your feelings and industry, than to less important members of a family and of society. If a rich man demands more frequent visits than are necessary, and if he imposes the restraints of keeping to hours, by calling in other physicians to consult with you upon every trifling occasion, it will be just to make him pay accordingly for it. As this mode of charging is strictly agreeable to reason and equity, it seldom fails of according with the reason and sense of equity of our patients. Accounts made out upon these principles, are seldom complained of by them. I shall only remark further upon this subject, that the sooner you send in your accounts after your patients recover, the better. It is the duty of a physician to inform his patient of the amount of his obligation to him at least once a year. But there are times when a departure from this rule may be necessary. An unexpected misfortune in business, and a variety of other accidents, may deprive a patient of the money he had allotted to pay his physician. In this case, delicacy and humanity require that he should not know the amount of his debt to his physician till time has bettered his circumstances." It is suggested by Achard that the only point on which we of to-day would be inclined to differ with Rush is the matter of sending a bill "at least once a year." Most physicians will probably agree that the account should be rendered at least quarterly.—*The Medical Standard*, October, 1912.

The Value of Enterprise.—R. A. Walker states that many physicians become victims of a deadening routine. When they have exhausted their immediate stock of medical knowledge, they rest upon their oars with the comforting conviction that they have reached the limit of medical science and that nothing more can be done. It seems never to occur to them that refractory and desperate cases offer a most appropriate field for experimental therapeutics. Here is the opportunity for breaking new ground and for testing therapeutic theories. The men who have the originality and the self-reliance to rise to the occasion are the ones who contribute to the progress of medical science. "Get out of the rut, read, think, experiment independently; try all things, prove all things, and hold fast to that which is good."—*Virginia Medical Semi-Monthly*, October 11, 1912.

I. SOME DATA CONCERNING A HUMORAL ETIOLOGY OF SPASMODIC ASTHMA. II. OUTLINE OF TREATMENT IN ACCORDANCE WITH THE FOREGOING.

BY BERNARD OETTINGER, M.D.,

DENVER, COLORADO.

NEUROLOGIST TO THE HOSPITAL FOR THE CITY AND COUNTY OF DENVER AND ST. ANTHONY'S HOSPITAL.

I.

IN 1905, at the Portland meeting of the American Medical Association, the writer propounded a humoral theory to explain certain beneficent effects of methemoglobin-producing drugs in diseases associated with dyspnea.[1] This hypothesis assumed that dyspnea resulted in these conditions from an intoxication due to the presence of an abnormally increased amount of intermediate products of metabolism which the organism could not chemically elaborate, thus failing to prepare them for elimination; furthermore, that these intermediate toxic products, themselves reducing agents of the blood and other tissues, were rendered innocuous by methemoglobin oxidation.*

Four years ago an editorial appeared in the *Journal of the American Medical Association* taking note of the fact that in three fatal cases of anaphylaxis resulting from single doses of diphtheria antitoxin, all the subjects were asthmatics. To-day, because of symptomatic analogies, asthma is looked upon as an anaphylactic phenomenon.† Under these conditions a comparison of mechanism as outlined respectively for asthma and anaphylaxis is herewith submitted. Regarding the latter Hektoen[2] in a recent comprehensive paper on anaphylaxis says: "(1) The present prevailing idea is that anaphylaxis (or allergy) both to portein in cells and to dissolved protein is essentially a humoral process marking a return to the general view expressed by Friedemann several years ago. (2) Friedemann and Isaac, as the result of their experiments, concluded that the first injection of a toxin (in the shape of a foreign protein), resulted in the formation of antibodies which caused rapid splitting of the same protein, if it was again injected, with the formation of toxic intermediate bodies. (3) The same investigators found also that 'when the foreign proteins are introduced parenterally (*i.e.* not through the alimentary tract), they are gradually reduced to urea in normal animals, but in animals treated with protein, the reinjection of that protein is followed by manifestations of anaphylaxis and evidence of protein splitting,'" *i.e.* in animals sensitized to foreign protein the normal production of urea cannot be accomplished. As against the foregoing, the mechanism underlying dyspnea, with or without bronchial spasm, as outlined by the writer included the following, viz., *a* "dyspneic conditions are always manifestations of an inadequate effort on the part of the organism sufficiently to oxidize cell disintegration products. Or, to express the idea from a different viewpoint, there is in the blood, in conditions which result in increased tissue metabolism, an accumulation of basic products which are prepared for further use or for body elimination by oxidation and cleavage processes," and again, *b*, "the interdependent relation, as based upon chemical formulæ, of some of these basic substances (leucomaines) to others of the same class and their final elimination products, has been identified with successive oxidation and cleavage processes, as for instance, those of the best known purin group form a continuous oxidation series with uric acid as the final product from which urea may be attained by cleavage."[1]

To-day the metabolism of anaphylaxis, in the sense of the failure of the organism to reduce foreign proteins to urea, herein permitting accumulation of toxic intermediate products, is discussed in biological terms, viz., of specific reaction between antigen and antibodies with the resultant manifestations of rapid protein splitting. Without a knowledge of antigens, antibodies, or complement, the writer's theory involving the same phase of metabolism could only take cognizance of certain chemical changes pertaining to the problem. The intensive oxidation required to convert the intermediate products of metabolism, in the time of their great increase, into such as the body can eliminate, I assumed could be accomplished by a therapeutic degree of methemoglobinemia. This, for the reason that such intermediate products reduce methemoglobin successively to oxyhemoglobin and reduced hemoglobin, whereas the body tissues can take no oxygen from this more stable blood pigment. The writer therefore has used since 1904 small doses of methemoglobin-producing substances, particularly sodium iodate, in the treatment of spasmodic asthma. In this connection two facts are significant: (1) A number of remedies used empirically in the treatment of spasmodic asthma and which do not depend upon narcosis for their effect, produce in some degree methemoglobinemia, viz., iodine and bromine salts, injections of epinephrin, inhalations of amyl

*One who is interested in this phase of the problem, I refer to the original communication;[3] but reiterate here that although the profession is daily using methemoglobin-producing drugs in therapeutic dosage, the tradition still exists that a drug capable of effecting methemoglobinemia in any degree must be tabooed.

†Meltzer[2] first pointed out the similarity of reaction during attacks of asthma and serum anaphylaxis but the analogy goes further. Immediately after anaphylaxis occurs antianaphylaxis or anergy, the refractory period during which the animal is immune to the same toxin which produced the attack. Every asthmatic immediately subsequent to a severe attack presents clinically a period of antianaphylaxis. At this time he may eat with impunity certain foods he cannot take at any other without initiating an asthmatic paroxysm.

nitrite, pyridin, smoking powders, etc. (2) Experiments on guinea pigs by Anderson and Shultz[5] showed that the most effective way to save animals in whom anaphylaxis had been produced by reinjection of foreign proteins was by the injection of epinephrin and later of chloral urethane both methemoglobin-producing drugs. That this good effect was enhanced by simultaneous artificial respiration of pure oxygen is further reasonable evidence that the neutralization of toxic proteins was effected by their oxidation.*

II.

In accordance with the foregoing, the writer submits a rational treatment for spasmodic asthma that has proved useful to him during a period of eight years. The procedure is not a cure-all. Strict attention to details of treatment aside from the giving of medicine is demanded at all times. Furthermore, the treatment is greatly efficient in uncomplicated cases only. Yet withal, the practitioner will annex some grateful patients in the course of months and years by careful application of this method in dealing with a troublesome affection.

There is little to be said regarding prophylaxis. Experience has taught the writer that aside from local irritants, such as dust and irritating gases and impure air,† there are four conditions which act as exciting causes of asthma, in predisposed persons. These are sudden disturbing emotions, continued anxiety, physical overexertion, and various infections grouped under the head of "colds." The last of these will be without effect if the patient be under the influence of the medication hereinafter described. How far these conditions can be avoided or counteracted will vary. Dominant influencing factors are temperament and conditions of livelihood. In practice the patient is probably visited the first time during an attack. He should be given 10 grains of blue mass (or an equivalent of calomel with soda). The mercurial itself often has the effect of ameliorating the attack in the course of some hours, but if the patient is suffering intensely I do not hesitate to give one morphine and atropine subdermal injection as part of the initial treatment. The use, however, of either morphine or alcohol during treatment is interdicted because both retard elimination. Whether or not morphine is given, several watery stools must be obtained the following morning from a sufficient dose of salts. For constitutional treatment I depend upon sodium iodate, an energetic methemoglobin producing drug. The adult dose is four or five grains given at intervals of four to six hours. Some appropriate nourishment, solid or liquid, is given at the same time. Mixing with the food, the medicine is more easily digested. One grain of caffeine citrate may be added to each capsule. As a rule the mercurial purge given once is sufficient, but may be repeated if the attack is not markedly better in 24 hours. Nightly repetition, however, is undesirable and will be without effect. Still referring to uncomplicated cases, dyspnea persisting in spite of medication, means continued action of an exciting cause. For this reason conditions and manner of life must be carefully investigated in all cases. Medicine alone will cure no case of asthma. In regard to the all-important factor of diet, this must be rigidly supervised, yet the patient need not be starved. No single dietary will suffice, but the following instructions and diet list are handed to each patient and are of service because the latter names certain articles of food which practically all asthmatics must eliminate at least in the beginning of treatment.

INSTRUCTIONS AS TO DIET FOR ASTHMATIC PATIENTS.

The following instructions are necessarily of a general character. Certain articles of food which usually cause no ill effects may produce stomach and bowel disturbance in your case. Return of asthmatic symptoms from such peculiarities, the patient himself must learn to guard against. Also, the patient must be certain what part of his diet, if any, is really at fault; a person may eat meat and potatoes, feel distressed, and think the meat disagrees, when, in fact, the potatoes should have been avoided. Eat heaviest meal at noon. The evening meal must be light, and should not be taken later than six o'clock.

Diet During an Attack: Take only broths at intervals of two to four hours.

Diet for Periods Between Attacks: Eat a variety of plain, coarse foods. Eat enough to satisfy hunger and no more. The patient need not starve himself, yet must remember that overeating cannot be indulged in, no matter what the diet. Soups—May be eaten (must be clear of fat). Fish—Boiled or broiled fresh fish, raw oysters, raw clams. Meats—Chicken, turkey, lamb, mutton, beef, venison (all tender and lean). Vegetables—May eat all that agree, but it will be found that heavy vegetables, *i.e.*

*Lately some German clinicians have pointed out the similarity of the vasomotor disturbance shown by the congested and edematous bronchial mucous membrane of asthma to that of the skin and mucous membrane in angioneurotic edema. In the vasomotor character of some of the clinical manifestations of asthma and the occurrence of dyspnea, localized edemas, urticarias, erythemas, etc., in various neurotrophic affections such as Graves' disease, osteomalacia, myasthenia gravis, etc., we may note a significant analogy. Again, emotional disturbance, so potent an exciting cause of asthma, is always an element in the clinical history of all vasomotor and neurotrophic disorders. Among other observations which bring vasomotor manifestations of asthma in analogous relation to diseases due to disturbed ductless gland functions are the following: *a*, the common experience that fright instantly affects glandular secretion under sympathetic control—the dry mouth—and the same shock inducing vasomotor contraction of like nature—the blanched skin. *b*, Cannon and de La Paz[4] have shown that in the cat emotional disturbance, *i.e.*, fright, is indicative of dominant sympathetic impulses by producing dilatation of the pupils, rapid heart action, erection of the hairs of the back and tail, and inhibition of the stomach and intestines. That the last phenomenon may be due to an increased amount of epinephrin in the blood is rendered possible first, by the experiments of Dryer and others that stimulation of the splanchnics increases the epinephrin content in the blood of the adrenal veins; second, by experiments of Cannon and de La Paz, who produced inhibition in longitudinal sections of intestinal muscle by exposing the same to blood containing epinephrin. This blood loses its effect on standing or if agitated by bubbling oxygen. Now, the relief of the asthmatic paroxysm by epinephrin injection is an established clinical fact, while the symptoms of anaphylaxis is guinea pigs, as shown by Anderson and Shultz[6] was best combated when in addition to injections of epinephrin, artificial respiration of pure oxygen was carried on. The foregoing therefore makes reasonable a sympathetico-humoral conception of anaphylaxis and hence of spasmodic asthma. Also, we can conclude that anaphylactic toxins are rendered inert by an internal secretion, *i.e.*, epinephrin. That this power is not confined to secretion of the adrenals is probable. And, finally, we recognize that not only anaphylactic toxins, as noted above, but also their physiological antidotes are rendered innocuous by means of their oxidation.

†At present we are unable to separate, as exciting causes, air rendered impure by strictly local irritants, solid or gaseous, as against those body emanations, which inhaled and acting chemically, rapidly produce toxins and anaphylactic symptoms. In this respect may be recalled the inability of some persons to be near certain animals, to enter a stable, or remain in a crowded auditorium without experiencing an asthmatic attack.

onions, cabbage, cucumbers, corn on cob, etc., usually must be avoided. Eat few potatoes, or better, none at all. The same may be said of legumes, *i.e.* peas, beans, etc. Bread—Eat only that which is well baked, or the same toasted thoroughly. Eat rice, cereals and eggs (except fried) in moderation. Of the last, not more than one or two at a meal. Eat no raw fruits, but take these as sauces or compôtes. Avoid hot cakes, pancakes, etc., also sweet cakes, pies, and other rich crusts. Avoid nuts, cheese, and any article of diet that experience has taught you produce belching, bloating, passage of gas from the bowels, or other distress. Avoid candy, jellies, preserves, or much sugar in anything, also much salt, much fat and all acids, *i.e.* the diet throughout should be plain and bland, not highly seasoned, nor rich. Drinks—May drink water, tea and coffee—the last two not strong. Avoid cocoa and chocolate. Take milk in moderation only; some patients cannot drink any without digestive derangement. Avoid all alcoholic drinks, especially beer and other malt beverages. Belching of gas after meals or passing of same from the bowels together with a feeling of heaviness, mean fermentation in the digestive tract. When this condition exists it must be corrected before lasting benefit from treatment can be obtained.

It must be understood that with greatest willingness to cooperate with the doctor, the diet cannot be left to the patient's sole direction. One asthmatic who was not doing well, was following instructions with a single exception. He clung to hot cakes for breakfast. Much delving into his dietary was required to elicit the fact. On the other hand, an attack was induced in another patient by eating spinach, which is ordinarily well borne. These examples show the need of careful scrutiny of the patient's selection of foods.

Paradoxical as it may appear, patients do best on the foregoing simple measures applied with thoroughness, although one is often called upon to extend therapeutic efforts. The solution lies in this: The procedures recounted suffice to overcome successive attacks of simple spasmodic asthma until a cure is finally accomplished.* In cases complicated by defective function on the part of the heart, referring here especially to myocarditis, or of the kidneys or bronchial mucous membrane results are quite different. Here treatment, dietetic and medicinal, including herein such special aids of which we may avail ourselves to ameliorate a dominant symptom, such as a racking cough, tenacious sputum, sleeplessness, cardiac exhaustion, etc., will fail to a greater or less extent.

Aside from attacks of dyspnea in diseased conditions of heart or kidneys, characteristic spasmodic asthma may be associated. The treatment heretofore outlined will improve the patient's breathing but relapses recur soon. Why these cases are so little helped by a therapeutic methemoglobinemia, which markedly benefits simple spasmodic asthma cannot to-day be answered satisfactorily. The degree of toxemia is a matter of moment. In asthma with coexistent lesions of the heart or kidneys the patient, with depressed metabolism which cannot furnish physiological antitoxins, is able neither to assimilate or react to the proportionately greater amounts of drugs required to neutralize more profound toxemia. But aside from this, every drug fulfills more than a single indication and a secondary effect may, in a given instance, do harm. Sodium iodate often relieves, temporarily, asthma associated with myocarditis, yet for the latter digitalis (containing methemoglobin producing saponins), is especially indicated. The same sodium salt will not relieve hay fever, although it will ameliorate an accompanying asthma. However, injections of epinephrin (also a methemoglobin producing substance), will often relieve temporarily hay fever, simple spasmodic asthma, and that of myocardial origin.* Asthma complicated by chronic bronchitis while less serious than that associated with cardiac or nephritic degeneration, is nevertheless of a class that only in young persons achieves a cure. Their obstinacy has long been recognized by practitioners who see much of this disease.† The halogen salts like most remedies given for constitutional effect in asthma, stimulate the bronchial mucosa and by increasing an already existing bronchial catarrh are ill suited for treatment of these cases. Injections of epinephrin are of service, but its effect is transient and therefore it must be repeated at short intervals.

Practically then, benefit from the sodium salt recommended is limited to those cases in which asthma appears as yet a functional disturbance. Of course, this does not exclude cases in which bronchial catarrh occurs during the paroxysm. The individual must, however, show recovery from the bronchitis after conquering the asthmatic attack. In young persons even if asthma has recurred from infancy the chances of ultimate cure are good. But the attainment of this happy condition is not confined to youthful sufferers as is proven by like re-

*Because of far greater reliance upon the treatment outlined, mere mention is made of several measures recommended for spasmodic asthma. Between attacks arsenic may be of service. During the attack, until the system is under the influence of sodium iodate, the patient may use the usual smoking powders or inhalants for temporary relief. Pyridin or the contents of an amyl nitrite pearl may be of occasional service. I have never had the heart to urge persistent and volitionally lengthened expirations while the patient is in the throes of agonizing dyspnea, nor have I attempted the effect of mental suggestion under these circumstances. However, I have witnessed the trial of mental therapy by others. Failure was invariable. Cauterization of certain asthma exciting points upon the nasal mucous membrane has resulted in occasional good effect, but since the same are not recognizable visually, their cauterization is necessarily a haphazard matter. I have seen practically no benefit resulting from operations in the nose, done with a view to eliminate peripheral irritation from abnormal growths of bony or soft tissues or to improve respiratory conditions as regards air space. An operation apparently successful in that it has improved palpable anatomical defects, usually leaves the patient in full possession of his asthma. Such experience accords well with a humoral theory for this affection.

*It cannot be said that because each of a number of drugs can produce a methemoglobinemia, they may be indifferently substituted in treatment one for another. Without doubt other affinities, too, of these remedies must decide our choice. The rapid but evanescent relief from dyspnea and vasomotor spasm effect by amyl nitrite or pyridin fumes could not well take the place of the prolonged effect on metabolism of potassium chlorate or the latter of the bromine salts which experience has shown approaches specific effect in epilepsy. Yet substitution of methemoglobin-producing drugs is, to some extent, efficient, as we have seen, and may again be noted herein, that the one vegetable drug which it has been found fills a serviceable place beside the bromides in the treatment of epilepsy is *Solanum carolinense*, a plant which belongs to one of several classes that contain saponin bodies, glucoside substances which produce methemoglobin[1]

†Forty years ago Hyde Salter[6] said: "Such cases are very intractable and from this reason, that we have two diseases to treat, bronchitis and asthma. The asthma is intractable because its exciting cause, the bronchitis abiding, any remedies that are brought to bear upon it are rendered inoperative or merely of transient efficiency."

sults obtained in well preserved individuals in the sixth and seventh decades of life. While the writer has purposely pointed out the limitations of a certain mode of treatment, one may say that in spite of them, cases are not few which will be benefited, provided always that the patient is taught how to care for himself and above all, that the proper diet is rigidly enforced until time discloses his ability to add previously prohibited things to his dietary. A single warning must be voiced. Sodium iodate must not be given to tuberculous patients and especially such as have had hemorrhages. That this contraindication arises solely from the presence of the iodine atom is proven by equally evil effects sustained by the same class of patients when taking any form of this element. Scar tissue is absorbed, cough and expectoration are increased, and hemorrhage is apt to recur.

In conclusion, a word respecting hemoglobin in the urine which a test will disclose as present during the administration of energetic methemoglobin producing drugs. It need cause no anxiety since it is but a transient occurrence. An allied fact is worthy of note, although I am unable to interpret it. Once the writer attempted to counteract the hemoglobin loss by giving iron. A severe attack of asthma supervened in a few hours. Subsequent experimentation in other cases, to learn if this first result was accidental, showed that a chalybeate given to an individual recovering from asthma would bring on an attack with certainty.

To recommend a single drug is equivalent to presenting a specific remedy. As the result of considerable experience it may be stated that sodium iodate is a specific for the paroxysm of uncomplicated spasmodic asthma. Moreover in these cases by repeatedly conquering the attack through measures remedial, dietetic, and withal educational, the cure of this affection, which gives the impression of a vicious metabolic habit, is finally achieved.

CONCLUSIONS.

1. The identity of the mechanism underlying the toxemia of anaphylaxis and spasmodic asthma is attested by many clinical signs.

2. Whether or not the toxic intermediate products of protein metabolism common to both conditions are rendered inert, depends upon the capacity of the organism to reduce them by oxidation and cleavage processes to end products capable of elimination, *i.e.* uric acid, urea, etc.

3. Methemoglobin, being a more stable oxygen compound than oxyhemoglobin, fails to give up its oxygen to the tissues. Herein arises a selective oxidation, since methemoglobin is reduced by the toxic proteins of disease.

4. The above conditions and the further fact that a methemoglobinemia is harmful only when profound in degree, justifies the use of small doses of methemoglobin producing drugs in the treatment of asthma to effect a therapeutic methemoglobinemia. In practice this procedure has been attended with success.

CHRONIC LYMPHATIC LEUCEMIA.*

STUDY OF A CASE, WITH PARTICULAR REFERENCE TO BLOOD PICTURE AND FERMENTS IN THE URINE.

BY M. B. WESSON, M.D.,

EL PASO, TEXAS.

THE word leucemia is used to indicate a disease, the characteristic symptom of which is an increase in the white blood cells in the circulating blood, associated with hyperplastic changes in the blood-making organs. The diagnosis of leucemia is made on the blood pictures alone. We have to differentiate myelogenous and lymphatic leucemias.

The principal symptoms of lymphatic leucemia are the increase in lymphocytes, and the tumor-like enlargements of lymphatic structures. This increase need not be absolute, but merely relative to leucocytes. Chronic lymphatic leucemia is differentiated from acute by its very protracted course and the enlargement of the spleen. Preponderance of large lymphocytes does not necessarily indicate acute form, as every leucemia has a greater or less number of these. Great stress must be laid on the clinical picture. Acute leucemia has a rapid course, terminating fatally in a few weeks (most authors give six weeks as a limit for the acute form, but Fraenkel conservatively proposes four months) with evidences of profound prostration and degeneration of the organs, and practically no enlargement of lymph glands and spleen. While on the other hand, chronic leucemia develops slowly over a period of months or even years, with gradually increasing and finally marked lymphomatosis; and becomes fatal through cachexia or a process simulating the acute form.

The patient upon whom this study was made is M. F., age 51, who entered the hospital (service of Professor Barker), January 12, 1910, complaining of leucemia. The family history is negative. Patient has always been a healthy man. Had measles, mumps, and whooping cough as a child; malaria at 11 (five months' duration); typhoid fever at 34; sciatic rheumatism at 41; no syphilis. Occasionally suffered from tinnitus.

The present illness began one year ago, when he noticed that the cervical and axillary glands were enlarged. Four months ago strength began to fail, and on climbing stairs ankles were swollen and discolored (circulation has been poor since attack of typhoid fever). This swelling gradually spread up to knees. Would disappear at night. About nine weeks ago noticed painful spot on left side over splenic area. Within past five weeks has had night sweats, cough on lying down, increased expectoration, and shortness of breath.

The *physical examination* showed a rather emaciated man (had lost 22 lbs.). The whole body is somewhat pigmented. No abnormal pigmentation about axillary and inguinal folds. Marked venous pulse—centrifugal pulse with systolic collapse. The mouth examination showed enlarged tonsils and marked alveolar pyorrhea. Epitrochlear

*From the Medical Clinic of the Johns Hopkins Hospital, Baltimore.

glands barely palpable; posterior cervical, submaxillary, axillary, and inguinals markedly enlarged, rather firm and elastic. The inguinals form a large tumor mass in each groin; glands for most part are separate, 1 to 3 cm. in diameter, and form mass 8 x 4 cm. on right, somewhat less on the left. There is slight tenderness over the sternum on pressure. *Lungs* clear except at bases. *Heart* is clear except for soft systolic murmur, which is not transmitted to axilla. The *spleen* is readily palpable, 5 cm. below costal margin in L. M. L. Descends with each inspiration, rather soft and rounded. *Liver* dullness extends from fifth rib to 6½ cm. below in R. M. L. Edge is fairly sharp and rather tender. It reaches a point 11 cm. below tip of ensiform and 3 cm. above umbilicus in M. S. L. The surface is smooth. *Extremities:* There is slight pitting on pressure over tibia; ankles not swollen. Large deep-brown pigmented areas cover medial surface of legs.

In practically all of the cases reported the first symptom has been swollen lymph glands, though some cases do not show any glandular enlargement till late in the disease. Generally the glands are largest in the neck and decrease downward; average 5 to 2 cm. in diameter, discrete or loosely joined in small groups, usually hard, rarely tender, and movable under the skin. These continue to increase in size until end, unless secondary infection causes them to disappear. They seldom give rise to temperature symptoms. A fever at other times than acute exacerbations is due to complications. During the two months this patient has been under observation both inguinal and axillary glands have gradually grown larger, and are very much more tender on palpation than at time of admission. One axillary gland measures 4 x 2 cm. There are no palpable popliteal glands.

Patient has had no fever except that probably due to a herpes zoster. Shortly after admission inunctions of arsenic were applied in right axilla, and on this site a very severe herpes developed. This caused marked discomfort and patient developed a temperature which lasted for some days. At the present time the herpes has healed, but an exceedingly painful neuralgia remains.

The enlargement of the spleen is a constant symptom. Occasionally it is palpable with difficulty, but it may extend to the umbilicus. However, in the average case, as in this patient, it extends about 3 to 5 cm. below the costal margin. Enlargement is regular in all directions and spleen is movable, descending with each inspiration. Very large and hard spleens, as a rule, belong to cases with slight lymphocytosis.

The liver is generally palpable and extends a few centimeters below the costal margin in the right mammillary line, but an enlargement as great as in this case is rather uncommon. On February 20 the liver reached a point 6½ cm. below C. M. in R. M. L. and 11 cm. below tip of ensiform in M. S. L. March 12 the liver extended 12 cm. below C. M. in R. M. L. and 17½ cm. below the tip of the ensiform. The enlargement rarely gives rise to subjective symptoms—has not in this case.

Intense pain in the bones is usually the result of secondary infection of the periosteum and abscess formation.

There is an intense itching of the entire skin, which is usually dry and withered, frequently associated with an eruption of urticaria, papulosa, and vesiculosa. Lymphomata in the skin, as tubercles or larger nodules, are frequently described. Hemorrhages from the skin are rare, occurring only during acute exacerbations toward the end. Edema arises over all parts of the body as a result of pressure of the lymphomata on the veins and the lymph vessels.

Patients generally lose a small amount of weight, but, in this case, though there was a loss during the first month in the hospital, he has gained slightly in weight.

The examination of a drop of fresh blood of our patient showed it to be dull and opaque, pale red in color, and to smear easily. Erythrocytes were somewhat pale; very slight anisocytosis. Leucocytes seemed to be nearly as numerous as red cells —an extreme and remarkable leucocytosis. Mononuclears predominated, several eosinophiles seen, very few polymorphonuclear neutrophiles; no parasites or pigmented leucocytes.

In a smear with Wilson stain the reds were slightly pale staining. Numerous normoblasts, intermediate and megoblasts seen. No basophilic degeneration observed. The predominating white cell was lymphoid in type, resembling a lymphocyte in size, with a pycnotic reticulated and almost segmented nucleus, not uniformly stained. Few myelocytes seen, a few eosinophiles, and camparatively no polymorphonuclear neutrophiles. Large mononuclears did not appear to be increased. The relative number of reds and whites in a field was remarkable; numerous fields where leucocytes predominated.

The red-blood cells in all cases are decreased in number. Cabot says they average 3,600,000, but toward the end drop below 2,000,000. According to the figures of other writers his average is too high. The count on our case has averaged about 2,250,000, the highest count being 2,620,000 and the lowest 1,920,000. On admission (January 12) it was 2,320,000, and at present (March 12) it is 2,240,000. There has been at times a faint suggestion of poikilocytosis and there is a moderate amount of anisocytosis—mostly microcytes, few macrocytes. The deformities in size and shape depend upon the anemia. There is a central pallor of the cells which is constant.

The majority of writers agree that the color index is high when the count is below 2,000,000, and at other times less than 1. In our case it has averaged about 1.30, the hemoglobin remaining at 60, which is a little high for a red count of 2,250,000.

There is rather a unanimity of opinion that nucleated reds are rare in this disease, and that when they do occur they are of the normoblast variety, megaloblasts being practically never found. Da Costa reports a case in which 10,678 per c.mm. were found—8,512 normoblasts and 2,166 megaloblasts. On two days our findings exceeded this. The day of admission patient was evidenly having a blood crisis, as 96 nucleated reds were found while counting 500 cells (unfortunately these were not differentiated). Four days later 17 nucleated reds or 19,612 per c.mm. were present—13,468 normoblasts, 3,108 megaloblasts, and 1,026 intermediate. No polychromatophilia was ever observed.

In our case the platelets increased, and on some days they have been so numerous as to interfere with the counting of the red cells. The majority of authorities, however, agree that they are decreased in chronic lymphatic leucemia.

According to Cabot the average ratio of white to red cells is 1:50. The white counts vary from

1,480,000 to 30,000, an average being 350,000, which decreases to 180,000 toward the end. Da Costa states that counts over 250,000 are rare. In our case the ratio is much smaller, varying from 1:5 to 1:8. The highest count was 500,000 and the lowest 168,000. For the six weeks following admission the number of white remained constant, about 500,000; then they suddenly began to decrease till they were reduced to about 225,000, at which level they have remained.

The increase of lymphocytes is both absolute and relative. The proportion of large to small vary at different times in the same case. In this case the total non-granular cell count has varied from 99 per cent. to 90 per cent. The number of small lymphocytes range from 94.2 per cent. to 80 per cent., the difference being counterbalanced by changes in the number of large lymphocytes and large mononuclears present. Azure granules, which Naegeli says are not found in the cytoplasm of lymphocytes in leucemia, are present in large numbers. This observation confirms that of a number of writers. The rods Ottenburg reported as present in the large lymphocytes in acute leucemia were not observed.

The small lymphocytes are of the same size or smaller than the erythrocytes; and show a small amount of protoplasm, and a round, usually feeble staining sharply circumscribed nucleus. Occasionally a smear shows nuclei that stain with marked intensity, and others that are very pale. The deeply staining nuclei seem to be smaller and to have less protoplasm about them than the others. Attempts have been made to differentiate these according to age, the dark ones being the older.

I found that in thick smears the deeply staining nuclei predominated, but that in thin ones, particularly if the cover glasses were squeezed together, the light ones were in the majority. So in my case, at least, the variation in age was an antefact, due to flattening out of the cells. There is a marked nuclear network with occasional nodular swellings, but no definite nucleoli. Sometimes the network shows no definite outline or pattern. The nucleus is most often in the center of the cell, but it may be eccentric. The protoplasm is small in amount, and as a rule acidophilic (stains pink with Ehrlich). They resemble nucleated reds—differ in that the reds possess more protoplasm, stain pinker, and the nucleus is more solid and deeply staining. There is a clear unstained space immediately about the nucleus. Occasionally this is encroached upon by nodular thickenings projecting into it on all sides from the nuclear network.

Large lymphocytes have more protoplasm than the small, vary much in size, and hence it is often difficult to differentiate them. The nucleus is extra central, ovoid as a rule, though at times flattened on one side. The nucleus stains less intensely and the nuclear network is rather vague. Many of the large lymphocytes, which have a relatively large nucleus deficient in chromatin and a faintly basic non-granular protoplasm, are regarded as the mother cells of the typical small lymphocytes.

There are a few large irregular-shaped faintly staining bodies in the smears, homogeneous, devoid of granules and nucleus. All agree that these are both large and small lymphocytes in an advanced stage of degeneration; but there is a difference of opinion as to whether they are extruded nuclei or the protoplasm of cells that have lost their nuclei. They are not present in fresh blood, hence are regarded as abnormalities artificially produced in the readily compressed lymphocytes, commonest in thin smears. Their formation is prevented by making thick smears, and drawing the covers apart rapidly.

The "mononuclears" are unusually large, and have a large, oval, vesicular, eccentrically placed, faintly staining nucleus, which may be overlooked, and abundant weakly basophilic protoplasm without granules. Many of the nuclei are egg-shaped, and quite rich in chromatin, the latter being scattered over some and collected in bunches in others. These cells vary much in size and a day or so preceding a decrease in the total white count they appear to be extra large. This was noticed most clearly in the counting chamber in the blood that had been prepared for making a leucocyte count, the reds being laked with acetic acid and the nuclei of the whites standing out sharply.

The number of polymorphonuclear cells is relatively low; rarely does it reach 10 per cent. I found that while the white-blood count numbered 500,000, 1.2 per cent. was the greatest number of neutrophiles found; and that it varied from this to 0. Since the decrease in whites the percentage has increased, and one count showed 8 per cent. Eosinophiles are said to be absent or less than 1 per cent.—an absolute and relative reduction. Our count showed a variation from .2 to .8 per cent. No mastzellen were seen at any time.

Myelocytes are reported as being generally present in very small numbers, but rarely exceeding 1 or 2 per cent. I found them to vary from 1.4 per cent. to 0. Eosinophile myelocytes are rare, but I found them in larger numbers than reported by other observers; however, 0.4 per cent. was the maximum number.

Occasional improvement in the blood picture is not uncommon. Apparent remissions lasting for months have been described, in which the swelling of lymphatic structures retrograde and the blood picture becomes nearly normal, though there is a considerable increase in lymphocytes.

The study of the urine has been of considerable interest. It has been reduced in quantity, dark yellow to orange in color, turbid, specific gravity 1,025, acid reaction, no albumin or sugar. There is generally, in a twenty-four-hour specimen, a heavy, voluminous, brick-red sediment of amorphous urates. Not infrequently uric-acid crystals are present. I found no record of their presence in reports of other leucemia cases; however, my review of the literature was not complete.

At the suggestion of Dr. Roger Morris Washington University St. Louis I made a search for ferments in the urine. The procedure for glucose, maltose, saccharose, and lactose was as follows: 5 c.c. of urine was added to 10 c.c. of a 2½ per cent. solution of the sugar, and to this was added 1 c.c. of toluol to prevent the action of bacteria. Two active and two controls, of boiled urine, were prepared of each. These were incubated for five days. Then they were removed from the thermostat and immersed in cold water to prevent further action of the enzymes. The solutions were filtered and examined with the polariscope. I found no differences between the active tubes and the controls in the glucose, saccharose, and lactose. But in the case of maltose, the control tubes rotated the light more strongly than the active, thus indicating that *there must have been some enzyme present (moltase) which had broken down the maltose molecule.* The following table shows the polari-

scope readings. Tubes No. 1 and No. 2 are active, No. 3 and No. 4 are controls:

Date	No. 1	No. 2	No. 3	No. 4
February 12.....	1.6 1.5 1.5	1.5 1.5 1.5	2.3 1.9 2.0	Lost
March 12.....	0 1.0 0.5 1.0	1.0 1.0 −1.0 −0.5	1.6 2.0 1.7 2.0	1.9 2.4 2.0 1.6

For the amylolytic ferment 10 c.c. of 1 per cent. starch water (boiled) was added to 5 c.c. urine and 1 c.c. toluol. The procedure was then the same as described for the sugars. The readings showed no differences between the active tubes and the controls. Hence there was no amylolytic ferment present.

The proteolytic ferment required a more complex medium. One part of ascitic fluid and two parts of normal salt were heated one-half hour at 75-80° C. Ten cc. of this product were used for each tube, and the same routine followed as already described. At the end of five days, 16 per cent. $MgSO_4$ was added and the solution heated, then acidified with dilute acetic acid and neutralized with $NaHCO_3$. This was filtered into a Kjeldahl flask and the routine oxidation done. The distillate was titrated against N/¹NaOH. The active tubes required 2.85 c.c. and 2.6 c.c. respectively, while the controls only needed 1.5 c.c. and 1.4 c.c. to neutralize. *This indicated definitely that a proteolytic ferment was present.*

Date	Alkali Added Before Incubation	ACIDITY EXPRESSED IN C.C. N/20 NaOH						Difference in Acidity
		Urine Unboiled			Urine Boiled			
		No.1	No.2	No.5	No.3	No.4	No.6	
Feb. 12	0	.9			.6			.3
			.85			.6		.25
Mch. 3	1.8	.6			.2			.4
			.6			.2		.4
Mch. 12	.6	1.0			.4			.6
			1.0			.4		.6
	0			1.5			.8	.7

Hewlett's method of testing for lipase is so clumsy that I discarded it and used a modification of Loevenhart and Kastle's method—such as is being used in the pathological laboratory. The tubes contained 8 c.c. water, 2 c.c. urine (single specimen), 0.52 c.c. ethyl-butyrate, and .6 c.c. toluol. They were titrated against N/20 NaOH after twenty hours' incubation, azo-litmus being used as the indicator. In the first experiment the active tubes required about 0.3 c.c. more alkali than the controls. This difference suggested the presence of a fat splitting enzyme, but was not very positive. The patient was then given sodium bicarbonate gr. xxv. t.i.d. for a week in order to make the urine neutral, but this was not accomplished. Another series of tubes was prepared, however (single specimen), and the active tubes found to require .4 c.c. more of the alkali to neutralize than the controls. It occurred to me that the enzymes might be concentrated by means of the heavy urate precipitate, so the last trial was made with a twenty-four-hour specimen of urine. About 5 c.c. of the sediment was obtained by means of a pipette. This was heated to 40° C, and the precipitate dissolved. The tubes were then prepared as before, having, however, three actives and three controls. Two of these pairs were neutralized by adding 0.6 c.c. N/20 NaOH and the third left acid. After incubation I found that the "neutral" active tubes required 0.6 c.c. more alkali than the controls, while the "acid" required 0.7 c.c. more than its control. *I think there is no doubt but what there is lipase present.* The following table shows the results of the various titrations:

HEMOPTYSIS IN TUBERCULOSIS: ITS SIGNIFICANCE AND ITS TREATMENT.

By THOMPSON FRAZER, M.S., M.D.,

ASHEVILLE, N. C.

On first thoughts it may seem like time wasted to discuss at any length a symptom such as hemoptysis, which has been a phenomenon familiar to the medical profession ever since the days when Hippocrates wrote: "In persons who cough up frothy blood the discharge of it comes from the lungs." One would think that there would indeed be little to be said about a symptom which has engaged the attention of the profession for centuries, but a little investigation will reveal the fact that, much as has been written on this subject, the opinions of physicians are still greatly at variance as to the frequency, the significance, and the treatment of

hemoptysis occurring in the course of pulmonary tuberculosis.

I shall, therefore, present in this paper the views held by different phthisiographers on this subject, taking up the incidence, the causes, the diagnostic value, and the prognostic import of bleeding from the lungs in chronic tuberculosis, concluding with a consideration of the therapeutic indications to be met in this condition.

Incidence of Hemoptysis.—As to the frequency of hemoptysis in tuberculosis there is a great difference of opinion. Flick says: "The frequency of this symptom is surprising and greatly exceeds the expectation of clinical experience."[1] In a series of cases observed during one year, there were hemorrhages in 51.03 per cent. Cornet,[2] quoting from various sources, finds that the estimates vary all the way from 24 to 70 per cent.; others make the percentage still higher. The differences in the figures given by competent observers are somewhat difficult to reconcile; it is probable that different classes of cases were under observation. At any rate, such wholesale statistics have but little practical value and they must be but "lame and impotent conclusions" that are based upon them, for, to be of diagnostic service, the stage in which hemoptysis is most common, must be known. Of greatest utility in incipient cases, its value varies indirectly with the progress of the disease, while in those cases in which death ensues shortly after an hemoptysis, this symptom, from a diagnostic viewpoint, approaches zero. A redistribution of these hemorrhagic cases must be made, they must be pigeon-holed according to the stages in which they occur before statistics can be of any great diagnostic significance.

This has already been done, although but to a limited degree. Cornet thinks that "most frequently the hemorrhage occurs in the very beginning of the disease," but he gives no figures. Minor[3] has found the symptom most common in "relatively advanced cases," but adds that careful inquiry might reveal the occurrence of blood-spitting in the earlier stages.

The conclusions of Anders[4] are of interest. He says that "In about 10 per cent. of cases of chronic ulcerative pulmonary tuberculosis, hemoptysis first directs attention to, and is almost invariably followed by, the demonstrable and conclusive evidences of the disease. In not less than 25 per cent. of all cases of chronic pulmonary tuberculosis, hemoptysis is among the ushering-in symptoms of the active, recognizable period of the affection."

The report of Smith[5] (dealing with hemoptysis) merits our attention. He believes that the disparate figures obtained by equally competent observers is dependent, in a measure, upon whether or not blood-streaked sputum is considered a hemorrhage. He goes on to say that the "importance of this symptom (streaked sputum) in establishing a diagnosis is great—practically as great as frank hemorrhage—and physicians dealing with early cases are not apt to make any distinction between the degrees of hemoptysis, but it is considered doubtful whether all cases of pulmonary tuberculosis do not have, at some time during the course of the disease, sputum streaked with blood from the lungs." In the series of cases which he reports he does not, therefore, consider streaked sputum as a hemorrhage, but regards it as being "sometimes, at least, indicative of a reparative process—an evidence of forming granulations." In spite of this non-inclusion of streaked sputum, the percentage of hemorrhagic cases in his series is rather high. Thus, in 1210 cases in all stages, 38 per cent. had one or more hemorrhages, while in 67 incipient cases 28 per cent. were hemorrhagic. If we include as hemorrhagic cases with streaked sputum, we shall not be guilty of an overstatement in saying that at least 50 per cent. of all cases of pulmonary tuberculosis have hemorrhages, one-half of this number having the first hemorrhage early in the disease.

Diagnostic Significance.—From what has been said above, the diagnostic value of hemoptysis is evident; for, while not absolute (on account of its occurrence in diseases other than tuberculosis), the aggregate of these cases is inconsiderable when compared with those in which tuberculosis is the undoubted cause. "All in all, one does not err in considering actual pulmonary hemorrhages to be of tubercular nature, although hemorrhages do occur in certain other diseases, in hemophilia, pneumonia (abscesses and gangrene), and aneurysms of the aorta. Diseases of the heart, especially mitral stenosis, and diseases of the tricuspid are important causes of bloody infarcts; but in such cases a careful examination reveals the etiology."[2]

The observations of Hirschfelder[6] are in accord with those just expressed: "As a result of engorgement of the pulmonary capillaries or of permanent injuries to their walls, hemorrhages from the lungs may occur in any acute cardiac overstrain, but they are most frequently seen in cases of mitral disease. . . . . It is always of the greatest importance to differentiate between such an hemoptysis and that of an early pulmonary tuberculosis, and only the most careful repeated examinations, coupled with the presence of the cardiac lesion and the absence of signs of pulmonary disease, give sufficient grounds to exclude the latter."

Hawes,[7] in a series of 114 hemorrhagic cases, says that 68.3 per cent. were either strongly suspected or proved to have tuberculosis. Miller[8] thinks that hemoptysis "should always be considered to be due to tuberculosis unless another definite cause can be demonstrated." Bartlett[9] is of the opinion that hemoptysis occurring in pneumonia, bronchitis, asthma, or following trauma should lead to the suspicion of an underlying tuberculous process.

The question as to whether hemoptysis may be, at times, a form of vicarious menstruation is still unanswered. The relationship between uterine and pulmonary hemorrhages was noted by the Father of Medicine in the aphorism "Hemoptysis in a woman is removed by an eruption of the menses" and we know that pulmonary hemorrhages are not uncommon at the premenstrual period, but whether we can consider hemoptysis as replacing, or equivalent to, the periodical uterine flow is extremely doubtful. Bartlett does not believe that an hemoptysis can occur in normal lungs, while Cornet thinks that vicarious menstruation "does undoubtedly occur, though on the whole but rarely."

In this connection a case that I have at present under observation is of interest. A young girl, sixteen years of age, consulted me recently on account of small pulmonary hemorrhages occurring at irregular intervals during the last eighteen months. Menstruation had never been established. Examination of the lungs revealed nothing, but the presence of an infantile uterus was discovered when a gynecological examination was made by Dr. Griffith. This would seem to be a case of vicarious

menstruation, but the patient must be kept under observation for several years in order to make sure that pulmonary disease has not followed the hemoptysis before one can, with any reasonable degree of safety, exclude tuberculosis as a cause of the hemorrhages.

The percentage of cases in which tuberculosis is the cause of pulmonary hemorrhage is variously estimated, but all writers agree that it is a considerable one. Thus Bartlett thinks that hemoptyses are tuberculous in origin in 90 per cent. of the cases, while Brown[10] says that 90 per cent. of all cases having hemoptyses develop at some time, sooner or later, pulmonary tuberculosis. It is not claiming too much for this symptom, therefore, if we rank it among the most important diagnostic features of tuberculosis.

Causes of Hemoptysis.—The cause of pulmonary bleedings is a topic that deserves and has prompted considerable investigation. Before enumerating what we may consider the actual exciting causes of hemoptysis, a brief consideration of the predisposing cause, the pathological condition of the pulmonary vessels may not be out of place. This condition, briefly, consists in the invasion of the walls of the smaller vessels by tubercle formation. It is easy to understand how these weakened walls might lose their power of resistance against the pressure of the blood, readily giving way if this pressure be sufficiently increased. Sometimes the new formation projects into the lumen of the vessel, giving rise to a local increased pressure at this point. Such are the conditions in the early stages. Later in the disease small aneurysms are formed in the walls of the larger vessels and it is these which rupture and give rise to the larger hemorrhages in advanced cases.

The actual exciting causes—which have been assumed directly responsible for pulmonary hemorrhages—are almost as varied as they are numerous. Mental excitement is not infrequently followed by a hemorrhage from the lungs, and physical overexertion—in the form of an acute strain or more prolonged efforts such as riding or mountain climbing—is a common etiological antecedent. An alcoholic debauch may bring on a hemorrhage; and sexual intercourse has also received its meed of blame.

A rapid rise in humidity with lessened excretion of water through lungs and skin and consequent increase of pressure in the pulmonary circulation, has been held accountable in some instances, and the drinking of large quantities of water during the hot weather probably favors the occurrence of hemorrhages for the same reasons. Plethora, predisposing to hemorrhage, may be due to overeating, and in women, the systemic plethora of the premenstrual period must also be counted as a possible cause of hemoptysis.

While the causes mentioned are varied in character, the action of them all can probably be referred to an increased blood-pressure. This is not always demonstrable—and, indeed, the hemoptysis frequently appears unheralded by any of the gathering clouds above noted—but the frequent recurrence of hemorrhages makes probable the explanation that they are due to an increase in the blood-pressure, which the vessels, in the eroded state of their walls, are unable to withstand.

Prognostic Significance.—Fortunately, the results of hemoptysis are frequently negative, although the percentage of cases in which this obtains would be difficult to estimate. In incipient disease of the lung the patient, following a hemorrhage, often finds that he is relieved of a sense of distress or constriction in the chest with which he had suffered for several days previous to the occurrence of the hemoptysis; and, if rest in bed be resorted to and proper treatment instituted it is not unusual for a marked improvement to take place. The depression of spirits which the hemorrhagic novice experiences is usually soon recovered from, and, as ill consequences so often do not occur, subsequent hemorrhages are tolerated with but little mental anxiety.

But the outcome of an hemoptysis can not be foreseen. In some cases a considerable amount of dissemination may follow an hemoptysis, in others a single large hemorrhage may be the starting-point of an acute bronchopneumonia with fatal outcome; while repeated smaller bleedings may carry off the patient through exhaustion. In advanced case swith cavity formation the bleeding, owing to inadequate thrombosis, is often uncontrollable and death may result from exsanguination or suffocation.

Smith[5] considers hemoptysis unfavorable from a prognostic standpoint. He says that patients who are "doing well, of whatever type or stage of the disease, do not become hemorrhagic and hemorrhagic cases do not bleed when they are improving." In his series of 417 deaths, 10 per cent. were due to hemoptysis, death occurring immediately or within two or three days. He thinks that "instances where overexertion, injury, or hard cough has been the exciting cause of hemoptysis are extremely rare, and are confined largely to hemorrhages occurring as the initial symptom of the disease."

Treatment of Hemoptysis.—Although there exists considerable difference of opinion as to the causes of hemoptysis, there is practical uniformity in the methods employed in the treatment of this condition, despite the use of drugs apparently antagonistic in their action and other minor details. The first indication is to reduce blood-pressure; as Smith says: "This constitutes the most rational and successful line of treatment."

As hemoptyses are sometimes preceded by a sense of tightness in the chest or by the presence of blood-streaked sputum, it may be possible to prevent their occurrence by insisting on absolute rest and by the administration of a drug—such as the nitrites—with the view of decreasing vascular pressure. Either of the following may be used:

Sp. nitroglycerin	♏ xv
Aquæ	℥ ij
Dose: ℥ j	
Sodii nitritis	gr. xv
Aquæ	℥ ij
Dose: ℥ j	

A teaspoonful of either of the above may be given every four hours for two or three days.

More commonly, perhaps, the patient receives no warning and the physician is summoned to treat an active hemorrhage. In the presence of this condition the indications are three in number: to secure absolute physical rest, to quiet the fears of the patient, and to lower the blood-pressure, attempting in this manner to favor the formation of a clot, which is nature's method of checking hemorrhage.

This means that the patient must be put to bed and all unnecessary movements on his part must be avoided: he is not allowed to get up to attend to the demands of nature, nor is he allowed to talk. A

comfortable position should be assumed: usually the semi-recumbent posture (with one or two pillows under the head) is best; and the patient should be assured in a few words that there is little cause for apprehension. My own practise is to break one of the little "packages" of amyl nitrite (such as are prepared by the different drug firms), holding it for several minutes under the patient's nostrils. This is the most rapid and effective means of securing vasodilatation that we possess, as the action of amyl nitrite begins within fifteen seconds (and lasts for about 10 minutes), according to the investigations of Hewlett, quoted by Hirshfelder. As a result of the vasodilation produced by this drug, and assisted in many instances by the quieting of the patient's fears which follows the appearance of the physician, the hemoptysis frequently comes to an end within a few minutes. Whether or not this occur, the patient should receive atropin gr. 1/50 hypodermically, and this dose may be repeated two or three times within the next twenty-four hours. Some advise an initial dose of gr. 1/25. This drug, though usually classed with the heart stimulants, acts most efficiently in cases of hemoptysis, the assumption being that the flushing of the skin, which is characteristic of the action of atropine, relieves the congestion of the deeper organs, with a consequent decrease of intrapulmonary pressure.

In place of atropine some prefer the use of nitroglycerin. This may be administered hypodermically in doses of gr. 1/100, repeated at short intervals, at first every half hour or hour, for three or four doses, later less frequently. After vasodilation has been obtained, more permanent effects may be secured by the use of sodium nitrite, gr. j, every three or four hours.

Morphine, although used considerably in hemoptysis, should not be resorted to as a routine measure. It is indicated if the cough be troublesome, but its field of greatest usefulness is in those cases where excessive nervous irritability exists.

It is customary, at the onset of a hemorrhage, to place a light ice-bag over the precordium, with a view to quieting the heart's action. A fuller discussion of this measure will occur later, in connection with the use of digitalis.

There is no specific diet for patients with hemoptysis; but the amount given should be small and fluid in character (milk in small quantities and egg-albumen are suitable); especially is it necessary to restrict the diet during the first twenty-four hours.

While depletion through the intestines by means of catharsis has been advised and is theoretically indicated, it is better to wait twenty-four hours before attempting to move the bowels on account of the exertion which this action imposes on the patient. Also examination of the chest should not be undertaken, or should be restricted to auscultation; under no circumstances should percussion be practised.

As to the length of time that a patient who has had an hemoptysis should stay in bed, there exists considerable difference of opinion: it is safer to insist on rest in bed for 24 to 48 hours after the expectoration of post-hemorrhagic clots has ceased.

Such, in brief, is the routine treatment of hemoptysis; but a discussion of this subject would be incomplete without an allusion, at least, to other drugs and measures which have been advocated in this condition. Thus, common salt, in doses of a teaspoonful, has been employed on account of an irritation of the vagus, with reflex constriction of the pulmonary vessels, which it is supposed to incite; its action, however, is hypothetical; while ice by mouth is probably to be regarded as a psychical hemostatic only.

Chloroform has been recommended because "it lessens the heart action, reduces the blood pressure and diminishes the respiratory movement."[11] Two to 4 c.c. are dropped on cotton and held near the patient's nostrils and the inhalation of a few drops is continued at one-hour intervals, for several days.

The use of emetics has been abandoned, practically, and ergot, once considered the drug par excellence, has been supplanted by the vasodilators.

A valuable procedure which should be borne in mind is the tying off of the extremities by means of bandages applied to the middle of the arms and thighs; it is especially serviceable in large hemorrhages where there is danger of exsanguination. The constriction, which should be great enough to interfere with the venous return without obstructing the arterial flow, should be gradually removed after having been applied for ten or fifteen minutes.

It is evident that the drugs and procedures above described depend upon one common principle, the reduction of blood-pressure. More recently attempts have been made to facilitate the formation of a clot by other means. Thus, drugs are employed which are supposed to increase the coagulative power of the blood; chief among these are gelatin and the calcium salts—the chloride and lactate.

More difficult of explanation is the rationale of the action of adrenalin in cases of hemoptysis. Being a vaso-constrictor, one would think that by defeating the very object ordinarily sought, *i.e.* the reduction of the blood pressure, it could exert only a baneful influence; yet, this drug is one of the most reliable agents at our command for the halting of a hemorrhage. Coleman recommends five drops of adrenalin chloride, or three grains of the suprarenal extract, every three or four hours. The action of the recently introduced pituitary extract has not been satisfactorily explained.

Another drug whose mode of action seems but imperfectly understood is digitalis. At one time held in high esteem as a hemostatic, its virtues are but seldom sung to-day. This is the more remarkable when we compare its effects with those of the almost universally used precordial ice-bag. In discussing the effects of the latter, Hirshfelder says: "Simultaneously the blood-pressure rises and the pulse increases in volume. There is evidently both a reflex vasoconstriction from stimulation of the vasomotor centre and a reflex stimulation of the vagus." Besides this, da Silva thinks that there is a direct stimulation of the heart muscle. It will be noted that these effects are exactly those brought about by digitalis, and hence enthusiastic hydrotherapists are in the habit of speaking of the ice-bag as "physiological digitalis." It is possible that digitalis, on account of its well-known tendency to upset the stomach, has for this reason been superseded by the ice-bag; but if the latter is indicated as often as it is prescribed, there surely must be a considerable number of cases where digitalis would be of benefit.

We have seen from what has been said that the profession is by no means united as to the significance, and the treatment of the symptom hemoptysis, occurring in pulmonary tuberculosis. And yet, in spite of the fact that this symptom is not in the strict sense pathognomonic, that it may appear early or late in the disease, or not at all—in spite of these

limitations and restrictions, hemoptysis must be regarded, diagnostically, as a symptom of great value, prognostically, as a sign of considerable, though still undetermined, import. And in spite of the advocacy, in this condition, of drugs antagonistic in their action—drugs which are classed as stimulants, depressants, dilators, and constrictors—we cannot disregard the accumulated clinical evidence at our disposal that all of these drugs have proved useful; and, perhaps, with a fuller knowledge of the action of drugs and a deeper insight into the cause and the "pathology" of hemoptysis, we may find that the antagonism is more apparent than real.

THE PHYSICIAN'S ROLE IN PREVENTIVE MEDICINE.*

By DANIEL B. HARDENBERGH, M.D.

MIDDLETOWN, N. Y.

That the opening address of the presiding officer should be general in scope is quite customary.

The physician's immediate employment is the treatment of disease. By education and experience, however, the physician is qualified to act in a capacity of equal importance as conserver of health. This function he fulfills while pursuing his practice. Seldom called upon except to treat morbid conditions already present, he nevertheless takes occasion to indicate the way along which lies greater immunity. To this individual instruction the physician may add his influence in favor of the great cooperative movements that make for the physical amelioration of the community, or of the nation.

In no sphere of human activity have results been more beneficent than in that of medical research. What more striking aspect of human progress is to be found than in the contrast afforded in the conditions of health and longevity in early periods and the present!

In the 16th century the average length of human life was less than twenty years, while to-day it is nearly forty years. In London in the 17th and 18th centuries the death rate ranged from forty to eighty per thousand; now the rate is fifteen per thousand. At present the mortality varies in different countries as does the dissemination of medical science. In Denmark it is fourteen per thousand, while in India famine and plague raise the rate more than three-fold.

Great as has been the advance in safeguarding human life never were the opportunities for further advancement more inviting. Not to the medical mind alone is this apparent. Some of the first economists recognize that no expenditure of effort and wealth may be made so productive as that directed to the conservation of human life and health. In the words of Prof. Irving Fisher "the conservation of human life constitutes, therefore, the grandest movement of the twentieth century."

This truth while recognized by many discerning intellects is yet so inadequately appreciated that men of education, particularly men of the medical profession, should join in advancing the propaganda, and recognize that no richer field for altruistic endeavor exists than in directing public attention and interest to the advancement of medical science, and its application to social life. Failure to appreciate these opportunities and duties by the masses, by mercantile interests, and by political bodies may as readily be indicated as the discernment of students. Before a recent legislature in Ohio were two bills, one appropriating $25,000 to equip a serum farm for the treatment of cholera in hogs, and one for the manufacture and free distribution of antitoxin serum for the cure of diphtheria in the human subject. The legislature passed the bill for the preservation of the swine, and rejected that for the human subject.

It may be contended that humanitarian purposes should not sway such a body. But from a materialistic standpoint what investments yield greater returns to the national wealth than those directed to the health of the nation? Estimating the economic value of life through the capitalization of earning power, and using the tables of Farr of England to which have been applied the increased wages in America it may be shown that the value of an average life rises from about $100 at birth to over $4,000 at 30. Nicholson estimated that human labor capitalized in Great Britain was worth five times all other capital. Consider the decreased mortality from typhoid fever that has followed the establishment of filtration beds for the water supply of Berlin. What wonderfully rich investments have been these expenditures!

The average earnings of the southern farm laborer is 75 cents per day; that of the victim of hookworm disease, 40 cents. The cost of drugs required to cure a case of hookworm disease may be about fifty cents. What a field for investment!

Leonard Wood has declared that the discovery of the mosquito as the carrying agent for yellow fever is saving more lives annually than were lost in the Cuban war, and that it is saving the commercial interests of the world a greater financial loss each year than the cost of the entire Cuban war.

Greater advance has probably been made in the prevention of disease than in its cure. Undoubtedly public appreciation of preventive medicine is more adequate than that of therapeutics. The profession is fairer in its attitude to new methods of treatment than is recognized. So far as is just to the public it assimilates and incorporates that which is valuable in such methods; but, while this public remains eager for that which is new rather than that which is best, the professional attitude of aloofness to these methods during the period of exaggerated regard for them must, in a measure, continue.

*President's Address at the Annual Meeting of First District Branch of the Medical Society of the State of New York, held at Poughkeepsie, N. Y., October 4, 1912

It may be chided for failing at once to incorporate the methods of Christian science or osteopathy, but while certain portions of the public are eager to apply one or the other of these methods to the greater number of ills, how can the profession hold such a tendency but as misguided? It will not itself encourage fallacies in order not to be displaced.

It is willing to concede all that is valuable in mental science, Christian science, hydrotherapy, hypnotism, massage, osteopathy, and electricity, as well as hygiene and drugs, but how can it be expected to yield to passing whims to apply single methods of treatment to all ills to the exclusion of all other methods! It will need wait until the public has upon a particular method become rational before it can satisfy the demands for such treatment.

The instruction of our best schools, and the attitude of our societies and press should be broad enough and progressive enough to seize upon all that is valuable in treatment from sources obscure as well as scientific. The attitude of many well-informed among the public has been to accept among the drugs a certain number such as quinine and mercury whose specific effect is too apparent, even to the casual observer, to be denied; to admit the degree of immunity that follows administration of certain of the vaccines; to accept the antidiphtheritic and other of the antitoxins; and to sweep away from consideration practically the balance of the pharmacopœia. We undoubtedly can and shall do with many less drugs, and yet the results of most painstaking observation, even while classified as empirical rather than scientific in origin, we shall not consent in a body to discard. We shall, rather, gradually relinquish that which is less valuable, and assume certain newer agencies, not in the belief that they are final, but according to the best of present knowledge. No remedy is too obscure to receive consideration, or too obvious to escape scrutiny.

The most sceptical are perhaps themselves harboring delusions. Should one venture to offer as wholly beneficent agents merely fresh air and light, he would not escape scepticism upon the latter, at least.

It would be urged that the greater number of animal creatures live in deep darkness at the bottom of the ocean, and that man himself lived, until recently, in the darkness of forest, cavern, and hut. That in the tropics animal activity is nocturnal and that the neurasthenia of the white race, and the extinction in certain latitudes of that race is due to the destructive over-stimulation of light upon nerve tissue. In time exception may be taken to over-abundance of fresh air if one judge the future from the past.

So long as the medical profession continues with the best knowledge obtainable, and applies that knowledge with the greatest zeal and honesty it may be trusted to discard the inferior, and to adopt the new and preferable with greater wisdom than can the public at large. A profession so informed and so disposed will maintain an ever increasing influence and respect.

Ever increasing demands are made upon our medical schools. I should deem advantageous the union of the medical schools in the large cities. Such seats of medical learning would secure greater influence and prestige, and would invite not only continued endowment from individuals but might well become recipients of State endowment and support.

Paternalism in government, however to be decried, is evidently increasing, and nowhere can public money be more profitably employed than in combating morbidity and death in the nation.

With all zeal to maintain a worthy leadership in matters of public health the physician should be observant and prompt to act upon opportunities for advancement of health measures that interest of the public, however aroused, may offer. The present interest in combating tuberculosis that is so general should be utilized to press reforms that at a later period may be far more difficult.

The enactment of law in this State permitting the establishment and maintenance of hospitals at county expense for the treatment of tuberculous subjects should be utilized to the fullest extent to provide asylum for the hopelessly diseased, to guard against dissemination by segregation, to instruct in the early and proper treatment of the malady, and to cure the incipient cases. The interest of cities and villages in establishing dispensaries and day-camps should be stimulated, and the willingness of physicians to render gratuitious service and assume chief labors in such maintenance continued.

The present effort so representative of the best thought in the nation to secure in the national government an independent department, or bureau of public health should enlist the active cooperation of all physicians. No body of physicians is so large and none so small to escape a burden of responsibility toward this measure.

That the agencies for public health should remain scattered in eight departments, and that there should be no official in the public health service independent enough to express an opinion on matters pertaining to his bureau without securing the approval of a superior charged not with maintaining the health, but the finances of the nation is absurd.

The sacrifice of an efficient officer of the government, Dr. Wiley, may be attributed not so much to the officials who surrounded him as to the system that maintained them.

An excellent example of sacrifice of public health that the present system entails may be found in the instance of the bubonic plague in California cited by Senator Owen. Recalling that this was the most dreaded plague, the black death of London, that in a single outbreak killed 200,000 in Moscow, and more recently 164,000 in Bombay, he relates that when in 1900 this plague broke out in San Francisco the city board of health quarantined the Chinese district. On June 15, 1900 a United States district judge influenced by the commercial spirit of San Francisco declared the quarantine illegal saying, "I should hold that there is not now and never has been a case of plague in this city."

This opinion was followed by an immediate federal quarantine by the Marine Hospital Service officials. The governor and commercial bodies of California proved a false case before the Secretary of the Treasury, who compelled his subordinate, the Surgeon-General, to yield. The Marine Hospital Service finally persuaded the Secretary of the Interior to cause an inquiry in January, 1901, by experts of the highest order, Prof. Flexner, Prof. Novy, and Prof. Barker. Their unanswerable authoritative report was made in February, 1901, finding numerous cases of bubonic plague in the heart of San Francisco. United States quarantine law required immediate publication. Senator Owen states that he was advised that the report was suppressed two

months. He states further that since then various experts in government service have discovered in the rodent, and occasionally in the human subject, bubonic plague all the way from Los Angeles to Seattle, and that rustication of the expert making such announcement regularly followed, and that now, such is the prevalence among rats and squirrels along the coast that a serious outbreak in the human subject is quite possible; even the city of San Francisco is stirred to an expenditure of millions for erection of concrete docks to guard against further invasion of rats.

The futility of the present subordination of health interests of the nation could scarcely be better illustrated than in this recent history.

Opponents of the Owen Bill have sought to stigmatize it as a measure of the "doctors' trust." False as is such designation it has been used to weigh down the bill. Such an effort on part of patent medicine manufacturers and other opponents of the bill to render the support of the American Medical Association and other representative bodies a handicap to the measure should be met with most resolute determination to bring the proposed legislation to public attention in the confidence that attention once secured approval will surely follow.

Why, with a lowered death rate from nearly every other cause, is there an increase in that of arteriosclerosis with its allied chronic degeneration of heart, kidney, and liver? The ill effects of alcohol in excess are appalling. Will there follow not only a frank acceptance of the danger of overeating as well as overdrinking, but will the conclusion be reached that as alcohol in excess is deadly so in whatever moderation consumed it remains harmful. Such broad minded men as President Taft and Roosevelt as also the Emperor William, have been led to such conclusion and recognizing the responsibility of example, refrain from the use of alcohol.

With a more exact application of science to living there will be ever a closer scrutiny of the physician's own measure of hygiene. Whatever the physician's opinions, the public will rightly expect of him an example to enforce his precepts.

A STUDY OF THE EFFECT OF EXPERIMENTAL HYPERTHERMY ON THE OPSONIC ACTIVITY OF THE BLOOD SERUM OF THE RABBIT.*

By G. A. RUECK, M.D.,

NEW YORK.

For a long time fever was considered to have a harmful and deleterious influence on the course of infectious disease, but recent study suggests that a moderately elevated temperature has little harmful effect on the body tissues and that, in a degree, elevation of body temperature may increase the protective resources of the body and thus be conservative in its action.

Rolley and Meltzer, Lüdke, Riethus, Horning and Rolley, and others demonstrated experimentally that the parenchymatous degeneration of the inner organs, the marked decrease of hemoglobin and erythrocytes found in rabbits as early as one to two days after the beginning of an infection, and that the increase of leucocytes and the increased decomposition of albumin present in infected animals must be attributed to the action of the toxins, of the pathogenic bacteria in the tissues and not to the action of the high temperature on the tissues. That the increase in body temperature may retard the development of infection is shown in Filehne's experiment. Animals were inoculated with streptococci which he isolated from cases of erysipelas. The inoculated animals when kept warm were only moderately sick and recovered. Controls untreated died. Löwy and Richter injected animals with the organisms of diphtheria, chicken cholera, swine plague and pneumonia, and elevated their body temperature by means of the "Wärmestich." When the body temperature was artificially raised in this way the animals resisted these infections better than untreated controls. Rovighi and other men have obtained similar results in their experiments by elevating the body temperature of the infected animal. They failed, however, to show whether an elevated body temperature favored leucocytosis or stimulated the different protective activities of the blood serum. Comparatively few investigators were led to assume that an elevated body temperature did not favor the course of infection. Among these were Ritzmann, Barankeieff, and some others.

Sulina and others studied the thermal limits of bacterial growth in test tubes and concluded that the growth of bacteria in the infected animal body must, in approximately the same way, be inhibited through an elevation of body temperature. Rolley and Meltzer and others have demonstrated experimentally that an elevation of the body temperature of animals increased the agglutinative, hemolytic, bacteriolytic, and complementary activities of the blood sera as tested *in vitro*. Sulina studied the influence of an elevated temperature upon phagocytosis *in vitro* with standardized suspensions of leucocytes and standardized suspensions of *B. typhosus*, *Staphylococcus pyogenes aureus*, and attenuated anthrax bacilli without threads. These organisms were opsonized by their serum. In exposures of 5 to 25 minutes at different temperatures the counts of 400 to 500 phagocytic cells revealed a maximum phagocytosis between 39° C. and 40° C. Wright and Neufeld each thought that the leucocytes from different normal persons do not vary in their phagocytic power. But in the studies of North and Park and Briggs they varied. Rosenow and Potter and Krumwiede observed that in pneumonia leucocytes have a greater phagocytic power than in health. Shattock and Dudgeon found that washed pneumonia leucocytes were more active in pneumonia serum than normal leucocytes, whereas in puerperal streptococcus infection the patient's leucocytes were less active as phagocytes than those of healthy persons in the same serum. Sauerbeck found that etherization of the animal injured the phagocytic activity of the leucocytes *in vivo*. The conclusions of Wright and of Neufeld, it thus appears, are not altogether accurate and the leucocytes may vary in their phagocytic activity, depending on the stage of infection, the amount of injury, or the degree of immunization acquired.

Summary of Previous Work.—These experiments of others demonstrate that the parenchymatous changes of the inner organs in infectious diseases are not wholly due to the fever but chiefly to the bacteria and their products. This previous work also suggests that an elevation of body temperature (up to 40° C. to 42° C., or 104° F. to

*From the Department of Bacteriology of the College of Physicians and Surgeons, New York City.

107.6° F.) may be unfavorable to the growth of pathogenic bacteria, although it does not destroy them. Hyperthermy artificially induced increases the agglutinative, hemolytic, complementary, and bactericidal activities of the serum. The phagocytic activity of leucocytes *in vitro* is greatest at 39° C. and 40° C. The phagocytic activity of the leucocytes in infection may be increased or diminished.

The purpose of my experiments was to determine whether the opsonic activity of the blood serum is increased or diminished by elevation of body temperature. In order to do this the opsonic action of the blood serum of animals was tested before and after inducing experimental hyperthermy in them by incubation. The determinations were first made on normal rabbits, then on immunized rabbits, and also on a rabbit in certain stages of infection.

Technique.—After recording the temperature of the rabbit a small amount of blood (3 c.c.) was obtained from the ear vein, then the rabbit was placed for two hours at 37° C. in the incubator, the doors of which were left open every twenty minutes for five minutes to insure proper ventilation and avoid excessive exposure. After two hours' exposure the animal's temperature was again recorded and blood collected as before incubation. The specimens of blood were kept in the icebox for twenty-four hours, when the clear serum was removed from the clot for study. Leucocytes were obtained from my own blood by Wright's method. The bacterial emulsion was prepared from a 24-hour agar culture of *Staphylococcus pyogenes aureus*. In 5 c.c. of normal saline solution the growth was broken up, pipetted off, shaken, and centrifugalized at low speed for 2 minutes to remove clumps. It was standardized so as to have 5,000,000 of bacteria in 1 c.c. Equal parts of leucocytes, serum, and bacteria were mixed in small agglutination tubes. These were immediately put into the thermostat at 37° C., so that the exposure was made under identical conditions. At the end of 10 and 20 minutes' incubation two smears were made from each mixture. They were stained by Jenner's method and the bacteria ingested by 100 phagocyting cells, were counted in each set of slides as recommended by Sauerbeck. By covering the labels of the slides and making recounts the errors were tested. They varied from 1 1/3 per cent. to 24 per cent. But by taking the average of three independent counts and by making two separate determinations this error was greatly diminished.*

From the results of these three experiments shown in the above tables it is evident that the temperature of a normal rabbit is increased by the prevention of heat loss during incubation, and that at the same time the opsonic activity of the blood serum of the normal animal so treated is definitely increased. In order to determine whether similar changes are produced in immunized animals the following studies were made on animals immunized by vaccines:

Opsonic action before and after incubation of the blood serum of rabbits immunized with vaccine: November 3, 1910: The three rabbits were each inoculated intravenously with 1 c.c. of a vaccine of *Staphylococcus pyogenes aureus* containing 250,000,000 of dead cocci in 1 c.c. November 5, 1910: Intravenous injection of 2 c.c. of vaccine of 500,000,000 of bacteria into each rabbit. November 7, 1910: Intravenous injection of 3 c.c. of vaccine, or 750,000,000 of bacteria. November 9, 1910: Intravenous injection of 4 c.c. of vaccine, or of 1,000,000,000 of dead staphylococci into Rabbits II and III. November 11, 1910: Rabbits II and III at this stage supposed to be in negative phase of immunization were incubated two hours and specimens of blood taken before and after incubation were studied.†

OPSONIC ACTION OF THE BLOOD SERUM OF THE NORMAL RABBIT BEFORE AND AFTER INCUBATION

	Temperature	Phagocytic Indices* 10 Min.	20 Min	Average	Percentage of Increase
Rabbit I, weight 2,001 grams:					
Before incubation..	99.6°F.	17.17	29.8	23.49	.....
After incbation for 2 hours ..	104.°F.	20.27	31.5	25.80	10.2
Rabbit II, weight 3,351 grams:					
Before incubation.	102.°F	5.49	6.43	5.96	
After incubation ..	103.6°F.	7.78	8.76	8.27	38.8
Rabbit III, weight 2,986 grams:					
Before incubation..	99.4°F	5.67	8.40	7.04	.....
After incubation ..	103.2°F	6.27	9.36	7.81	10.9

*The suspension of bacteria was heavy and not standardized in experiment with serum of rabbit No. I. This accounts for the high phagocytic index.

OPSONIC ACTION OF THE BLOOD SERUM OF THE IMMUNIZED RABBIT BEFORE AND AFTER INCUBATION.

	Temperature	Phagocytic Indices 10 Min.	20 Min	Average	Percentage of Increase
Rabbit II:					
Before incubation.	100.8°F	5.49	7.99	6.74	.....
After incubation..	103.6°F	9.39	9.64	9.52	41.2
Rabbit III:					
Before incubation.	98.8°F.	5.61	10.11	7.86	.....
After incubation ..	105.2°F	6.11	11.77	8.94	13.7

November 21, 1910: Nine days after the last immunization with vaccine Rabbits II and III, at this stage supposed to be in positive phase, were incubated two hours, and specimens of blood taken before and after incubation were studied.

OPSONIC ACTION OF THE BLOOD SERUM OF THE IMMUNIZED RABBIT BEFORE AND AFTER INCUBATION.

November 21, 1910.	Temperature	Phagocytic Indices 10 Min.	20 Min.	Average	Percentage of Increase
Rabbit II:					
Before incubation.	99.8°F.	7.34	10.33	8.84	.....
After incubation	104.0°F.	7.41	13.50	10.47	18.4
Rabbit III:					
Before incubation.	101.2°F.	7.85	15.11	11.48	.....
After incubation .	104.°F.	10.80	21.26	16.03	39.6

These two experiments demonstrate that the serum of an animal immunized by a vaccine has greater opsonic power than a normal serum and that its opsonic activity is still further increased by an artificial elevation of the body temperature of the animal.

* Three counts of two sets of slides means the counting of 600 phagocyting cells with their contents for each average index.

†November 8, 1910: Rabbit I which had emaciated considerably after the first injection of the vaccine died after the third injection. The autopsy revealed no lesion. A culture from the heart blood was negative.

The following experiments were carried out to determine whether this experimental hyperthermy would produce any more marked changes in the opsonic activity of the blood serum of the rabbits when immunized by living bacteria:

Opsonic action before and after incubation of the blood serum of rabbits immunized with living bacteria; intravenous inoculation of Rabbits II and III: November 22, 1910, 0.5 c.c.; November 25, 1910, 1 c.c.; November 28, 1910, 1.5 c.c.; November 30, 1910, 2 c.c., and December 2, 1910, 3 c.c. of a living 24-hour agar culture of *Staphylococcus pyogenes aureus* suspended in 4 c.c. of sterile normal saline solution.

One day after the last immunization with living bacteria Rabbit II in positive and Rabbit III in negative phase were incubated two hours, and specimens of blood taken before and after incubation were studied.

OPSONIC ACTION OF THE BLOOD SERUM OF THE IMMUNIZED RABBIT BEFORE AND AFTER INCUBATION.

December 3, 1910.	Temperature	Phagocytic Indices			
		10 Min.	20 Min.	Average	Percentage of Increase
Rabbit II, somewhat emaciated, but does not appear sick:					
Before incubation...	100.6°F	9.26	10.12	9.69	
After incubation....	104.2°F	11.6	19.44	15.52	60.2
Rabbit III*:					
Before incubation...	99.8°F.	3.25	4.00	3.63	
After incubation....	104.8°F.	4.14	4.05	4.10	12.95

*Rabbit III greatly emaciated, diarrhea; later, at autopsy, December 15, 1910, found to have developed renal abscesses.

December 13, 1910, eleven days after the last immunization with living bacteria Rabbit II in positive phase and Rabbit III in negative phase were incubated two hours and specimens of blood taken before and after incubation were studied.

OPSONIC ACTION OF THE BLOOD SERUM OF THE IMMUNIZED RABBIT BEFORE AND AFTER INCUBATION.

	Temperature	Phagocytic Indices			
		10 Min.	20 Min.	Average	Percentage of Increase
Rabbit II (in good condition, positive phase):					
Before incubation...	101.6°F	10.82	14.37	12.60	
After incubation....	105.0°F	11.87	21.67	16.77	33.1
Rabbit III*:					
Before incubation..	102.0°F	6.79	8.94	7.87	
After incubation...	105.0°F.	6.21	10.00	8.11	3.05

*Rabbit III, emaciated, in marked negative phase; diarrhea has continued and rabbit has fallen in weight (from 2,986 grams to 2,205 grams —781 grams).

December 15, 1910, to test the immunity developed in Rabbits II and III by the previous treatment, they were inoculated each with 5 c.c. of a dense suspension of a 48-hour growth of *Staphylococcus pyogenes aureus* on agar. Rabbit III was dead the next morning. At the autopsy well-developed abscesses of the kidneys were found. Rabbit II, apparently well next morning, recovered. The resistance of Rabbit II had been enormously increased during the course of immunization so that it was able to overcome a lare dose of these virulent staphylococci. Rabbit III, however, having developed renal abscesses during the immunization with living bacteria was killed by the large test dose in less than 18 hours.

In studying the slides of my experiments with immune sera an agglutination of bacteria was noticed which was absent with sera from the normal animals. The fact that the agglutination of the bacteria is a disturbing factor in estimating the opsonic indices of immune sera has been recognized by other observers.* This agglutination of bacteria may account for some of the variations in my phagocytic indices, but it was a disturbing factor of minor importance. Although the series of animals was limited the results of the foregoing experiments were especially significant because the study was made on the same animals in different stages of immunization and infection. Furthermore, a technique similar in each experiment was used, rendering comparison of the results of interest. To facilitate these comparisons the results have been arranged in the following table:

	Rabbit II			Rabbit III		
	Before Incubation	After Incubation	Percentage of Increase	Before Incubation	After Incubation	Percentage of Increase
Normal serum	5.96	8.27	38.8	7.04	7.81	10.9
One day after immunization by vaccine	6.74	9.52	41.2	7.86	8.94	13.7
Nine days after immunization by vaccine	8.84	10.47	18.4	11.48	16.03	39.6
Twenty-four hours after immunization with living cultures	9.69	15.52	60.2	3.63	4.10	12.95
Eleven days after immunization with living cultures	12.6	16.77	33.1	7.87	8.11	3.05

Rabbit II throughout these experiments was in excellent condition. At no stage of immunization was it seriously affected by the inoculation, and during incubation it never suffered from the exposure. The opsonic action of its serum increased steadily with immunization. There was no evidence of a negative phase in the development of immunization in the animal. The opsonic action of the serum taken after two hours' incubation at all stages of immunization was invariably greater than before incubation, but the percentage of increase varied. The percentage of increase through hyperthermy in this animal II under normal conditions before immunization was exceptionally high. other normal or unimmunized animals, it may be recalled, increased in I, 10.2 per cent.; in III, 10.9 per cent, averaging 10.6 per cent. Immediately after immunization, whether by vaccine or living cultures, the effect of incubation was greatest. The percentages of increase of 41.2 per cent. and 60.2 per cent. obtained are so well marked as to exclude any possibility of error in the determinations. Nine and eleven days after immunization the opsonic activity of the serum was greater than immediately after immunization, yet the increase effected by hyperthermy was proportionally less. Rabbit III was in good condition at the beginning of the experiments, but during immunization with living cultures it became seriously infected. During immunization with vaccine the opsonic activity of its blood serum increased more markedly but less regularly than in Rabbit II. No evidence of a negative phase in the immunization was manifested up to this stage. During immunization with living cultures and the development of infection the

*See Wadsworth, "Studies on Pneumococcus Infection in Animals," *Journal of Experimental Medicine*, July 1, 1912.

opsonic action of the serum decreased, but after a rest, even though antemortem, the serum regained some of its former activity. The animal was, therefore, clearly in negative phase. There was an increase of opsonic activity of the serum due to two hours' incubation at all stages of the experiment. This varied, but was marked as in the previous animal before and during immunization, but when infection developed and the animal was badly poisoned by continuing the immunizing injections under these conditions, the experimental hyperthermy increased the opsonic activity of the serum very little—less than at any other stage of the experiment.

Conclusion.—In my experiments as in those of all previous observers the opsonic activity of the blood serum of normal animals was greatly increased by immunization with dead organisms in vaccines, and with the living bacteria as well. And, further, in the processes of immunization the animal may be so poisoned that for a time there is a so-called negative phase in which the opsonic activity of the blood serum is diminished or fails to increase. But this negative phase was found in my experiments only in Animal III when, after inoculation with living cultures, fatal infection developed.

In a vigorous animal the opsonic activity of the serum may thus increase gradually and steadily with immunization without necessarily showing a negative phase. Artificial elevation of the body temperature obtained by incubation (*i.e.* without exception in all my experiments) increased the opsonic activity of the blood serum in the normal, the immunized, and even in the sick rabbit. The effect of experimental hyperthermy in augmenting the opsonic activity of the blood thus varied greatly, depending upon the condition of the animal and upon the degree or stage of immunization or infection. The effect of hyperthermy was usually more marked in the immunized animal than in the normal. The increase was most marked in the healthy Rabbit II during active immunization. The increase was least marked, practically nil, in infected Rabbit III, antemortem.

In conclusion I desire to express my thanks to Dr. Augustus Wadsworth for suggestions and help in this work.

THE UNFORTUNATE PREDICAMENT OF THE MEDICAL PROFESSION.

By THOMAS DIXON, M.D.,

BROOKLYN, N. Y.

Those of the medical profession who have its best interests at heart, who feel a sincere pride in its past achievements and in the high ideals it has always striven to maintain, cannot contemplate the present economic conditions of the practice of medicine without experiencing a feeling of alarm in regard to the future. The leading economists of to-day now place our profession in the unremunerative class, and state that under present conditions matters will not improve but on the contrary will tend to grow worse. As time goes on we find paying patients grow fewer each year. We go on hoping for better times only to encounter worse ones. We think that possibly depression in commercial business is affecting the situation but, on looking over our books, the unfortunate fact is demonstrated, whether the times be good or bad commercially, our business year by year has been progressively worse. This shows that there must be something radically wrong in the conduct of our affairs, that is, that the prosperity of the community at large does not necessarily mean greater financial returns to the profession. The average physician at present is unable to earn more than a bare living and there are many who cannot even do that. What will be their position a few years hence? This situation not only affects the poor men in the profession, but it also concerns those who are now financially comfortable; for, with the progressive decline of income they will eventually find themselves in the same distressing situation as those who are earning but a bare living at present. It may be thought that I exaggerate the poverty of the profession, but I beg to call the reader's attention to the fact that a short time ago one of the representative medical societies of our city with a membership of about one thousand

physicians called for a subscription of two dollars from each member. How many responded? Less than one-third. An alumni dinner of a class of seventy-nine physicians, graduated during recent years, had a dinner at five dollars a plate. How many were present? Only six!

It is indisputable that the physician is the only real altruist in any community. He alone endeavors by every means in his power, with all his knowledge, scientific, economic, and ethical, to combat disease which is his only resource of livelihood. He is himself or through his representatives constantly making researches in the causation of diseases and the methods of limiting their spread or preventing their occurrence; and this is done without any remuneration whatever. What other profession or trade does anything approximating to this work of the physician? He has always subordinated his personal interests, the most vital to his existence, to the interests of his fellow man. Can it be possible that the profession we all love, through poverty, will disintegrate, become disorganized, lose its high ideals and descend to baser motives? Can it be possible that as fine a class of men as there is in the community, who give more to charity than any other class, who sacrifice their personal well-being for others and who have given untold benefits to the world are going to the wall? There is a general impression among medical men that the position taken by the public toward the physician is unfair, sordid, and selfish. It assumes that the doctor is a public altruist, who may disregard his obligations to his family and to himself, at all times, in order to serve the public. This finds expression in the disregard of obligations to the physician and in the unjust discrimination against them by our lawmakers. This singular attitude of a people toward a class of men who are continually working for its benefit is a cause of resentment, sorrow and regret to the profession.

Let us not be unjust to the public. We have not taken it into our confidence. Ours is an exclusive profession and has kept its affairs to itself. So how could the public know our real economic condition? Not knowing the real facts, it judges from surface appearances. Many think we are paid for our services in hospitals and dispensaries. How often we hear the remark: "Oh, you doctors have plenty of money!" The abuses that the profession suffers from are of their own making, and the remedy is in their own hands. The remorseless law of evolution must be met. Great changes have been and are now going on in economic conditions of this country. Lines of thought that would formerly do will not answer now. Combination, organization and fraternity now make for progress. There is absolutely no hope for better economic conditions in the profession without an organization whose sole work shall be devoted to improve these conditions. Our present medical societies cannot do this work, for they are too much interested in medical research to have any time to give to economic conditions. Properly organized with but one purpose in view, there is not the slightest doubt that we can remedy many of the existing evils and prevent future ones from afflicting us. Does anyone suppose that the numerous bills inimical to the medical profession would have been passed by the State Legislature had the seven thousand physicians of Greater New York been organized for economic purposes? Does anyone suppose that a committee representing such an organization would be kept waiting hat in hand outside the legislative chamber while some small ward politician is promptly admitted to the inner sanctum? The ward politician receives greater consideration than the doctor because he has an organization behind him, and it will always be so until the physicians have sufficient strength through organization to insist upon a square deal. Some medical men advocate State control of physicians, that is, the State should pay salaries to them for services to the community. Such an arrangement would constitute a condition of paternalism and would place us under political domination. This would degrade the profession and tend to retard progress.

In order to secure the proper support of the public, we should no longer conceal from it our real economic condition. Medical men should write extensively on the subject in magazines and the press, so that the community may have an opportunity of obtaining the real facts and be fair to us. Influences are at work to induce physicians to organize for the purpose of investigating the economic condition of the medical profession and to devise means to solve the problem. The situation demands immediate action. Are you going to permit this state of affairs to continue? It means the loss of your independence, your happiness, and the cherished traditions of your profession. Let us bury our selfish motives and petty jealousies and support this movement with all the intelligence and energy at our command.

MANIC-DEPRESSIVE INSANITY.*

By ARTHUR K. PETERY, M.D.

NORRISTOWN, PA.

ASSISTANT PHYSICIAN, STATE HOSPITAL FOR THE INSANE.

In considering the manic-depressive groups of insanities, it might be well to first take up the definition as given by Kraepelin, which is as follows: Manic-depressive insanity is characterized by the recurrence of groups of mental symptoms throughout the life of the individual, not leading to mental deterioration. These groups of symptoms are sufficiently well defined to be termed the manic, the depressive, and the mixed phases of the disease. The chief symptoms usually appearing in the manic phase are psychomotor excitement with pressure of activity, flight of ideas, distractibility, and happy though unstable emotional field. In the depressed phase we expect to find psychomotor retardation, absence of spontaneous activity, dearth of ideas and depressed emotional attitude; while the symptoms of the mixed phase consist of various combinations of the symptoms characteristic of the manic and depressive phases.

This classification as one of the insanities as devised by Kraepelin has been the subject of much criticism, which appears unjust. It is one of the most common forms of insanities; the average percentage of admissions to hospitals ranges between twelve and twenty per cent. and many of the cases appearing under forty or fifty years of age and diagnosed according to the old classification as melancholias and manias would probably come under this present classification.

Of the causative factors in this disease heredity stands out in the foreground and ranges high in the percentage of the relatives who have often suffered from the same form of psychosis; frequently

*Read before the Montgomery County Medical Society, June 26, 1912.

the individual is noticed to be defective before the onset of the disease; some are peculiar, others are excitable and subject to frequent and apparently causeless changes of mood.

Alcoholism plays also an important role in this as well as in the other forms of insanities. In a study of the heredity of eighty cases the following results were determined: On the paternal side of the cases there was a history of twenty-four who were distinctly alcoholic, eight were insane, three were tuberculous, and one distinctly neurotic. On the maternal side there were three who were addicted to the use of alcoholics, seven were insane, four were tubercular, and one was subject to distinct periods of depression. There were eight of the cases who had insane brothers and five whose brothers were excessive users of alcoholics, and twelve had insane sisters.

The father and paternal uncle of one patient now in this hospital with this psychosis, both died here and probably with this same form of insanity. Another case, who is a lawyer by profession, had one brother who was an epileptic, a nephew an epileptic, one brother committed suicide during a period of depression, a first cousin was an idiot, and another cousin insane. Still another case had his mother and maternal grandmother commit suicide during periods of depression.

There were sixteen cases in which no taint of insanity was found, however; in two of the sixteen the history was unsatisfactory.

This psychosis almost always occurs independently of external causes; its nature is rather obscure, as there are no demonstrable anatomical or pathological lesions characteristic of the disease. The symptoms of this disease divide themselves into two large groups, the manic and depressive, with a third group which consists of a combination of the symptoms of these two groups called the mixed phase.

The manic phase might be further divided into the states of hypomania, mania, and delirious mania; the first representing the mildest type, the second the more severe, and the third characterized by a "pronounced dreamy clouding of consciousness, intense psychomotor activity, great incoherence of speech, a marked flight of ideas, numerous hallucinations, and dream-like delusions." However, this group is rather rare.

In this phase of the disease consciousness in the severe cases might be disturbed, while in the less severe the disturbance is very slight. Apprehension of external impressions in the manic state is usually disturbed, due largely to the great distractibility of attention. Memory in the milder forms is seldom disturbed, while in the more severe cases it is not always correct. Disturbances of thought are quite prominent symptoms; in the less severe grades they may show flight of ideas, but in the more severe conditions this is quite pronounced; their conversation is broken up, there is no controlling goal idea, and consequently their conversation consists of many words, but few finished ideas. The following is an extract from the notes of such a case: "Three cheers for the red, white and blue—the lodges want me—throw away the keys and die (the latter caused by an attendant coming into the room and unlocking a closet)—never was a lunatic. I have been hung. Go to the State doctor," etc.

In the mild state hallucinations are rather rare, while they may be present in the more severe, they are usually transitory and not persistent features. The delusions are usually those of exaltation; they boast of their own actions and abilities and often the more severe cases think they are persons of rank and of great importance, etc.

The most prominent symptom of all is their marked psychomotor activity. They are restless, doing something all the time; however, only things that are agreeable to them, and consequently changing from one thing to another. Their sense of fatigue seems diminished and they see no need for rest. In the more severe cases they may become destructive, decorate themselves with all sorts of things; are usually rather irritable, and if crossed become quarrelsome.

The duration of these conditions varies from several days to several years.

The depressed phase is further divided into two groups: that of simple retardation and the delusional form. The first is defined as the "mildest form of the depressive states and is characterized by the presence of simple retardation, unaccompanied by any hallucinations or delusions." The onset is rather gradual. They lose interest in their surroundings, have difficulty in expressing themselves, are undecided which words to use in the formation of their sentences; volunteer little or no conversation; consciousness is only slightly clouded, although they appear rather dull, are inactive; their work appears much larger than it really is, and in everything they do their retardation is evident. Their emotional attitude is that of depression, frequently talk of suicide as they have nothing to live for, nothing holds any pleasure for them and they worry over all sorts of imaginary troubles.

The second division, or the delusional form, is characterized by the presence of varied delusions, especially of self-accusation and of a hypochondriacal nature, in addition to the evidences of retardation. These patients become markedly depressed, think that they have committed unpardonable sins, are responsible for much embarassment to their families, that they must die; there is marked psychomotor retardation present. They are quite inactive, answer questions poorly or not at all; are unable to apply themselves to any form of mental work. External stimuli make their impressions slowly, and when once impressed do not give way to other ideas with any degree of rapidity. Numerous hypochondriacal delusions may be present, that they are seriously ill, their stomachs are all withered, their blood contains no corpuscles, and their conversation chiefly centers about their delusions. Hallucinations are rather uncommon, although they might be present. At times some cases are rather restless, pace up and down the ward and frequently pull patches of hair from the scalp; they may even attempt suicide. Occasionally in this condition a state of stupor might develop; consciousness becomes quite clouded, retardation is quite marked, they make no attempts to care for themselves. External stimuli make little or no impressions; they are rather restive, quite fearful, and frequently make unexpected attempts at suicide.

The third group or the mixed phase, there occurs simultaneously varying combinations of some of the fundamental symptoms characteristic of both the manic and depressive phases; this group is most prominently seen when the cases are passing from one group into the other; for instance, the excitement might give way to retardation, their feelings of exaltation to those of a more depressive nature; their flight of ideas to retardation of thought or vice versa.

There are six types of this mixed phase, the first of which is irascible mania. This is a manic condition in which a marked degree of irritability and aggressiveness is present. The second is depressive excitement, which is a condition where the emotional attitude is that of depression, although they are quite restless and fault-finding with their environment.

The third, that of unproductive mania, which is the manic state, although the patients are slow in perceiving external stimuli. There is pressure of activity, but not so marked as in mania, they are irritable and frequently inclined to be mischievous.

The fourth or manic stupor, which often occurs during a pronounced manic state, they become quite dull, take no notice of their environment, are resistive, and frequently have to be fed mechanically.

The fifth division is the depression with a flight of ideas and the sixth the depressed state with flight of ideas and emotional elation; these latter names mention the chief characteristic of their condition.

The course of manic-depressive insanity is marked by the recurrence of the various phases. Some cases clear up between the various stages and are able to attend to their business affairs, returning again to the hospital at their next attack. One patient in mind has been admitted to this hospital seven times. There are several who have been here three or four times. Some of the attacks occur at regular intervals and have earned the name of circular insanity for this disease; others are irregular in their recurrence; frequently they pass from one stage to the other immediately. In a large majority of cases the first attack is that of depression and several depressed periods may be had before a manic period is reached. On the other hand, if the first attack is manic in type, the following attacks are usually manic. The mixed phase does not usually occur until after they have had several attacks of either the depressed or manic phases.

The prognosis in this condition as far as a permanent cure is concerned is bad, but as far as each attack is concerned is favorable, unless the condition is so severe as to cause them to pass directly from one attack into another. Mental deterioration occurs in only a small percentage of the cases.

Under the treatment of this condition, as well as in all the forms of insanities, the first thing to be considered should be the prophylaxis. In view of the pronounced hereditary findings (only twenty per cent. of the cases studied being without taint) and the poor chances of the offspring to escape some form of mental disease, the prevention of intermarriage between persons of such tendencies should be made possible.

But as we have the conditions to combat, they, too, must be considered. The treatment of the various phases differs and is only effective during the attack, with the exception of where the attacks are superinduced by the excessive use of alcoholics and in which the total abstinence might lengthen the intervals between the attacks.

In the treatment of the manic phase all irritating influences should be removed. If possible they should be sent to a hospital, for the home treatment is always more or less unsatisfactory. The activities of the patient should be lessened as much as possible; rest in bed is about the best way to accomplish this. In the use of the baths opinions differ, but are usually controlled by the case. Some physicians prefer warm baths, others cold. If the baths are not available the various packs might be tried. The sedatives, such as the bromides, hyoscine, paraldehyde, and trional are frequently employed. In cases of extreme excitement the case must be carefully watched for symptoms of collapse and strenuous treatment resorted to if required. The general management of the case is also an important item. A nurse who is able to control herself under all circumstances, be free from prejudice, but still be able to maintain the proper discipline for the benefit of the patient, should be selected.

Frequent weighing of the patient is also necessary, so as to keep informed as to the proper nourishing of the case. An increase in weight is also frequently an indication of the mental improvement of the patient.

The treatment of the depressed phase varies according to the condition of the patient; if he is run down physically the general health must be improved; he must be watched carefully to see that sufficient food is consumed; should be weighed frequently. If quite weak he should be placed in bed and, if possible, in the open air. If physically able he should be persuaded to perform some light work, such as weaving of baskets, braiding of rope, or, in fact, anything that will tend to lead his thoughts away from his own condition. Hospitals should have workrooms under capable supervision for this purpose. If the patients are inclined to sleep rather poorly the various hypnotics may be employed. If the continued use of the hypnotics is necessary, these should be varied.

The patient must be guarded continually to prevent suicidal attempts, even though apparently improving, for his recovery may just be an interval between attacks.

A CASE OF MYOPIC REFRACTION RELIEVED BY EYE EDUCATION.

By W. H. BATES, M.D.,

NEW YORK.

For more than ten years the method of eye education in relieving functional disorders of vision has impressed me with its value. The following case is a type of many hundreds benefited and is described with some detail in order to illustrate the method of treatment.

An intelligent man, aged 25, was seen August 30, 1912. Right vision 1/5 normal. Has been wearing constantly for this eye—1.00 D. S.—0.50 D. C. at 180 deg., vision normal. Left vision, 2/3 normal. Wearing a plane glass for this eye.

After an ophthalmoscopical examination the patient was told that he was not near sighted and did not need glasses to improve his vision but that his eye defect was due to improper use and was curable by a little instruction in the art of seeing. To this method of treatment he agreed, followed instructions and obtained normal vision without glasses in forty minutes, which pleased him more than a prescription for glasses.

First, the right or defective eye was covered by a screen. Then the better eye, the left, was instructed in the proper methods of obtaining normal vision with the aid of a Snellen test card at 20 feet. He was told that perfect sight was only possible by regarding one letter of the distant card at a time or by regarding a small part of each letter in turn. It was important to regard one letter on a line in such a manner that the one following it appeared

less distinct. This was in the beginning difficult for him to do because he said he could see all the letters of the same size on one line equally well and at the same time or simultaneously. He was convinced that he did not see with the same distinctness all the letters on one line after he tried to read them when regarding a point several feet to one side of the card. He was urged to make an effort to see clearly one letter while its neighbor appeared less distinct. In a few minutes this was accomplished. The next step required more concentration, namely, to acquire the ability to see the top of a small letter better than the bottom or to see the left side of a small letter better than the right side of the same letter. It was difficult for him to accomplish this because he had a strong tendency or inclination to attempt to see a number of letters simultaneously or to regard all parts of one letter at the same moment. He was anxious to do the proper thing and tried to understand and carry out my suggestions. He was liable to forget the directions and try something else which might occur to him. But by insisting that he try my methods instead of experimenting with his own inclinations he was soon able to say that when he regarded closely one part of a small letter the other parts of the same letter were less distinct. He was learning the proper methods of obtaining normal vision and became conscious of the methods practised by the normal eye, usually unconscious, to see properly and perfectly.

Having now learned the necessity of directing the eye accurately to distant objects in order to obtain good vision, his attention was next called to the importance of a proper focus. He was requested to hold his fore finger at ten inches from his left eye with the tip of the finger placed close to a line from the eye to the large letter on the Snellen card. When he regarded the tip of his finger closely he was unable to distinguish the distant letter at the same time. He was told that this phenomenon was one of great importance as the cause of the defective vision of the other eye, the right, was the fact that the eye was focussed for near vision when regarding distant objects. He learned that he could not see even large letters on the Snellen card at 20 feet when the better eye, the left, was focussed for the near or reading distance. Although self evident to many people he had not realized this fact before. I believe that the few minutes devoted to the demonstration that the normal eye could not see distant objects clearly when focussed for near vision was an important factor in the subsequent rapid relief of the defective vision of the poorer eye, the right, by education. The demonstration was made quickly and in less time than one might expect, about five minutes. At this time it was found that the vision of the left eye had improved from vision of 2/3 to vision normal.

The left or normal eye was then covered by a screen during the time that the right was exercised. He was shown how the vision of the right eye was further lowered when the gaze was directed to one side of the distant card. When he regarded a point three feet or further to one side of the card he was unable to distinguish the large letter. The point of eccentric fixation was brought closer and closer to the card until he was convinced that he saw the letter worse when he looked only a few inches to one side instead of directly at the letter. Central fixation or the ability to direct the eye directly at one point and to hold the eye steady was difficult and was not accomplished immediately. He was surprised when told that he did not practise central fixation. When the effort was made to see a small letter unsuccessfully the eye was seen to move in various directions. I come now to a description of an original procedure which gave him complete relief in some minutes. It has proved of such great value in so many of my cases of real and functional myopia that I feel that it should be emphasized. It has never done harm. It has always been beneficial. All oculists may disagree or oppose my facts with theories while they are unable to stop the increase of many cases of myopia even with glasses. The procedure is as follows:

He was directed to make an effort to see a small object held so close to his eye that it was impossible for him to see it clearly.

For convenience a fine point on the end of my finger nail was the visual object employed. It was held about three inches in front of his eye while he made strenuous efforts to see it, but was not successful. In a short time his vision for distance was tested and found improved. By alternately regarding the finger nail at three inches and the Snellen card at 20 feet the vision rapidly improved from vision 1/5 to the normal. The good result was obtained in less than twenty minutes. He was told that the relief was not due to suggestion, hypnotism, or to some unknown agency, but that he became able to see as he should, normally, because he had learned how to use the eye properly by education.

To prevent a relapse he was recommended to practise daily regarding small letters or small objects at a distance in such a way that he would see one part better than another part of a small letter or other small object. He was to do this with each eye separately, covering or closing the other eye. He was given a Snellen test card for exercises in distant vision.

938 St. Nicholas Avenue.

Neurofibroma of the Supraorbital Nerve in the Orbit.—W. H. Battle reports the case of a girl aged 22 years who, ten years ago, was under his care for a neurofibroma of the left median nerve above the internal condyle of the humerus. He removed it without difficulty, and there had been no trouble with the nerve since. Five or six years ago she came with a pachydermatocele on the right side of the head, behind the ear, two inches in circumference. There was a change in the bone underneath. The portion of scalp affected was excised, and numerous little plexiform neuromata were found. The surface of the skull could be felt to be considerably changed, the external table appeared to be hollowed out, as if there had been pressure over it by a firm tumor. A few days ago she came with neuralgic pains over the right forehead and scalp, which appeared to be due to small neurofibromata in the supraorbital nerve. The patient thought her pain was due to them, but the tumor which appeared to be about the size and shape of a small date-stone, was found on examination of the course of the nerve at the junction of the inner with the outer two-thirds of the orbit. The lesion was awkwardly placed for operation, and it was a rare position for neuromata. She had molluscous tumors about the body, with pigmentation of the skin over them. No other disease or tumors could be found anywhere. Apparently she was naturally dark-skinned, and the author thought it possible from that and other signs there was some mixed blood in her. Her brother had had a painful tumor removed from the right side of his neck, and the mother was said to have tumors on the back of the left forearm.—*Proceedings of the Royal Society of Medicine.*

New York, November 9, 1912.

THE PROBLEM OF THE MENTALLY UNBALANCED AND DEFECTIVES.

No question bulks more largely in all civilized countries than the increase of the insane, the defective, and the mentally unstable. It would be superfluous to discuss the point as to whether the increase is more apparent than real. Although statistics may be to some extent misleading, there can be little doubt that the increase of the various forms of mental defect is only too real. When the conditions of modern life are taken into consideration most of the causes for the increase stare us in the face. The trend of population to overcrowded centers, the conditions under which toil is carried on both in factories and in homes, the high pressure at which the toilers labor, all provide obvious explanations for the large number of individuals whose brains give way under the strain or who by heredity and environment are unfitted for the strenuous battle of life. The most sinister feature of the situation, however, is the fact that it is not only in old overworked, overcrowded, and in some respects poverty-stricken Europe that mental defects and aberrations are daily becoming more evident, but in sparsely populated lands, such as this country and Canada. At the meeting of the Canadian Medical Association, held a few months ago in the far northwest, a somewhat lamentable picture was drawn of the state of affairs with regard to mental disorders in that almost virgin territory. A bitter cry has gone up recently from this State of New York relating to the alarmingly rapid increase of the population of institutions for the insane and feeble minded, and in all parts of the country thinking men and women are bewailing the degeneration of the people mentally and physically. Now, allowing for exaggeration, and probably some exaggeration exists, there is, nevertheless, a sound foundation for these alarmist cries.

A letter contributed to the *New York Times* of Oct. 24, 1912, by Dr. Lewellys F. Barker of Johns Hopkins University provides quite sufficient ground for the statement. This authority says that more than 200,000 of our people are insane, and the number is increasing at the rate of three to four for every increase of 1,000 in the population. Exact data regarding imbeciles, epileptics, and criminals are lacking, but the numbers are known to be large. Barker suggests that support should be given to the National Committee for Mental Hygiene founded in 1909 and gives it as his opinion that there are great fields in which such a committee may advantageously work: First, in supporting and directing original inquiries by experts regarding the problems of mental hygiene; second, in educating the nation to use the knowledge already placed at our disposal; and third, in organizing agencies by which the campaign is to be carried on, and in cooperating with other associations, national and international, which have allied philanthropic aims.

Of course, the root of the matter is to prevent as far as is possible the conditions which tend to produce mental disorders and to create an atmosphere of mental hygiene. The conditions which bring about forms of mental disease are many and varied and the basic remedy lies in social reforms. Syphilis, for example, is a potent factor in the causation of mental derangements and the stamping out of this disease is more a social problem than anything else. As Barker truly says, the task which the National Committee has set itself is an enormous one, but it will not be too great for our heads and hands once our American people have it at heart. Educate the mass of the people as to the causes of insanity and in the course of time these causes will be removed and a race sane in mind and sound in body will be the result.

SEX DETERMINATION.

DRELINCOURT, in the eighteenth century, brought together 262 "groundless hypotheses" concerning the nature of sex and its determination; Blumenbach followed him with the caustic observation that Drelincourt's own theory made the 263d; and subsequent observers have added Blumenbach's theory of "formative impulse" to the scrap heap. Today perhaps the most prominent of the theories of sex determination are the five following: 1. That environmental influences, operating on the sexually undetermined offspring (after fertilization) may at least have a share in determining the sex. 2. That the sex is undetermined until the germ cells unite in fertilization, when it is decided by their relative condition, or by a balancing of the tendencies they bear, neither sperm nor ovum being necessarily decisive. 3. That the sex is fixed at a very early stage by the constitution of the germ cells as such, there being female-producing and male-producing germ cells, predetermined from the beginning and arising independently of environmental influences. 4. That maleness and femaleness are Mendelian characters. 5. That environmental and functional influences, operating through the parent's body, may alter the proportion of effective female-producing and male-producing germ cells.

Concerning all these theories one may venture upon a paraphrase of the "Scotch verdict," that nothing conclusive has as yet been proven by any one of them, or any combination of them. We are, scientifically speaking, after centuries of theorizing and experimentation, about as much in the dark as ever regarding what factors determine sex and as to the possibility of bringing about, by human volition, the sex that might, for reasons of State

or otherwise, be desired. J. Arthur Thompson, Regius Professor of Natural History in Aberdeen University, who (with P. Geddes) has written "The Evolution of Sex," states his conviction that there is no sex determinant or factor at all, but that "a rhythm of bodily changes" settles the sex of the offspring. Throughout sentient, organic nature there are alternatives or antitheses between liberal expenditure of energy and a more conservative habit of storing. These phenomena primarily depend on the ratio between disruptive (catabolic) processes and constructive (anabolic) processes; and the sexes are regarded as expressions of the same contrast within a given species.

From this viewpoint the profound constitutional difference between the male and the female, which makes of the one a sperm-producer and of the other an ovum-producer, is due to an initial difference in the balance of chemical changes. The female seems to be relatively more constructive, whence her greater capacity for sacrifices in maternity; the male relatively the more disruptive, whence his usually more vivid life, his explosive changes in action. (It is, as has been said, that woman is the physiological miser, man the physiological spendthrift.) In Thompson's words, "the sexes express a fundamental difference in the rhythm of bodily storage and discharge." This initial difference not only leads to the primary functional distinction between male and female, but it also determines, either from the start, or after maleness and femaleness have been in part established, what particular expression will be given to a whole series of secondary characters—both structural and functional—whether a masculine or a feminine expression. Many series of facts would lead to the conclusion that each sex cell has a complete equipment of masculine and feminine characters; and perhaps the liberating stimulus which calls the one set or the other into expression or development, is afforded by the conditions of change that have been set up in the cell structure.

Thompson considers that, as regards the general question of the determination of sex, we are probably on safer ground when we pass from the higher animals to such organisms as starfish and sea urchins, in which it is often impossible, without the microscope, to distinguish the two sexes. It were profitable to press the problem to its simplest expressions, as in volvox, a beautiful sphere of cells with whiplike processes, which phenomenon illustrates a body in the making. From this ball of cells reproductive units are sometimes set adrift, dividing then without more ado to form other colonies. But in other conditions, when nutrition is checked, a less direct mode of reproduction occurs: Some of the cells in the ball become large, well-fed elements—the ova; while others, less constructive, fade from green to yellow, and divide and redivide into many minute units—sperm cells.

Sex may change in the course of life, as in the experiment of Prof. F. Braem with a simple Annelid worm (*Ophryotrocha puerilis*). A female which had ripe eggs and showed no trace of double sex was divided in two; the head portion, with thirteen segments, was isolated. In three weeks it had regenerated several segments with lateral feet; it was then killed and found to be male. Braem suggests that in consequence of the amputation the very young indifferent germ cells had developed into male cells, which require less subsistence than ova. It is certain, however, that the reproductive organs had changed from producing eggs to producing sperms; such cases would indicate that sex difference is fundamentally physiological.

NATURE OF ECK'S FISTULA INTOXICATION.

In building up a doctrine of hepatogenous autointoxication due to hepatic insufficiency, pathologists have usually laid great stress on the line of evidence obtainable from the elimination of the portal circulation. Nutriment, chiefly proteins, entering the systemic circulation without a previous so-called detoxicating or purifying of the liver, was apparently shown to be highly toxic to the organism, and the organ was hailed as a "line of defense" from this viewpoint.

That the liver exerts a detoxicating action in certain cases appears to be proven, nor is there anything violent in such a conception, since all the ingesta are temporarily arrested in this gland, and opportunity is afforded for the binding and storage of certain substances, chiefly extraneous toxic agencies, in connection with the anabolic and catabolic activities of the cells. But that the liver has any special function of detoxicating ordinary nutriment is probably insusceptible of proof by Eck's fistula experiments. If the liver is actually eliminated then the fact remains that these animals sometimes keep well for weeks even on an exclusive protein diet. The claim is made, however, that the liver is not eliminated—that the substances which enter the systemic circulation eventually reach the liver again and again by the hepatic artery until the same end is attained as by passage through the portal vein.

How then explain the toxic syndrome which sometimes appears in Eck's fistula dogs?

At a debate last June before the Physicomedical Society of Würzburg (*Muenchener medizinische Wochenschrift*, October 8) the claim was made that hepatic insufficiency does not in the least develop. Bile and urea are produced in their full values. The intoxication sometimes seen can hardly be explained save by an anaphylaxis. The operation, no doubt, prejudices the digestion in some way, so that an autotoxemia develops, comparable with those seen in disease. The liver would, doubtless, widely detoxicate these substances or at least deprive them of any anaphylactic power; but entering the systemic circulation they first sensitize the blood albumin and later produce the characteristic shock. The same class of substances is doubtless responsible for the development of hepatic cirrhosis.

ANAPHYLAXIS AND SHOCK IN GENERAL.

Since it has been learned that anaphylaxis is manifested in certain cases by purely shock or collapse symptoms, the question of an anaphylactic component in so-called traumatic shock is given new

importance. Shock following injury has always been a mysterious phenomenon; for while often attributed in part to hemorrhage and psychic inhibition, to pain, and to the anesthetic used, there is a pronounced element which is not dependent upon any of these factors. The old writers on clinical surgery have often warned us against shock as a sequel of relatively insignificant procedures of minor surgery, notably of puncture of cysts. It was a foregone conclusion that sooner or later this phenomenon would be attributed to an anaphylaxis. The phenomenon has been noted with especial frequency in connection with hydatid cysts, and in past decades attempts were made to show that the possibly absorbed echinococcic fluid was eminently toxic. This claim was naturally disputed, but eventually by French writers the possibility of a pure anaphylaxis was interjected.

At a meeting last summer of a medical society in Hamburg (*Muenchener medizinische Wochenschrift, October* 15) Graetz brought up this subject, and adduced evidence to show the probability of anaphylactic shock following rupture or puncture of echinococcus cysts. It is known that the albumin in the contents of the latter is heterologous, and thus it engenders the formation of antibodies in the blood, so that the possibility of a serodiagnosis has been claimed. The author, however, is as yet noncommittal in regard to the existence of a pure anaphylaxis, for the possibility of a synchronous intoxication must not be excluded outright. Certain cleavage products of the albumin of these cysts are believed to be able to cause an intoxication syndrome which much resembles the symptoms of anaphylaxis. The differences between a simple intoxication and an anaphylaxis are of course sufficiently well known. In the former there is no history of previous sensitization, such as might be supposed to result from the first reaction of the organism toward the incorporation of the parasite.

Reminiscences of Lister.

Since the death of Lister there has been a mass of writing bearing upon his qualities as a surgeon and as a man. From the material it is gathered that Lister was almost an abnormally modest and conscientious man. In these days of self advertisement, ofttimes carried to unseemly extremes, it is at once remarkable and refreshing to meet with a man of this type. On the other hand, it is a matter for regret that the great surgeon carried his conscientious scruples to such lengths that during his lifetime and while pursuing those experiments which ended in the revolution of surgical methods, he refused to publish or in any way to make public the results of his investigations. Sir W. Watson Cheyne probably knew more of Lister's work and life than any man and in his presidential address before the Medical Society of London, on October 14, 1912 (*Lancet*, October 19, 1912), he made his hero the theme of his discourse. In the course of his remarks Cheyne said that the part of Lister's work which concerned what may be termed the experimental stage, although he had convinced himself that he was on the right track with regard to the abolition of septic diseases, he never would publish. Cheyne often urged him to do so, and offered to collect the material for him if only he would publish it, and failing that, to act as Boswell to his Johnson if only he would permit the publication from time to time of records of the actual practice he was carrying out, but Lister's reply was always in the negative. The great objection in his mind was that he felt that until every surgeon was convinced of the necessity for asepsis and of the value of the methods which he advocated, and was efficiently skilled in them, it would be a very serious matter to publish successful results of operations which it would be practically criminal to perform unless complete asepsis were secured. He feared that the publication of such cases might induce others who were neither convinced of the necessity for the aseptic precautions which he advised, nor skilled in that work, to perform similar operations with disastrous results to the patient. He could not but feel that if this occurred he would be a party to such disasters, and that such results would reflect on and prevent the extension of the new method of treating wounds which he looked on as a matter of much more vital importance than the introduction of new methods of dealing with surgical cases. In a few words, Lister was one of those rare men, who in this material age seem to be becoming more rare, who regarded the welfare of mankind as of far more importance than the gaining of fame and money. It is too often the case nowadays that a discovery will be announced before its details have been properly worked out, apparently because the discoverer is afraid he may be forestalled, and not infrequently the commercial aspect is given a prominence which to a man of Lister's way of thinking would be abhorrent. If Lister erred on the side of modesty and self effacement it was a fault on the right side.

Acidosis in Diabetes.

The causation of diabetic coma is still to some extent obscure. Acidosis, according to the latest investigations, clinical and experimental, is the main factor in the pathogenesis of this condition, but there are observers who hold that acidosis does not explain all the features of diabetic coma. H. Montlaur, writing on the subject in the *Medical Press and Circular*, October 16, 1912, points out that Lépine believes that diabetic intoxication is derived from both beta-oxybutyric acid and other concomitant toxins. Morel and others, however, in view of the fact that the reduction of the alkalinity of the blood due to the acidosis does not account for the production of coma, hold that the substances which tend to enhance the toxicity of the acetone bodies belong to the quaternary derivatives of albumin. They believe that the solution of the problem lies in the products of disintegration of the molecule of albumin, the peptides, which are eliminated by the urine as part of the unestimated "organic residue." These peptides may be produced in unduly large quantities, or they may fail to undergo destruction, or it may be that, produced only in normal quantities, they are the outcome of an abnormal process of elaboration. Labbé holds that acidosis is the principal cause of diabetic coma, and in fact says that acid toxicity stands for three-quarters of the toxicity of the condition. In consequence he regards intensive albuminization of the organism as the basis of the treatment of diabetic coma.

News of the Week.

Medical Clinics.—Over two hundred physicians, mostly alumni of the Iowa State University, attended the annual alumni clinics of the University College of Medicine in Iowa City on October 22 and 23. At the opening session President Bowman of the University delivered an address and was followed by the dean of the medical school, who gave the history of the school. In the evening Dr. William Jepson of Sioux City held a general surgical clinic.

The fourth annual reunion and clinic of the Western University Medical Department was held in London, Ontario, on October 21, and was attended by nearly four hundred men. Dr. L. F. Baker of Johns Hopkins University conducted a medical clinic during the afternoon and Dr. William J. Mayo of Rochester, Minn., spoke on cancer of the stomach and intestine, giving a lantern demonstration. The following officers of the alumni were elected: *President*, Dr. Hugh A. McCallum, London; *Vice-President*, Dr. Frederick Guest, St. Thomas; *Secretary*, Dr. E. Spence, London.

Clinical Conference.—The Medical Board of the Children's Hospitals and Schools on Randall's Island, New York, held a clinical conference on Tuesday afternoon, October 29. The following topics with illustrative cases were discussed: Radical mastoid operation in children; Ethmoiditis in Children; Effects of oophorectomy upon the mentality of idiots; Reconstruction of the hip joint by bone grafting; Value of the open-air treatment of pneumonia; Chronic Purulent conjunctivitis; Flaccid cerebral diplegia; Goiter complicating cretinism; Panniculus adiposus and marked enteroptosis relieved by resection of the abdominal muscles; Complete hysterectomy and appendectomy under spinal anesthesia.

No Common Cups.—The Secretary of the Treasury on October 30 issued an order prohibiting interstate carriers from providing any drinking cup, glass, or vessels for common use in cars, vessels, or other conveyances or in depots or waiting rooms used by the passengers of such railways. The regulation does not forbid the use of drinking cups, glasses or vessels, which have been thoroughly cleansed by washing in boiling water after use by each individual, nor the use of sanitary devices for individual use only. The Treasury Department did not find that it had authority of law permitting it to order that common carriers shall furnish individual drinking cups to passengers, its authority extending only to the prohibition of vessels for common use. Several of the States have laws compelling railways to furnish such individual cups, while others merely forbid the use of the common cup as is now done by the Federal Government.

American Surgical Association.—This Association has appointed a committee, consisting of Dr. William L. Estes, South Bethlehem, Pa.; Dr. Thomas W. Huntingdon, San Francisco; Dr. John B. Walker, New York; Dr. Edward Martin, Philadelphia, and Dr. John B. Roberts, *Chairman*, 313 S. 17th street, Philadelphia, to report on the operative and non-operative procedures of closed and open fractures of the long bones and the value of radiography in the study of these injuries. Surgeons who have published papers relating to this subject within the last ten years, will confer a favor by sending two reprints to the chairman of the committee. If no reprints are available, the titles and place of publication are desired.

Street Accidents.—During the month of September 24 persons were killed and 178 seriously injured in accidents on the railway and street car lines of New York City. This is an improvement over last September, when 37 persons were killed and 196 seriously injured. The total number of accidents, however, was increased, numbering 5,901 in September, 1912, as compared to 5,720 in September, 1911, and 5,439 in September, 1910.

Hearing on Tuberculosis Hospital.—Dr. Eugene H. Porter, New York State Commissioner of Health, held a hearing in White Plains, N. Y., on October 28, at which arguments for and against the establishment by the Westchester County Board of Health of a tuberculosis Hospital at Yorktown, were heard. The residents of Yorktown are opposed to having the hospital on the site selected, a two hundred and seventy acre farm; and there is also some opposition from New York City because of its situation in the watershed of Croton Lake and the consequent danger of contamination of New York City's water supply. The decision of the matter rests with the State Board of Health.

New Pennsylvania Hospitals.—The managers of the Children's Hospital of Philadelphia have begun the collection of a fund of $1,000,000 for the erection of new buildings and the formation of an adequate endowment fund. A site having a frontage of 300 feet and comprising one and a half acres, situated on Eighteenth street and extending from Bainbridge to Fitzwater, has already been purchased at a cost of $100,000, provided for by a donation from one of the managers. The contemplated buildings will be set well within the grounds and be surrounded by lawn and shrubbery. Work upon the out-patient annex is to be started at once. Dr. Robert G. LeConte is chairman of the building committee.

The sum of $0,500 has been raised for the establishment of the Abington General Hospital, which is to form a memorial to the two members of the Widener family lost in the foundering of the *Titanic*. Work will be begun as soon as pledges amounting to $100,000 have been secured, although the total amount desired is $250,000.

Montefiore Home.—The corner-stone of the new pavilion of the Montefiore Home at Gunhill road and 210th street, New York, was laid on October 27. The building will, it is estimated, cost $2,000,000. At the dedicatory exercises Mayor Gaynor delivered an address in the course of which he predicted State care for the aged, sick, and infirm at a no very distant day.

Hospital Dedicated.—The Joseph E. Shoenberg Memorial Hospital Building, which is a part of the National Jewish Hospital for Consumptives at Denver, Col., was dedicated on October 27. The building was erected at a cost of $40,000. At the same time announcement was made of a gift of $25,000 for the endowment fund of the hospital.

X-Rays in Gynecology.—Dr. Foveau de Courmelles of Paris has been asked to make a report on the use of *x*-rays and radium in gynecology for an address to be delivered before the combined sections of radiography and gynecology of the Seventeenth Congress of International Medicine, to be held in London on August 12 and 13, 1913. In order that the report may be as complete as possible, Dr. Foveau de Courmelles, who may be ad-

dressed at 26, rue de Châteaudun, Paris, requests that his colleagues send him their detailed observations on this important question.

Gifts to Charities.—By the will of the late Mrs. M. C. Dodge of New York, the Adirondack Cottage Sanitarium at Trudeau, N. Y., receives a gift of $10,000.

By the will of the late Laura A. F. Pichou of Philadelphia all of the books contained in her library are bequeathed to the Pennsylvania Hospital for the use of patients, while of her estate of $11,200, one-fourth each is devised to the German Hospital and the Home for Incurables of Philadelphia, for the establishment of free beds, and one-fourth to the Pennsylvania Hospital to be applied to the endowment fund.

Personals.—Dr. Paul Segond of Paris, professor of clinical surgery in the Faculty of Medicine of the University of Paris, and surgeon in chief of the Salpêtrière, died on October 27 from uremia.

Dr. Simon Flexner of the Rockefeller Institute, New York, delivered the annual Huxley Lecture to the Faculty and students of the Charing Cross Hospital, London, on October 31.

Dr. Anthony Bassler has been appointed clinical professor of medicine in the New York Polyclinic Medical School and Hospital.

Texas State Homeopathic Medical Association.—At the annual meeting held in Dallas on October 22 and 23, the following officers were elected: *President*, Dr. Frank H. Anthony, Dallas; *Vice-Presidents*, Dr. Charles C. Bowes, Greenville; Dr. T. E. Williams, Shreveport, La.; *Secretary*, Dr. J. H. Bass, Austin; *Treasurer*, Dr. W. D. Gorton, Austin.

Mississippi Valley Medical Association.—The following officers were elected at the annual meeting held in Chicago on October 23 and 24: *President*, Dr. Albert E. Sterne, Indianapolis, Ind.; *Vice-Presidents*, Dr. D'Orsay Hecht, Chicago; Dr. Hugh Cabot, Boston; *Secretary*, Dr. Henry Enos Tuley, Louisville, Ky.; *Treasurer*, Dr. Samuel C. Stanton, Chicago. New Orleans was selected for the meeting place next year.

Medical Society of Virginia.—At the annual meeting held in Norfolk on October 24 the following officers were elected for the ensuing year: *President*, Dr. Southgate Leigh, Norfolk; *Vice-Presidents*, Dr. H. S. MacLean, Richmond, and Dr. M. M. Pearson, Bristol, Tenn.; *Treasurer*, Dr. Mark W. Peyser, Richmond; *Secretary*, Dr. Paulus A. Irving, Farmville.

Wabash County (Ill.) Medical Association.—The annual meeting of this association was held at Mt. Carmel on October 22, when the following officers were elected: *President*, Dr. P. G. Manley, Mt. Carmel; *Vice-President*, Dr. John J. McIntosh, Allendale; *Secretary*, Dr. Edwin R. Lescher, Mt. Carmel; *Treasurer*, Dr. John B. Maxwell, Mt. Carmel; *Censor*, Dr. W. H. Roberson, Mt. Carmel.

Charleston County (S. C.) Medical Association.—On Friday, October 25, the Charleston County Medical Association was formed, with the following officers: *President*, Dr. J. M. Thompson; *Vice-President*, Dr. William H. Johnson; *Treasurer*, Dr. H. J. Prioleau; *Secretary*, Dr. M. M. Edwards.

Obituary Notes.—Dr. John W. Woods of New York, a graduate of the New York University Medical College in 1892, visiting physician to the Northwestern Dispensary, and a member of the New York State and County Medical Societies, died suddenly on October 28, in the Polyclinic Hospital, of pneumonia, at the age of 51 years.

Dr. Arthur Tracy Cabot of Boston died at his home in that city on November 4 at the age of 60 years. He was born in Boston and was graduated in medicine from Harvard in 1876. Upon returning from a period of post-graduate study in Europe he was appointed attending surgeon to the Massachusetts General Hospital and held this position for a number of years, being appointed consulting surgeon at the end of his active service. He was a member of the American Surgical Association, the American Association of Genito-Urinary Surgeons, the American Medical Association, and was an ex-president of the Massachusetts Medical Society.

Dr. William Herbert Pattee of Manchester, N. H., a graduate of the University of Vermont College of Medicine, Burlington, in 1877, a member of the American Medical Association and the New Hampshire State and Hillsboro County Medical Societies, died at his home on October 21, aged 57 years.

Dr. Dennis J. Sullivan of Providence, R. I., a graduate of the Bellevue Hospital Medical College, New York, in 1876, died at his home suddenly on October 20, aged 62 years.

Dr. Ralph Sherwood of St. Albans, Vt., a graduate of the Berkshire Medical College, Pittsfield, Mass., in 1863, a surgeon in the United States Army during the Civil War, and a member of the Vermont State and Franklin County Medical Societies, died at his home on October 19, aged 70 years.

Dr. James Warren Stitt of Berkeley, Cal., a graduate of the Bellevue Hospital Medical College, New York, in 1878, died at his home on October 14, after a long illness, aged 58 years.

Dr. William Lenneker of Chicago, Ill., a graduate of the Missouri Medical College, St. Louis, in 1882, died at his home on October 15, aged 63 years.

Dr. John E. Link of West Terre Haute, Indiana, a graduate of the Northwestern University Medical School, Chicago, in 1865, and a veteran of the Civil War, died at his home on October 13, aged 73 years.

Dr. Frederick G. Cretors of Paris, Ill., a graduate of the Chicago Homeopathic Medical College in 1901, and a member of the Illinois State and Edgar County Medical Societies, died suddenly at the Mercy Hospital, Chicago, on October 18, aged 45 years.

Obituary.

MAJ.-GEN. ROBERT MAITLAND O'REILLY.

MEDICAL CORPS, U. S. ARMY.

General O'Reilly, whose death occurred at his home in Washington on Saturday of last week, was born in Philadelphia January 14, 1845. During the Civil War he was a medical student at the University of Pennsylvania, and was appointed a medical cadet in the U. S. Army in 1864. At the close of the war he resumed his studies and was graduated in 1866. The following year he entered the regular army as assistant surgeon and passed through the various grades until, in the fall of 1902, he was appointed Surgeon-General of the army, with the rank of Brigadier-General.

Gen. O'Reilly served in a number of Indian campaigns in the West and Southwest, was with the regular troops in the strike troubles of 1877 about Baltimore and Pittsburgh, and at the beginning of the war with Spain was appointed chief surgeon of

volunteers, with the rank of lieutenant-colonel, serving as chief surgeon of the Fourth Army Corps. At the end of the war he was a member of the Evacuation Commission at Havana. While surgeon-general he was earnest in his advocacy of anti-typhoid inoculations and was largely instrumental in having them employed in the army.

In January, 1909, Gen. O'Reilly was retired for age, at which time he received the rank of major-general for Civil War service, being, it is said, the only medical officer of the regular army who ever held this rank.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent)

INSURANCE DIFFICULTIES AND THE CHANCELLOR—ROYAL SOCIETY OF MEDICINE—INJURIES TO KNEE—WEST END SOCIETY—ROYAL HOSPITAL FOR DISEASES OF THE CHEST—A NEW DEPARTURE—ITEMS—OBITUARY.

London, Oct. 18, 1912.

At the meeting of the Cabinet on Wednesday "it is understood" that the question of the doctors' remuneration under the Insurance Act was not discussed. It is "understood" in the same way that the Chancellor's promised statement for this week is put off until next.

The Council of the Royal College of Surgeons at a special meeting yesterday elected Mr. Edmund Owen to the vacancy occasioned by the lamented death of Mr. Clinton Dent.

Mr. Lloyd George attended the dinner of the Journalists' Union, and, responding to a toast, boasted of the success of his "stamp-licking" plan. He said stamps had been affixed to insurance cards at the rate of £12,400,000 a week, and last week the number exceeded £15,000,000. He had had no complaint from great employers of labor, and many had told him they had had no difficulty, though booming trade might have something to do with that. He looked forward confidently to the time when the act, which he admitted to be "in many respects a revolutionary one," began to work. It must be somewhat disconcerting to this complacent self-confidence to find so many interests protesting against the provisions which concern them—most of all, the clubs and unions, whose votes he expected to gain. Here is a sample of how the workingman may meet an offer which he thinks unfair: Mr. Stutters, Chief Ranger of the Ancient Order of Foresters, has written to the Chancellor to ask how he means to secure a proper medical service under his act. Until it was passed, he says, arrangements were made on agreed terms, but widespread trouble began when the Government disturbed existing customs. "The medical profession—and, I think, quite properly—have put forward certain demands and they advance a threat that unless these are conceded they will decline to accept service." He adds that, recognizing the right of any body to say what is the real value of their services, he does not complain of them, but, on the contrary, is constrained to support them in the determination not "to permit even a Chancellor of the Exchequer to fix remuneration for services rendered without first consulting them as to its being adequate." Such usurpation of individual rights, he holds, must be fought to the end. Remarks made by the Chancellor as to increased cost he puts aside, telling him as responsible for financing his act it is his business to find the ways and means. Then he repeats his question as to how the Government means to secure his society the measure of medical benefit it has hitherto enjoyed, adding: "It had better be recognized once for all that nothing short of the quality of attention hitherto enjoyed—attention ungrudgingly given by the doctors—will satisfy." The reply of the Chancellor through his secretary only refers to Mr. Masterman's statement in the House of Commons as to possible monetary equivalent, and to this Mr. Stutters at once retorts that could only be "the sum claimed by the doctors" for their services. Any "less is not equivalent." He goes on to remark that the Government are suffering the penalty of legislation in a hurry and their error of judgment in failing to secure the cooperation of the profession instead of "this miserable exhibition of bargaining." They will find no disposition among insured persons to assist them in evading their obligations, "nor can it be supposed that the medical profession will surrender an impregnable position." The Government's loud talk of freedom of the democracy does not square with a hint of compulsory subscription to a national service in substitution for voluntary selection, nor with its enormous increase of officialism. He closes with a repetition of his question, and asks for a reply "germane to the point."

At the Royal Society of Medicine on the 8th inst. the surgical section had before it two papers on injuries to the semilunar cartilages. Mr. A. J. Walton read one dealing chiefly with anatomical points, from which he inferred there is a tendency toward displacement on full extension, increasing with the degree of force put forth. The tendency is most marked at the anterior end of the internal cartilage, as this part is narrower and, owing to the screw action, in full extension is more forcibly compressed between the tibia and femur than anywhere, and is here loosely attached. He found no evidence of a tendency to fracture or displacement when the joint is not fully extended. He had investigated seventy-seven cases at the London Hospital, and found the lesions identical with those artificially produced by hyperextension and the terminal screw action. The histories and etiological factors confirmed his opinion. The second paper was by Mr. Albert M. Martin of Newcastle, and based on his personal experience of 449 cases, all operated on during the period 1900-1911. All made good recoveries, there being no case of joint infection or instability of the joint. In some cases there was complaint of unrelieved symptoms; otherwise the results were all that could be desired. Two hundred and eighty-two patients were miners, who are very liable to this injury from sudden wrenching or twisting while the knees are flexed. Eighty-two happened when playing football. In 92 per cent. it was the internal cartilage. The injury might be a simple longitudinal split or a portion might be quite detached. If it lay in its normal position it might be easily overlooked. It might be curled up and only attached at each end. A split at posterior part might only be shown by a strong pull on the anterior. A tear across the cartilage, starting from any point on the knee border, or a split through the thickness, the under portion thus able to engage between the joint surfaces, or a small pedunculated disc with rounded edges might be found, resulting from the free border having been torn. In a few cases the cartilage had been mutilated beyond recognition. With regard to

treatment, Mr. Martin held operation necessary for men engaged in manual labor if no contraindications existed; it was also desirable for men and women intending to continue outdoor sports. The best time to operate is after the first week or ten days. He used a transverse incision and removed the detached piece and also the part remaining. In nearly all cases the joints were as good as before. He was skeptical of cures by rest.

Mr. McAdam Eccles remarked that the external cartilage was the more movable at the circumference, but much more strongly tethered at the extremities, and so could move more with less likelihood of being torn. It was almost impossible to say the exact injury before exploring, but when signs and symptoms suggested definite injury the case should be treated as such. He advocated plaster-of-Paris over a thick layer of cotton wool immediately after the accident, and kept on for four weeks, followed by passive movements, and massage for another four weeks, as giving a chance of union. But if symptoms recurred, removal of the cartilage, which he never sutured.

The West London Medico-Chi. opened its thirty-first session on the 4th inst. when the new president, Dr. G. P. Shuter, as his first act, presented his predecessor with the Keeley memorial medal which it is the custom of this society to present to each retiring president as a memento of his tenure of the chief office. The gift was acknowledged by Mr. Eccles (retiring president) and some official business transacted, after which Dr. Shuter delivered his inaugural address in which he sketched in a most interesting way the history of conasthesia by nitrous oxide, dividing it into three periods: (1) From Davy's researches, in 1800, to its use by Horace Wells in 1844 in dentistry. (2) From then to 1864 when it was revived after a period of neglect. (3) From that revival until the present day. The improvements in instruments and in the preparation of the gas and its supply were also passed in review by Dr. Shuter.

Yesterday a tuberculosis department was opened at the Royal Hospital for diseases of the chest. It is intended to establish a dispensary under the Insurance Act, and to provide training for medical officers to such institutions and to sanatoria. The departure is at the cost of a generous anonymous benefactor, who makes his gift on condition that provision is to be made for research work as well as for scientific instruction. The new department includes a lecture room to accommodate 100 persons, an *x*-ray room, a dental room, an electrocardiograph room, an operating theater, three laboratories equipped for microscopic and vaccine work, outpatient accommodation for about 200 patients, and the usual consulting rooms and other offices. Sir William Osler presided at the opening ceremony, at which the profession was well represented. He considered the association of a tuberculin dispensary under the act with a special hospital as an interesting development to be recommended to every hospital that specializes in tuberculosis. The plan proposed for filing cases and contacts he commends as a model.

Professor Nietzer, secretary of the German Central Committee for Preventing Tuberculosis, gave an address on the work among children. He said that at first the committee was mainly concerned with the care of curable cases, but latterly it had given more attention to preventive methods. They now saw the necessity of beginning with the child, for they found that though the incidence of the disease was steadily decreasing in Germany the children did not participate in this decrease. Recent researches showed that the majority of cases were infected in early life and that most likely through the close intercourse of the members of the family. This should be the basis of preventive methods.

The Industrial Diseases Committee, sitting at the Home Office, is considering whether Dupuytress's contraction, cowpox, and clonic spasm, apart from nystagmus, should be scheduled under the Workmen's Compensation Act, so as to enable workmen to claim for disablement due to their occupation.

Hospitals are suffering much from the fall in securities of late years. Sir E. Elles, treasurer of the Surrey County Society, told the governors at a meeting on Monday that if they were obliged to realize their investments at the present time it would entail a loss of £10,000.

Dr. F. H. Low, honorary secretary of the Röntgen Society and vice-president of the West London Medico-Chirurgical Society, died on the 8th inst., after a short illness, at the age of 58. He had been *x*-ray physician at several hospitals, and done much to establish their departments.

The death is reported of Dr. Robert Laing, Medical Health Officer of Blyth. He was a Durham student and took several medals. He qualified L.R.C.P., Edinburgh, and M.R.C.S., England, 1869. In 1889 he added the D.P.H., Cantab., and has held several health appointments. He was a Justice of the Peace for the county of Northumberland.

THE FIFTEENTH INTERNATIONAL CONGRESS OF HYGIENE AND DEMOGRAPHY.

(Special Report to the MEDICAL RECORD.)

WORKINGMEN'S INSURANCE IN GERMANY—WOMEN IN INDUSTRIAL LIFE—INDUSTRIAL ACCIDENTS AND TRADE DISEASES IN THE UNITED STATES—NOTIFICATION OF INDUSTRIAL ACCIDENTS—ALCOHOLISM IN RELATION TO ACCIDENTS, SICKNESS, AND MORTALITY—SPREAD OF COMMUNICABLE DISEASES THROUGH TRAFFIC—STATE AND NATIONAL SUPERVISION OF TUBERCULOSIS—DISSEMINATION OF TYPHOID FEVER.

IN the Section on Demography Ministerialrat Dr. Friedrich Zahn, Direktor d. K. Bayer, Statistischen Landesamts, Munich, Germany, read a paper on "Workingmen's Insurance and the Care of the Poor in Germany." The relations between Workingmen's Insurance and the care of the poor bring two questions into prominence: (1) Has the Workingmen's Insurance produced a lessening effect in the care of the poor? (2) Is there a relation between the Workingmen's Insurance and the increase of the German poor budget? Enlightenment on these questions is to be desired. The German Workingmen's Insurance has actually lessened the care of the poor. There are now in round numbers 13,000,000 persons insured against sickness, 15,000,000 against invalidism, and old age, and 24,000,000 against accident. This includes not only the upper class of laborers, but also the broad masses of wage-workers and with them a noteworthy part of the earlier body of dependents on the administration for the care of the poor. Over 7,674 millions of marks (nearly $1,918,500,000) were expended for workingmen's insurance in the period between 1885-1909;

1.8 million marks (nearly $450,000) on an average daily to the advantage of those insured. By reason of this, results are accomplished in sickness, accident, disability and old age, and these come also to the share of the family. The insurances are permanent and the extent of the same suffices at present in many ways for the alleviation of the state of need and will continue to improve. It produces besides an energetic struggle against the causes of disturbances of the industrial life and for that reason results in an extensive prophylactic activity of the Labor Insurance organs, so that the Workingmen's Insurance has straightway become the foundation and cornerstone for our preventive social hygiene. The moral influence in this connection is not to be overlooked. The ameliorating influence of the Workingmen's Insurance is most evident in small, poor communities where the care of the poor must be restricted to the most needy; the care of the poor is a heavy expense to the community. The large cities can, on account of their financial condition which as a rule is more favorable, practice a more broad-minded care of the poor. They devote means released by the Workingmen's Insurance to new cases of assistance hitherto left unnoticed and to new and more intensive support of single cases. The author discussed the rapid increase of population in the last twenty-five years, also the powerful and swift process of placing affairs under municipal control. He discussed further the elevation of the welfare and betterment of the mode of living which have appeared with our recent economic development; he also discussed the increase in the cost of living. Dr. Zahn also read a paper on "Women in Industrial Life—An International Statistical Examination." He said that the most precious possession of a nation is the nation itself, its national strength. The organic national capital (wealth) must be used sparingly, so that without injury to its inner worth new evolutionary values may continually develop as the interest and compound interest on this capital. The woman is a most valuable productive and reproductive factor of this national capital. Her work as mother and educator of the working forces, as wife, as the soul of the family, as a working force in industrial pursuits outside the home, as a fellow worker in the service of public interests, is extremely important for the entire advancement in the making of a living. The performance of these various industrial occupations by women has experienced great transformations during the last decade, but not to the advantage of the productive and reproductive strength of women. For the sake of preserving the family, and furthering culture and morals, as well as in the interest of political economy and the economy of nations, a greater economy of women is needed. At the present time the national and international statistics relating to the participation of woman in industrial pursuits for a livelihood are very incomplete and require greater study and development.

During the afternoon at the New National Museum there was held a joint session of the Section on Occupation and the Section on Military, Naval, and Tropical (Colonial) Hygiene. The first symposium considered was the "Measurement of the Healthfulness of Occupations," and this was opened by Frederick L. Hoffman, LL.D., Statistician, Prudential Insurance Company, Newark, N. J. He read a paper on "Industrial Accidents and Trade Diseases in the United States," and emphasized the necessity for accurate records of industrial accidents and industrial diseases. He suggested the enactment of compulsory notification laws. The utility of the proportionate mortality method is emphasized as the most useful means available in the United States for the practical needs of industrial hygiene. He gives a brief outline of the industrial accident problem, stating that approximately 25,000 deaths annually result from industrial accidents among approximately 30,000,000 males employed in gainful occupations. He estimates that about 15,000 fatal accidents occurring annually among persons employed in industry are not directly attributable to industry. In view of the immense importance of industrial hygiene in a nation which is to-day foremost in industrial activity, it would seem eminently proper that the whole problem should be considered by a national commission, in conformity with the principles advanced in the Memorial to the President of the United States, and presented to him at the request of the First International Congress on Industrial Diseases, held in Chicago in 1911.

Robert E. Chaddock, Ph.D., Associate Professor of Statistics, Columbia University, New York, read a paper on "Reporting of Industrial Accidents." He reviewed the nature of the inquiries made by the various States concerning industrial accidents. One aim of the paper was to promote a clearer understanding of the nature of the problems, in the solution of which statistical data are essential. Such an understanding was preliminary to the collection of the facts themselves, and should be their guide as to what facts to collect in the future, and how to collect and arrange them. Mr. Henry J. Harris, Chief of the Division of Documents, Library of Congress, Washington, D. C., read a paper on the "Present Position of Accident Statistics in the United States." This paper was followed by one on "Demography of Industries and Professions," by M. Lucien March, Directeur de la Statistique Générale de la France, Paris, France. In France in 1906 they had obtained a double classication of individuals, on the one hand according to the industry to which they belong, on the other according to their special occupation. To obtain reliable statistics of occupational mortality it would be necessary to establish two tables based on the same principle and requiring the same control, the same precision, one for the number of living and the other for the number of deceased.

The rest of the afternoon was devoted in this joint session to the consideration of the "Relation of Alcoholism to Accident, Sickness, and Mortality." Dr. Jacques Bertillon, Chief of the Bureau of Municipal Statistics, Paris, France, read a paper "Concerning the Existing Relation Between Phthisis and Alcoholism," a very close one. Every one knows that alcohol attacks the liver of its victims, but let us add that twice as often it attacks the lungs, by causing tuberculosis, pneumonia or bronchopneumonia. Alcohol may be called the principal cause of phthisis. Edward Bunnell Phelps, editor *The American Underwriter*, New York, read a paper on the "Mortality From Alcohol in the United States—the Results of a Recent Investigation of the Contributory Relation of Alcohol With Each of the Assigned Causes of Adult Mortality." These results were published recently in book form under the title of "The Mortality of Alcohol." The total arrived at for an estimated population of 86,874,990 was 65,897 deaths in which

alcohol might have figured as a factor, or 5.1 per cent. of the supposed total mortality at all ages and 7.7 per cent. of the supposed adult mortality at age 20 and upward. This approximation of about 66,000 deaths has received strong confirmation since the publication of Mr. Phelps's book.

Dr. William F. Boos of Boston, Mass., read a paper on "Alcohol as a Predisposing Cause of Accidents and Occupational Disease." A German physician finds that alcoholic workmen between the ages of 25 and 44 have over three times as many accidents resulting in injuries as all the other workmen put together; and that the days of illness resulting from such injuries are nearly four times as many as those incurred by all the workmen. It was also determined that if the accidents caused by the use of alcohol could be eliminated, 7 per cent. of all accidents would be prevented and the saving to the German sick benefit societies for the year 1897 alone would have been 4,500,000 marks. The seriousness of the accident at Corning on the Lackawanna Railroad, on July 4th, does not lie so much in the loss of thirty-nine lives because an engineer was drunk, as in the fact that it was possible for the engineer to enter his cab in a drunken condition. We need thorough control of all railroad employees. The first step in this direction has been taken by the management of the elevated and underground railways of Berlin, which employ careful and responsible officials to whom all the men must report before they go on duty.

The Section on Microbiology and that on the Control of Infectious Diseases held a joint meeting devoted to the discussion of "The Spread of Communicable Diseases Through Traffic," in which Dr. Eduardo Liceaga of Mexico City, Mexico; Dr. Shibasaburo Kitasato, Tokyo, Japan; Surgeon General Blue of the United States Public Health Service; Assistant Surgeon-General William Colby Rucker, Dr. W. R. Watson, Director of Sanitation, of Porto Rico; Dr. William F. Snow, Secretary of the State Board of Health of California; Dr. Harold B. Wood of Rochester, Minn., and Passed Assistant Surgeon Allan J. McLaughlin took part. There was a decided unanimity of opinion as to the spread of plague, which is summed up by saying that "the problem of the eradication of plague is the problem of the extermination of the rat." Nothing less than a world-wide campaign will do this. The first element in preventing rats from taking passage in ships is a ratproof waterfront. As it is not practicable to secure the adoption of world-wide measures for extermination periodical fumigation of ships is desirable. No portion of the vessel should be overlooked. Attention was called to the need of getting rid of the marmot and ground squirrel. Whereas the acute form of plague affects rats, squirrels are subject to a chronic form of the disease which serves to perpetuate it. Dr. William F. Snow declared that we need a rigid State and national supervision of the migration of tuberculosis patients. He also approved England's new plan of compulsory insurance in order to provide adequate sanatorium treatment for tuberculosis patients. As to the dissemination of typhoid fever, Dr. Allen Freeman said preventive efforts have been confined almost entirely to cities. The principal factors in transmitting typhoid infection between urban districts and from rural to urban districts are: by persons; carriers, temporary or permanent; persons in the incubative stage of the disease, and persons actually sick with typhoid; by food and drink, including water, dairy products, garden truck, fruits and shellfish. A careful and comprehensive campaign against the disease will result in a large reduction in the amount of infection thus transmitted. Dr. Harold B. Wood thought the country's typhoid was rural and could be ameliorated by the establishment of bureaus for the collection of sociological and health statistics and for public instruction and gratuitous advice. Morbidity reports should include location and kind of occupation. Better trained whole time rural health officers having wide jurisdiction are needed. In giving advice use judgment to advise methods which can and will be adopted under local conditions.

Passed Assistant Surgeon Allan J. McLaughlin said that to prevent waterborne disease in lake and river traffic it would be necessary to proceed along the following lines: 1. Popular education is necessary to prevent drinking unpurified surface water. 2. Public water supplies in communities engaged in interstate traffic should conform to United States standards. 3. United States standards should be based upon the bacterial count and the quantitative estimation of *B. coli* and should be the minimum requirements to prevent the spread of disease, such as typhoid fever or Asiatic cholera, in interstate traffic, the various States retaining the right to impose additional requirements, consistent with State laws where such laws exist. 4. United States regulation is necessary requiring vessels engaged in interstate traffic to fill their water tanks only from public water supplies certified as safe and conforming to United States standards. 5. Inspection of vessels by United States officers and by state and municipal officers duly qualified to enforce this regulation. In the discussion of these papers it was stated that the problem of abolishing typhoid fever was the greatest problem before sanitarians because the control of typhoid fever would mean the control of other communicable diseases, and in order to accomplish this a large State force of inspectors was needed; this was often difficult to secure as different portions of the same State have very different ideas as to the need of medical inspection.

1. Muscle Training in Infantile Paralysis.—W. G. Wright concludes as the result of six years' experience as an assistant in the treatment of infantile paralysis by means of muscle training, massage, and electricity that better results have been obtained from the combination when physician and parents cooperated than when the management of the exercises has been left to an unskilled gymnast or masseur, who has neither the scientific knowledge of the physician nor the patience and enthusiasm of the parent. The training of the muscles should be begun as soon as the patient can move his limbs freely without pain. In most cases this will be from three to six weeks after the initial attack. It is possible also to accomplish a great deal for cases that have been neglected for years.

3. **Excretion of Formaldehyde Following Administration of Urotropin.**—O. R. T. L'Esperance notes that when Burnham's test is applied to the urine of patients taking urotropin it is found that about 50 per cent. of these patients excrete formaldehyde. Age, sex, well or sick individuals, normal or pathological conditions of the kidneys, and the reaction of the urine do not influence the ratio of excreting and non-excreting kidneys. The time of the appearance of the drug in the urine is about one hour after ingestion by mouth. The excretion continues for from four and one-half to six hours, with a maximum at about two hours. In view of these facts it is necessary in order to get uninterrupted excretion to repeat the administration of the drug every four hours. The reaction of the urine is of no importance. Alkalies taken with or in combination with urotropin have no effect on the excretion. The duration of the excretion of formaldehyde is about four to six hours. The increase of dosage does not affect the excretion in negative urines. Urotropin is practically symptomless in an average dose. The urine of all patients taking urotropin should be tested for formaldehyde. Patients not excreting formaldehyde are symptomless regardless of the amount of urotropin taken.

2. **Membranous Perienteritis.**—By A. E. Isaacs. (See MEDICAL RECORD, Vol. 81, page 1208.)

5. **Medical Economics.**—T. F. Reilly states that medical economics includes the study of a vast number of subjects. From a business standpoint it covers: (1) The importance of honor and probity in all transactions; (2) the fundamental principles underlying a physician's compensation, dealing with the subject of fees both for ordinary and extraordinary work and for operations; (3) the necessity of modern methods of medical bookkeeping; (4) the importance of collections; (5) how to secure prompt payment; (6) the various extra-practice means of obtaining a livelihood; the evils and dangers of lodge practice; (7) the abuse of medical charity; (8) the dishonesty of division of fees; (9) the value of cooperation as opposed to the old spirit of rivalry; the absolute necessity of organization and its advantages; finally medical ethics is of prime importance, both as a guide to proper living, as well as to success from a business standpoint.

7. **The Specific Treatment of Cancer.**—I. Levin believes that ultimately a specific remedy will be found, at least in experimental cancer. But at present all the results are unsatisfactory. The true nature of the therapeutic action of the substances is not known. The same autolyzed tissue, the same chemical combination of eosin and selenium may be active in one series of experiments and not in another. It will require years of laboratory research before real light is thrown on the subject. Even then, there will still remain unsolved the most difficult question as to the manner in which the results can be transferred to the treatment of human cancer. To the profession at large the most practical advice which a laboratory worker can give is to wait at least five years before trying a new specific cancer cure, no matter how great the reputation of the man who advocates it. Meanwhile, in early diagnosis and radical operative treatment lies the only hope of the patient.

8. **Urinary Changes in Nervous Diseases.**—S. R. Klein points out that quantitative changes in the urine are often observed in diseases of the nervous system. Attacks of hysterical excitement are followed by copious polyuria of short duration, and in all patients of the neurotic type any nerve tension may induce a milder degree of polyuria which may continue for days or for weeks. In such cases the urine is light in color and of low specific gravity, differing from the normal excretion only by its extreme dilution. Less frequently, on the other hand, oliguria may occur; even complete anuria has been met with in hysterical women, a condition not to be confounded with the frequently encountered hysterical retention of urine. Mendel of Berlin has observed that in 90 per cent. of epileptic cases there is excess of uric acid, also of urea and phosphates. In cases of neurasthenia, Defleury observed a diminution in volume, with high specific gravity, and an increase of earthy phosphates in relation to the alkaline phosphates; he also noticed an increase in the chlorides, and lowering of the oxidation coefficient. The occurrence of an excess of phosphates in the urine in cases of nervous disease was first noted in relation to meningitis. Albumin is frequently found in the urine after attacks of apoplexy, in cerebral growths, and in various inflammatory processes affecting the brain. Occasionally sugar may also be present, most frequently when hemorrhage takes place into the fourth ventricle. In Graves' disease polyuria frequently occurs, with or without the presence of sugar. In various forms of mental derangement, delirium tremens, paranoia, and melancholia sugar has been found in the urine. In 20 per cent. of melancholic cases Arndt detected alimentary glycosuria. Indicanuria is found mostly in cases of melancholia, paranoia, mania, and especially delirium tremens.

1. **Injuries of the Spinal Column.**—E. D. Fisher discusses the operative treatment of traumatisms of the cord uncomplicated by fractures or dislocations of the spinal column. The author would depend more largely on the sensory disturbance than on any other symptoms in deciding in regard to the operation. When there is absolute loss of sensation, together with the usual loss of reflexes, and rectal and vesical paralysis and well-marked transverse demarcation of anesthesia, the case is regarded unfavorably for operation. Any variation from that one condition indicates the possibility of a good result from operation. Since many cases have been reported of gradual return of sensation without an operation, the

author would almost always wait for this and until all sensory improvement had ceased before beginning to operate. When it ceases or the condition becomes worse operation should be no longer delayed. After a paralysis has existed for several months operation is almost futile. When the symptoms have not changed from the early condition of loss of reflexes, continued loss of sensation and a tendency to contraction of the paralyzed muscles, it seems that operation is useless, whether done in a few months or many months after the injury. The author would operate when there is the slightest chance of recovery, because in the hands of a skilful surgeon there should not be any special danger in the operation itself.

5. **A Six-Day Fever in the Canal Zone.**—W. E. Deeks describes an epidemic of a peculiar tropical fever which prevailed in Panama last summer. Two clerks who handled the incoming foreign and domestic mail exclusively in the Ancon postoffice first showed symptoms of the fever in April. From them it spread to the other three clerks and to individuals outside, and at the date of the report was spreading in Panama. At first the disease was taken for malaria, but no parasites were found in the blood and anopheles breeding places were lacking. The chief features of the disease are: the high infectiousness, probably antedating the fever; the lack of prodromi; the abrupt onset with chills and a fever temperature of 101.4°; the six days' course with slight morning remissions and more or less abrupt ending, generally without recurrence; the practically normal pulse and respiratory rates; the splenic enlargement; the unchanged blood-picture; the anorexia and after-depression, greater than after malaria. The incubation period is apparently ten days. Widal reactions were negative. The author thinks this disease probably identical with the seven-day fever referred to by Castellani, and that this is its first appearance in the Canal Zone since the American occupation, having been probably introduced through the mails. Though some of the cases have been very severe, there have been no fatal ones.

7. **Psoriasis.**—Dr. W. Montgomery has found that baths of pure warm water act powerfully and beneficently on psoriasis. Sulphur baths made by the addition of potassium sulphide may act badly, especially when the skin is in an erethistic, irritable condition. Tar and permanganate of potassium are often valuable additions to baths given for psoriasis. The addition of the blander salts, such as bicarbonate of soda, boracic acid and common salt probably decrease the effect of the bath by reducing the osmotic pressure of the water. Maceration under impermeable coverings acts in much the same way as baths.

8. **Protein Metabolism in Late Pregnancy and Puerperium.**—J. R. Murlin and H. C. Bailey conclude that the average of many determinations shows that the nitrogen factors of the urine in the last month of pregnancy are the same or but slightly different from those in the non-pregnant. Normal women in the last month of pregnancy may have an ammonia-nitrogen as high as 17 per cent. and a combined amino-acid and undetermined nitrogen of 10 per cent. Percentage figures are deceiving and of no value, for the total nitrogen is dependent on the amount of food absorbed, and this is affected by intake, nitrogen content, catharsis, etc. With all the clinical signs of pre-eclampsia, the nitrogen partition may be normal, even up to and for twenty-four hours following the development of convulsions. Following convulsions the ammonia factor may or may not be high, depending, we believe, on the development of ammonia within the bladder, owing to contamination by the catheter. The nitrogen partition as an evidence of metabolic processes cannot be said to offer an index to the pre-eclamptic or the eclamptic condition.

9. **Books as Carriers of Scarlet Fever.**—O. R. Nesbit notes that (1) if books act as carriers, it is only immediately after being contaminated with the discharges of the patient; yet the author's investigation has failed to reveal a single instance of this kind. (2) Books that have been used by scarlet fever patients do not long contain the infection in such a way as to transmit the disease to man. (3) Any book which has been handled by a scarlet fever patient should be burned or fumigated. The most practical method for general book disinfection at this time is the Beebee carbogasoline method. This consists in using gas-machine gasoline and 2 per cent. phenol crystals; the books are immersed in this mixture for twenty minutes, removed and placed before an electric fan for two minutes, and then set on end for from twenty-four to forty-eight hours.

11. **Cultivation of Filarial Embryos.**—C. Wellman and F. M. Jones present a preliminary note on their successful experiments with the culture in artificial media of the embryos of the *Filaria immitis*, (Leidy). Experiments were devised to determine the influence of various whole bloods, serums and other media, and also the effects of temperatures, air, etc., on dog's blood at 28° C. The embryos die out in from three to eight days at 37° C. Other media, such as hemoglobin, agar, bouillon, citrated dog blood and human blood were less successful. The best results were obtained with dextrose dog serum at low temperatures, and it is rather curious that, after the low temperature, the next best temperature for producing the growth of the parasites is as high as 40° C. Cultures contaminated with bacteria in many cases gave as good results as sterile ones, especially at low temperatures, and even at room temperature the embryos seem to thrive in the presence of certain bacteria.

1. **Surgery of the Peritoneum.**—By H. Macnaughton-Jones. (See MEDICAL RECORD, October 12, 1912, page 671.)

3. **Injuries to the Semilunar Cartilage.**—A. M. Martin remarks that the bulk of the sufferers from torn semilunar cartilage give a typical history, and emphasizes the fact that in the majority of cases one has to diagnose the condition from what one is told. It may be that when the physician first sees the patient the primary tear occurred months or years previously, and the subsequent attacks of "something going wrong with the joint" have been comparatively slight, consisting, perhaps, of little more than experiencing a click or a snap at the inner side of the knee with pain in the same situation. The patient then finds that momentarily the joint locks, *i. e.*, he is unable to extend it completely; then suddenly, after moving his knee himself or after somebody moves it for him, another click or snap is experienced, and full power of movement is again regained. Attacks such as these occur more or less frequently and at various intervals after the primary tear, and are often followed by no effusion, the only symptom remaining being a tender point at the inner or outer side of the patella somewhere in the line of the articulation, according as it is the internal or external cartilage that is injured. These subsequent attacks are often determined by very slight causes, such as catching the bedclothes with the toes, etc. When the primary tear takes place the symptoms are much more severe, and are often

as follows. In consequence of a severe wrench or twist the patient is suddenly seized with severe pain. The pain is at first often felt over the whole joint, later becoming localized at the inner or outer side, and is frequently so bad as to cause faintness and vomiting. At the same time a click or snap is felt, or a feeling of something slipping. If running, he falls to the ground, and finds he is unable to completely extend the knee. In a few hours swelling occurs, the result of effusion in the joint, and this, in consequence of rest, disappears in the course of two or three weeks. In some cases the inability to extend persists for a week or more, and in others only disappears when an anesthetic is given and certain manipulative procedures carried out or the offending cartilage is removed. For some weeks after the accident, and after all swelling has disappeared, a tender point persists at the inner or outer side of the patella according as the internal or external cartilage has been torn. In deciding upon a line of treatment the question arises as to whether it is necessary for the patient to have a perfectly sound joint or not. If he is engaged in manual labor the answer must be in the affirmative, and in the absence of any contraindication, such as intercurrent disease, operation is demanded. This decision, the author maintains, must also apply to active men and women who are still wishful to spend their leisure in open-air sports, such as football, cricket, hockey, shooting, and riding.

4. Changes Induced in Blood by Feeding.—G. Mann and J. G. Gage report as the result of their investigation that during the digestion period there is a marked increase in the staining intensity of all nuclei; the rim of cytoplasm in the lymphocytes becomes narrower; the granules in the leucocytes decrease both in size and number, and the leucocytes may also show a diminution in size. As far as the deeper staining of the nuclei is concerned two explanations suggest themselves. One may assume, since there is an actual increase in the number of white cells after a meal, that these new cells in the circulation, being younger, are therefore smaller, and that for the same reason they stain more deeply. Analogously younger leucocytes might contain fewer and smaller granules. This explanation of the change in the microscopic appearance of the blood does not seem to the authors to be the correct one, as one would have to assume either a vast increase in the number of new cells or a correspondingly large destruction of those white cells, which were circulating in the blood before food was taken, to produce the great changes we have found to occur. The second explanation is based on the fact that the nucleated corpuscles in the blood must get nourishment from the blood plasma and must metabolize as long as they are alive. One would further expect the nucleated corpuscles to be feeding at such times when the blood plasma contains the most food material—that is, while food is being absorbed from the alimentary canal. There is thus definite evidence that the metabolism of all nucleated cells is inseparable from the increase in the nucleoprotein radical in that cell, and one has therefore to solve the problem of the manufacture of purin substances from non-purin radicals. It is more difficult to account for the diminution in the size of the neutrophile corpuscles. The authors suggest the explanation that the irritability and the contractility of the white corpuscles are increased in feeding, in consequence of which fed cells are more likely to become spherical and less likely to be spread out by the pressure of the glass slide used in making a film; and further than this, they also maintain that the increased osmotic pressure in the blood plasma during the absorption of food may cause a certain amount of exosmosis, from which probably follows a marked shrinkage of the white cells apart from the diminution caused by the partial disappearance of the zymogen granules.

5. Some Remarks, with Statistics, on the Treatment of 1,305 School Children (London County Council) at the Royal London Ophthalmic Hospital (Moorfields). F. Moxon.
6. Transitory Bigeminal Pulse. Sir Lauder Brunton.

2. Albuminuria in Pregnancy.—E. H. Siedeberg states that the proportion of pregnancies in which albumin is present is a very large one. Out of 1,127 cases albumin was present in 289, or 25.6 per cent. There is a remarkable preponderance of complications in cases in which albuminuria has been present. The latter is only the visible sign of profound metabolic changes which are taking place in the body.

3. Persistent Occipito-Transverse Presentation.—H. Chapple emphasizes the necessity of always determining in a case of labor the size and shape of the pelvic outlet. In forming an estimate of the amount of obstruction likely to occur at the pelvic outlet we should be guided both by the distance between the ischial tuberosities and by the subpubic angle. The existence at the pelvic outlet of a presentation is here described as an occipito-transverse. The rational treatment of such a presentation, should it persist, consists in an application of forceps in an oblique diameter of the outlet, and while traction is being made the forceps should be rotated into the opposite oblique, with the result that the occiput is swung under the symphysis and then delivery is promptly effected in the usual way.

4. A Standard of Childbed Morbidity.—A. W. Russell makes a plea for a uniform standard for the scientific records of morbidity in the puerperium. For this purpose only thermometers of ascertained correctness should be used. The observation should always be made in one place, preferably the mouth, and extend over a fixed time. The temperature should be taken at stated intervals and at the same time of the day, and the first day should be included. The record should include all abortions and also all deaths with a previous morbidity. Both temperature and pulse should be taken, and the normal lower limit in each should be determined finally by resolution of the International Congress for Obstetrics and Gynecology, and thus become a recognized, universal, uniform standard of morbidity for use in all scientific communications—a manifest improvement.

6. Transitory Bigeminal Pulse.—Sir Lauder Brunton reports a rare case in which there was a bigeminal pulse without any apparent cause other than the slight excitement of applying the sphygmograph. The patient was a young man, aged 19, who had been suffering from albuminuria for more than two years; he also had enlarged glands behind his sternomastoids, and in the axillæ and left groin. The pulse was small, soft, and regular. The tension was only 97. The urine contained a few swollen renal cells, very few casts, and no crystals. With the exception of slackness he had no symptoms, and when excited showed considerable activity and would play four sets of tennis one after the other. He had no other complaint. His systolic tension 108 and the diastolic 60. The cardiac dullness and sounds were perfectly normal. There was still a large amount of albumin; he had several glands in the back of the neck, in the groins, and in the front of the abdomen. His pulse was quite regular, but while the author was taking it it assumed a bigeminal character. The author believes that the peculiar rhythm of the pulse was due to the partial interference of two rhythms—muscular or nervous, or both—though the exact *modus operandi* may require a prolonged investigation and discussion.

Berliner klinische Wochenschrift

October 14, 1912.

Principles of Up-to-Date Tuberculin Treatment.—Möllers claims that the most practicable and efficacious treatment of human tuberculosis consists of a combination of hygiene and a diet as carried out in sanatoria and of the specific tuberculin treatment. In the initial stages selected cases may also benefit by these principles in dispensary practice. The characteristic of to-day's tuberculin treatment is its mild "insidious" method in which the full dosage is attained with maximal avoidance of reaction. The selection of a particular make of tuberculin is of less significance than the choice of the method. Treatment should not be schematized, but strongly individualized, regard being had to individual susceptibility and the course of the disease. The most appropriate form of administration is the subcutaneous. Permanent cure does not, as a rule, follow a single cure. In many cases the treatment must be renewed throughout one or more years. These principles of treatment should not be left wholly to specialists in sanatoria, but should be carried out, the author says, by the profession at large.

Apical Emphysema.—Ország considers the relationship of this condition to tuberculosis. We know that a circumscribed emphysema may not occur in this locality and the possibility of tuberculosis must be borne in mind, because in such a case diagnosis of the latter would be obscured. It is assumed that in lesions in the apex the so-called Krönig's area is diminished in extent, but in certain affections it is increased—apical emphysema, cavities, relaxation and pneumothorax. The decrease of intensity of a dulled percussion sound over the apex is not unconditionally a sign of a decrease in the amount of infiltration, for it may be due to the supervention of apical emphysema. In the examination of the apices both the gentle and the vigorous method of percussion should be undertaken in different intensities.

The Iodine Therapy of Tuberculosis.—Nieveling has been testing this ancient resource and announces the following conclusions: Iodine promotes expectoration through rendering the sputum less tenacious. It also favors respiration, but whether through the first-mentioned property or others is not discussed. The cardiac action is often benefited, the beat becoming stronger, and palpitation is overcome. Iodine exerts no influence over fever. The healing and cicatrization of cavities seem to be promoted. In general, the author believes that iodine can do all that creosote does and do it better. He appears to depend on some of the organic iodine compounds as substitutes for potassium iodide. The germ of the idea of an iodine therapy for phthisis, as far as modern practice extends, is the known power of this remedy over asthma.

Practical Studies of Bile in Vivo.—Királyfi has made many studies of living bile from the bacteriological and chemical viewpoints. Medical cases were alone used as material, the bile being obtained by the natural passage. Of special interest is the diagnosis in this connection of latent typhoid. A Boldyreff oil breakfast was first given, this causing the appearance in the stomach of a mixture of bile and pancreatic juice. Conclusions reached after examination of 60 subjects are in part as follows: The upper portion of the duodenum is usually sterile in the normal. A diagnosis of cholecystitis is usually justified if the bile shows infection with pyogenic germs, but absence of finds does not justify the opposite conclusion that this affection is absent. Again in actual gastric disease biliary finds may be masked. Of great significance was the recognition of Eberth's bacillus in pure culture, even in cases giving negative Widal. As a rule, an unusual albumin content of the bile means an infection and may check up the bacterial find, but the negative results possess no corresponding significance.

Münchener medizinische Wochenschrift.

October 8 and 15, 1912.

Non-operative Treatment of Cancer.—Czerny discusses all the methods thus far recommended under this head, which when summed up make a considerable showing, and in view of the fact that 50,000 die every year in Germany from cancer, the quest for non-operative procedures for delayed and relapsing cases must be praiseworthy. We know that nature sometimes, however rarely, cures or arrests malignancy and that it sometimes yields to other diseases, notably erysipelas. The various products known by such names as cancroin, antimeristem, etc., probably act as toxins only and have no true specificity. Favorable results referable to them may be reckoned with those due to Coley's serum. All these are imitations of what we see in nature. Cancer is usually regarded as an anomaly of metabolism, which makes possible the active manifestations; but attempts to cure or prevent it from this viewpoint are not attended with success. Immune- and antisera accomplish nothing. Of recent years chemotherapy, involving the selective destruction of the tumor cell has been and is still being extensively tested. The idea is by no means new and the ancient use of arsenic belongs here. A competitor is the use of radiant energy in its various forms, while fulguration also deserves mention although it is practically electrosurgery. The hope of the future in addition to all surgical and local procedures seems to be in a combination of active remedies—salvarsan or other arsenical, thorium and other radiations and in fact of any resource which does no harm. Czerny uses silica inwardly as a routine remedy.

Telangiectatic Granuloma.—Konjetzny makes an attempt to throw light on the causation and pathology of this affection at a time when our knowledge is at a minimum. At present the dispute is still forward that it is a granuloma on the one hand and a true tumor on the other. Recently the latter view has been making converts. There is of course the possibility that different processes present a common clinical picture. The author has studied two cases and has not the slightest doubt that both were examples of proliferating angioma. The author is not the first to note that these formations may appear on the site of a minute congenital angioma. The author's second case is peculiar in that it occurred on the tongue in the form of a pedunculated structure resembling a strawberry. It developed after the patient had bitten his tongue, and bled copiously. The author looked in vain for any specific formations. As the tongue is a favorite site for congenital angioma, the most plausible view is that embryonal tissue becomes activated to proliferation as a result of traumatism.

Contagiousness of Warts.—Stern describes briefly a small episode involving the possibility of the transmission of ordinary warts. Two servant girls who had worked in the same establishment for a long period had typical multiple flat warts on the backs of the hands. One girl developed later ordinary prominent fissuring warts between the fingers. The author constructs a sequence as follows: One maid had had the flat warts for about nine months when the other first began to show them. Transmission was probably effected through a towel used habitually in common. The later appearance of proliferating warts on the soft thin skin between the fingers which occurred in the girl first infected was an example of local extension and is not necessarily transmissible in that form.

Thyroid Preparations for Sterility.—Weil mentions the astonishing results of hormone physiology, pathology and therapy, and selects for special consideration the apparent correlation between the thyroid and ovary, which comprises not merely one but a series of possibilities, some

antagonistic, some complemental or synergistic. During menstruation and pregnancy the thyroid swells, while in castrates the latter organ may be seen to be atrophic. It occurred to the author to test thyroid preparations in primary sterility assumed to be due to ovarian insufficiency. A barren woman with simple goiter received thyroid preparations on general principles and in the course of two or three months became pregnant. The author then exhibited the remedy to two other barren women who aside from a slight enlargement of the thyroid showed nothing to suggest a reason for failure to conceive. After several months conception took place in both women. Of four pregnancies while taking thyroid two ended in abortion while one conception is recent and the only case which went to term required forceps. Whether these results are coincidences or indicate a general insufficiency for child bearing is not argued. There appears to be no doubt that the thyroid hormone artificially supplied determined a physiological congestion of the ovary which promoted conception. On the other hand none of these women appeared to have had any trouble in connection with ovulation and menstruation, so that a rationale for conception is not suggested.

Diffuse Gonorrheal Peritonitis.—Albrecht has controlled four cases of this affection of the gynecological type. Owing to the somewhat rare and disputed incidence of this condition the author gives each case in some detail. One of these may be repeated here. The patient was a girl aged 18, single, who while getting over a menstrual period developed sharp abdominal pains with the entire picture later of diffuse peritonitis. Although the pain and soreness were most marked to the left the diagnosis of perforating appendicitis was made. In the hospital this diagnosis did not appear to be warranted. Incidental examination of the genitals showed acute gonorrhea, which with the relatively mild character of the symptoms gave rise to the diagnosis of gonorrheal pelviperitonitis. The case evidently not demanding any immediate surgical intervention was treated with posture, ice bags and intestinal evacuation. After temporary benefit the patient became much worse and the full picture of diffuse septic peritonitis was not long in developing. The original diagnosis of perforative appendicitis was now made and laparotomy performed. The inflammation was seen to have extended from the pelvis. The tubes were markedly swollen, discharging pus into the latter. Gonococci were cultivated from the peritoneal pus. Despite the apparent severity of the case the patient rapidly improved after cleansing and closure of the abdominal cavity, thus bearing out Döderlein's teachings. The gonococcus may attain such virulence as to infect the peritoneum but nevertheless the prognosis may be good.

Drug Treatment of Tuberculosis Pulmonalis.—Hecht enumerates the drugs which aid in the management of tuberculosis. Pyramidon is almost indispensable for the reduction of high temperatures, and has come to be looked upon as a quasi-specific. Preparations of the creosote type, notably guaiacol, are also popular, and seem to act favorably upon the symptoms of the disease, both physical and rational. General tonics which contain quinine, arsenic, iron and strychnia in combination with some of the alleged specifics find much vogue. Among the latter the author enumerates a supposed antibactericide, introduced about 15 years ago, but fallen into disuse. It is said to be a camphor (alantol) from the root of a species of ailanthus.

Deutsche medizinische Wochenschrift.

October 17, 1912.

Goiter Heart.—Bauer attempts a description of the combined cardiac symptoms of goiter familiarly spoken of as goiter heart. He recognizes an erethetic and a torpid form and ascribes both to dysthyroidism. In endemic goiter there is a cardiac form which differs from the erethetic and is characterized by an accidental systolic murmur most marked over the pulmonic artery by an accentuation of the second pulmonary sound and a slight widening of the area of cardiac dulness to the left. The apex beat is not more pronounced than normal nor are there either acceleration of the pulse or any striking subjective symptoms. This form of goiter heart is probably thyreotoxic like the others and may be termed the "torpid" form to bring it into sharp contrast with Kraus's erethetic form. There are numerous transitions between normal, chlorotic and thyroid hearts.

Pancreas in Chronic Alcoholism.—Lissauer states that the pancreas frequently shows organic disease in alcoholics and that the alterations involve both parenchyma and connective tissue. We may see an interstitial pancreatitis due to inflammation of the connective tissue and a fatty degeneration of the parenchyma, and both these lesions may be regarded as especially ethylogenic, as the author has not encountered them save in alcoholics. The two types of lesion conform to the finds in the livers of alcoholics—fatty liver and cirrhosis. Friedreich has already described "drunkards' pancreas," so that the author claims no priority. In theory alcoholics should be prone to pancreatic diabetes and, as a matter of fact, they are known to be subject to the latter.

Rationale of the Tuberculin Reaction.—Meyer and Schmitz state that despite all efforts this reaction remains a mystery. We only know certain truths which bear directly or indirectly on the subject. The authors have carried out a research with bovine bacilli and tuberculin upon rabbits, which are very sensitive to the latter. They believe that they have shown the existence of a reactive substance in the erythrocytes of the tuberculous animal which is absent in the healthy subject. When tuberculin is injected in minimal amounts it is taken up by the erythrocytes and carried to the focus of the disease, where a receptor apparatus binds it and at the same time a hyperemia is set up. The combination of receptor plus tuberculin is a toxin and sets up a general reaction. Eventually with repeated injections the receptors are used up, no more combination toxin is formed and acquired immunity results. Abderhalden has also recently shown by the optical method that the blood plasma of the tuberculous is able to disintegrate the peptone of the tubercle bacillus, while healthy plasma has no such power. He brings this discovery in relationship with his own, but this inference does not seem directly forthcoming.

An Alleged Prophylactic for Tuberculosis.—Jarosch under a proprietary name discusses the recent free use of aluminium chloride as a prophylactic in pulmonary tuberculosis. The drug had previously been shown to exert great antiseptic power in local catarrhal conditions. It is now being used as a mouth wash and gargle and as an inhalation in a number of sanatoria where tuberculosis subjects run the risk of contaminating one another. It has been noted that to this prophylactic action is added a definite curative property for patients who began to use the inhalation as a disinfectant only for the common good began to exhibit direct improvement in symptoms referred to the upper air passages.

A Case of Ununited Fracture of the Ulna Treated by Bridging the Gap with a Slice Sawn from the Tibia.—C. H. Fagge reports the case of a boy, aged 11, who was admitted into Guy's Hospital on September 16, 1910. About two months before admission he had fallen, breaking both bones of the right forearm. On admission there was a marked deformity with large bony bosses at the middle of both bones and complete loss of pronation and supination. Examination under the X-ray screen showed that this was due to cross-union, with much overlapping of the fragments of both bones. On September 30 the site of the fractures was exposed, a wedge including callus was sawn from the radius and the ends were joined by a Lane's four-hole plate: the ulna was divided and plated in the same way.—*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE MEDICAL EDITOR.

COMPLETION OF THE EXAMINER'S REPORT.

ERRORS AND OMISSIONS.—The examiner should review every answer in his report before forwarding the papers to the company so as to assure himself that there are no omissions or incomplete answers. If all necessary information is supplied and errors revised at this time, both the examiner and the company will be spared the trouble and annoyance of further correspondence, and the agent will not incur the danger of losing his business through delay which might have been avoided. It is most important for the agent to receive the policy for delivery as soon as possible after the examination has been made on account of the liability of the applicant to change his mind, or to become influenced by the arguments of busy rivals who are always in the field.

A record of the omissions and incomplete answers for each examiner has been kept at the home office of the writer's company, and it shows that many examiners who are undoubtedly well qualified and competent cause considerable correspondence, trouble, and delay by not properly completing their reports.

ALTERATIONS AND ERASURES.—The medical examiner's report should be free from ditto marks, alterations, interlineations, or erasures; furthermore, it must be kept in mind that a dash does not constitute an answer to a question. An application is an actual legal contract and must be drawn up with the requirements of the law in mind. Corrections are, however, unavoidable at times, and, when demanded, should be made by drawing a line in ink through the words at fault; the correction should then be duly attested by the initials of the examiner with date of the attestation. This procedure is especially important in the blanks of companies operating under the laws of a State which require that photographed copies of applications be attached to the policies.

CONFIDENTIAL INFORMATION.—Whenever an examiner declines or postpones an applicant he should mail a confidential letter to the company *at once*, giving his action and the cause for it. Furthermore, even if he recommends the applicant for insurance, the examiner should inform the company by means of a confidential letter as to anything brought out in the course of the examination which may affect the insurability of the risk, even though the examiner is not certain that this information will prevent the issuance of insurance to the applicant. Many companies supply their medical examiners with blanks and addressed envelopes to be used for this purpose.

This procedure gives the examiner an opportunity to express his private opinion of the real insurable worth of the applicant to the company. It happens, not infrequently, that an examiner is reluctant or even unwilling to incorporate certain information in his report for the reason that it might hurt his own interests or those of a friend or patient if these facts were known in his community. The examiner in such cases may be fearful that the secret would be divulged were it to come to the eyes of the agent or manager in writing. It is the manifest duty of an examiner, however, to give the company the benefit of his knowledge of everything of an adverse nature affecting the risk, and he can do this quietly and without any publicity by means of a confidential letter. The items which render the risk questionable may occur in the family history, in the personal record of diseases or injury, or in the matter of habits or environments.

In order that these letters may prove of value to the company they must be written and mailed immediately after the examination and investigation of the applicant is completed. The information contained in such letters will always be treated by the company as strictly confidential, and the examiner need not, therefore, hesitate to furnish facts of any nature.

Confidential letters are especially important for the reason that the examiner's report is sometimes lost and the company has then no record of the adverse information unless notified by one of these letters. Another reason is that in the case of companies which allow their agents to receive the report from the examiner, some agents will occasionally suppress or destroy an unfavorable report in the hope of getting a more complacent examiner to recommend the risk.

Trauma and Pulmonary Actinomycosis.—Rauth reports a case of actinomycosis of the lungs in which the question of the relationship of the latter with accident came up. The subject was a young locksmith who, while lifting a heavy load, felt a lancinating pain on the left side of the chest. At the same time the latter came in sudden contact with the object lifted—an automobile axle. Thereafter he began to have pains in the back and left side, so that he was soon forced to give up his work. He did not improve and sought the clinic, where he was found to be in high fever, with the heart dilated and a systolic murmur at its base. The fever was apparently due to pleurisy, as a friction murmur became audible. There was diminished resonance over the left upper lobe. The evidence day by day pointed to some process in the latter locality which was not tuberculous. Finally a swelling appeared on the back, to the left of the middle line between the fifth and twelfth dorsal vertebræ. Exploratory puncture led to the diagnosis of actinomycosis. Death occurred seven months after inception of the disease, and autopsy left no doubts as to the correctness of the diagnosis. The pleurisy had disappeared without traces and it became apparent that this lesion had not been due to the fungus. The author assumes that actinomycosis was originally present in the hilus of the lung in a latent state and that the overstrain and concussion—which also caused pleurisy—mobilized the fungus and thereby enabled it to set up active disease in the lung.—*Zeitschrift für Versicherungsmedizin*, July, 1912.

The Selection and Training of the Medical Examiner.—A paper with this title was read before the Medical Section of the American Life Convention, held in Chicago Sept. 8, 1912, by Dr. E. A. Babler, of St. Louis. Dr. Babler thought that the question of selecting and training a local examiner was of such great importance that the convention should have a committee to be known as "The Committee on Examiners," with such duties and powers as would be necessary to secure for the members of the convention the best of service in every locality in which the companies represented at the convention did business.

Book Reviews.

Surgical Clinics of John B. Murphy, M.D., at Mercy Hospital, Chicago. Volume I, Number III. Octavo of 174 pages, illustrated. Published bi-monthly. Price per year: Paper, $8.00; Cloth, $12.00. Philadelphia and London: W. B. Saunders Company, 1912.

The present number is a continuation of the series, and following an account of the cases exhibited on previous occasions, there are clinical discussions of several bone cases, tuberculosis of the intestine, cystic goiter, tumor of the kidney, cholelithiasis, cerebral hemorrhage, and an account of the so-called five diagnostic methods frequently referred to by Dr. Murphy.

Fever-Nursing. Designed for the use of Professional and Other Nurses, and especially as a text-book for Nurses in training. By J. C. Wilson, A.M., M.D. Author of "A Text-book Treatise on the Continued Fevers," and "A Handbook of Medical Diagnosis," etc. Seventh edition, revised and enlarged. Price $1.00. Philadelphia and London: J. B. Lippincott Company.

This little book is too well known to need any extensive notice. The present edition has been revised and brought up to date. The work is thoroughly reliable, and will form a useful addition to the library of every nurse.

Aids to Ophthalmology. By N. Bishop Harman, M.A., M.B. Cantab., F.R.C.S.Eng., Lecturer in Ophthalmology, West London Post-Graduate College; Assistant Ophthalmic Surgeon, West London Hospital; Ophthalmic Surgeon to the Belgrave Hospital for Children; Chief Clinical Assistant, Royal London Ophthalmic Hospital, Moorfields; Oculist, London County Council Blind Schools; Late Examiner in Anatomy, Cambridge University; Lecturer in Anatomy, King's and Caius Colleges, Cambridge; Senior Ophthalmic Assistant, The Middlesex Hospital. With 100 illustrations. Fifth edition. Price $1.00. New York: William Wood and Company, 1912.

We are not surprised to see that this compend has reached a fifth edition. The book has undergone a thorough revision, and is larger than the previous edition by about fifty pages. The chapters on Glaucoma, Optic Neuritis, and Muscle Balance have been amplified; the section on Refraction has been recast; rare diseases are intentionally omitted; and the student will find this volume, as formerly, one of the best of a good series.

Lehrbuch der Krankheiten des Säuglings. Von A. Lesage, Médecin des Hôpitaux in Paris. Übersetzt und mit Anmerkungen versehen von Prof. Dr. Rudolf Fischl in Prag. Price 12 marks. Leipzig: Verlag von Georg Thieme, 1912.

The purpose of this work is the discussion of the diseases of the nursling whose physiological peculiarities are bound up with its delicate constitution, its rapid growth, and its special mode of nourishment. The pathology of the nursling reflects these peculiarities. The first part of this volume deals with the physiology of the normal infant, a knowledge of which is essential to a proper understanding of the diseases affecting it. The author notes that many conditions during infancy that are denominated gastroenteritis are in reality a clinical manifestation of a general morbid derangement, such as septicemia or meningitis, and that the scope of strictly local disorders of the digestive organs has within recent years become narrower and narrower. The author describes the newer conceptions regarding spasmophilia, the disturbance of equilibrium of the bodily temperature, heat stroke, summer diarrhea, scarlatina, scarlatinal albuminuria, the cachexias and the anesthesia of the weaning period, the dermatolymphatic cachexia, the septic infections, cerebrospinal meningitis, tuberculous meningitis, and the care of infants during the first three months of life. The German translator has shown a nice discrimination in choosing this work as a means of introducing French pediatric conceptions to his countrymen and has admirably acquitted the task of editing and supplementing the original. To the English reader this work provides the unusual opportunity of viewing French pediatrics through German eyes.

Die Vasomotorisch-trophischen Neurosen. Eine Monographie, von Dr. R. Cassirer, Privatdozent an der Universitat Berlin. Zweite umgearbeitete und vermehrte Auflage. Mit 24 Abbildungen in Text und 24 Tafeln. Price 30 marks. Berlin: Verlag von S. Karger, 1912.

During the twelve years that have elapsed since the first edition of this work appeared many additions have been made to the subject of the trophic neuroses, which account for the large size of the present edition, which consists of 988 pages of text, together with a series of 24 plates. The titles of the chapters are as follows: Anatomical and physiological introduction; the acroparesthesias and allied conditions; erythromelalgia; Raynaud's disease; chronic acroasphyxia; sclerodermia; acute circumscribed edema, and multiple neurotic cutaneous gangrene. The vast ramifications of the trophic neuroses into the various domains of medicine is seen in the synopsis of the topics discussed in the chapter on acute circumscribed edema. These include rheumatic affections, intoxications, psychical and physical traumata, cutaneous edemas, swellings of the mucous membrane of the upper air passages, gastrointestinal manifestations, urticaria, purpura with transient edema, serum sickness, chronic neuropathic edema, trophedema, etc. The author has presented his subject with characteristic German thoroughness. The extensive bibliography appended to the volume gives only a hint of the vast amount of labor expended by the author in developing his theme. This work will undoubtedly be valued by all neurologists as an important contribution to the literature of the trophic neuroses.

Tuberculin Treatment. By Clive Riviere, M.D. (Lond.), F.R.C.P., Physician East London Hospital for Children, Shadwell; Physician to Out-patients, City of London Hospital for Diseases of the Chest, Victoria Park; and Egbert Morland, M.B. and B.Sc. (Lond.), M.D., Beme, of Arosa Switzerland; Visiting Physician to the English Sanatorium (Villa Gentiana). Price $2.00. London: Henry Frowde, Oxford University Press; Hodder & Houghton, 1912.

The methods of tuberculin treatment have been developed to a greater extent in England than anywhere else. The present manual is the fruit of a ripe experience acquired in the application of the methods by two separate workers who were about to publish individual manuals on the subject when they decided to merge the two books into one. In this manner they have been able to widen the scope of the entire volume, for the personal experience of the writers was in different fields. The text is subdivided into three parts. Part I discusses the general lines of tuberculin administration. It deals with the action of tubercle products in general, the tuberculin reaction, the standard of dosage, the route of administration, the selection of cases, etc. Part II discusses the method of immunization with tolerance (Koch) or the treatment of autotoxic tuberculosis. Part III deals with the method of immunization without tolerance (Wright), or the treatment of localized tuberculosis. The theme of this volume is a complicated one, and one difficult to master, but the authors have succeeded in presenting the subject in a skilful manner. The book is compact and well printed, and suitable as a working manual.

Infant Mortality and Milk Stations. Special report dealing with the problem of reducing infant mortality. Work carried on in ten largest cities of the United States. Together with details of a demonstration by public and private agencies in New York City during 1911 to determine the value of milk station work as a practical means of reducing infant mortality. Edited by Philip Van Ingen, M.D., Member of the New York Milk Committee and Medical Director of the Committee for the Reduction of Infant Mortality, and Paul Emmons Taylor, Secretary of the New York Milk Committee and Director of the Committee for the Reduction of Infant Mortality. Price $1.00. New York: The New York Milk Committee, 1912.

The title page of this volume fully indicates its content and scope. No better brief has ever been prepared in advocacy of the campaign for the prevention of infant mortality. In the first chapter there is stated the problem, and statistics are presented showing the conditions regarding infant mortality that obtain in foreign communities and in the United States. In Chapter II is discussed the campaign against infant mortality in New York City prior to 1911. The next chapter describes this campaign as it was carried out in 1911. Chapter IV shows by means of comparative tables the results of this campaign. There then follows a description of the milk stations of the New York Milk Committee. The titles of the succeeding chapters are as follows: Campaigns in other cities, general conclusions, the extension of relief through milk stations, the establishment and operation of milk and health stations and the extension of milk stations' activities. The book is illustrated with a large number of photogravures of milk stations, charts, circulars, etc.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

FIRST DISTRICT BRANCH.

Sixth Annual Meeting, Held at Poughkeepsie, October 4, 1912.

THE PRESIDENT, DR. DANIEL BAILEY HARDENBERGH OF MIDDLETOWN, IN THE CHAIR.

Amendments to the By-Law.—The following amendments to the by-law, proposed at the meeting held in Yonkers, October 12, 1911, was acted upon and passed: Amend Section 3, Chapter II, by striking out the words "on January 1st of" and substituting the words "at the close of the annual meeting of the Medical Society of the State of New York."

President's Address.—Dr. DANIEL B. HARDENBERGH of Middletown delivered this address (see page 843).

The Owen Bill.—Hon. RICHARD E. CONNELL of Washington, D. C., member of the House of Representatives, said that he had been invited to speak on the measure introduced in the Senate by Hon. Robert L. Owen of Oklahoma, providing for the establishment of a National Health Department, which, in short, was intended to establish a department of government possessing the powers of a board of health—powers in our time so tremendous and so necessary when conditions called for their application. Senator Owen called his measure "A Bill for Race Conservation—A Conservation of Human Life and Efficiency." Briefly epitomized, the bill provided that there should be at the seat of government an establishment, known as the United States Public Health Service, and a director of health, who should be the head thereof. The director should be appointed by the president. As assistants to the director of health, the bill provided for three commissioners of health, two of whom should be skilled sanitarians, and one a skilled statistician, also to be appointed by the President. The one sentence in the bill told the whole purpose of such a department of government. It was in Section III as follows: "That it shall be the duty of the Health Service to collect and disseminate information relating to the public health and to enforce the observance of all regulations and laws of the United States relating to health: Provided, That this act shall not be construed as attempting to authorize the health service to exercise, or attempt to exercise, without express invitation from the chief executive, or other proper authority of the State, any function belonging exclusively to such State, or to enter any premises without consent of the owner or occupant thereof; but the director of health, upon request of the chief executive, or other proper authority, of any State, Territory, the District of Columbia, or any insular possession, may detail for limited periods an officer or officers, employee or employees, from the health service to assist the health authorities of such State, Territory, District, or insular possession, in protecting the health of the people of such jurisdiction."

At the outset the bill had encountered powerful opposition founded on the belief that the purpose of the medical profession which had been urging this department was to favor, by law and the great powers which went with such a bureau, one school of medicine to the exclusion of all others. On this point, Senator Owen, in one of his recent speeches in the Senate, said: "I am entirely opposed to promoting one school of medicine over another school of medicine. My purpose in urging a department of public health has been to establish a department of human conservation, educational rather than regulative, which would deal with the matter from an educational standpoint, so as to make effective and efficient the knowledge which we are slowly acquiring with regard to the preservation of human life." Then, in order to meet the objection which was brought forward by the League of Medical Freedom, the friends of the bill voluntarily presented this amendment by way of emphasizing the sincerity of their purpose: "And provided further: That the health service established by this act shall have no power to regulate the practice of medicine or the practice of healing, or to interfere with the right of a citizen to employ the practitioner of his choice, and all appointments within the health service, including the head of the service, shall be made without discrimination in favor of or against, any school of medicine, or of healing." Such a bureau would not attempt to heal people, or to treat plagues, or fevers, or epidemics, because its mission would be to prevent all these, leading the great power of the government to the saving science of sanitation. Such a bureau would deal with sanitary engineering, sanitary construction of streets, alleys, house-sewage, water-supply, milk-supply, and food-supplies in general. It would have to do with the proper care of markets, the control of insect life, which was so frequently the cause of disease, with the extermination of the house-fly, and with the education of the people through authoritative publications, the schools, and special instructors on the rules of right living. These were but a few of the purposes set forth in the debates in the Senate on the Owen Bill.

The present Congress established a bureau to be devoted to the investigation and remedying of conditions surrounding children and their employment and at its head was placed Miss Julia C. Lathrop, a graduate of Vassar College. This bureau expected to set up standards of cleanliness and to demand that the souls of children should not be stifled in loathsome employments. It was not his purpose to discuss the mission of the League of Medical Freedom, for his confidence in the American people and the spirit of the government was such that he knew an injustice to an honest project had but to be pointed out to be remedied. That humanity had suffered at the hands of the quack, the impostor, and the unscrupulous vender of nostrums and humbug remedies, there could be no doubt. But these were not going to be exterminated by an Act of Congress. They could not save people from the consequences of their own credulity, ignorance, or mistake by an act of the legislature. This much the government could do. It could cultivate among the people an intelligent understanding of health conditions, from the use of the bath to the necessity of pure air. It could point out the consequences to the human race of the violation of the laws of health. It could lend its power to the work of cleanliness in places from which disease might spring if neglected. Mr. Connell closed his paper by paying a tribute to the unselfish patriotism of the medical profession which would, if it could, prevent disease and sickness of all kinds, thus sacrificing its own calling for the good of the human race. What profession ever undertook a more noble work?

Functional Nervous Diseases Due to Eyestrain.—Dr. PETER A. CALLAN of New York read this paper and presented the following conclusions: In all functional neuroses involving the head and torso, the eyes should be carefully examined and in order to do so the ciliary muscle must be fully paralyzed and then the usual tests employed, the ophthalmoscope, shadow test, and lenses, not neglecting the ocular muscles. Correcting lenses should be prescribed and constantly worn and in no other way could the eyes be excluded as causative agents of an existing neurosis. The slighest refractive error, especially astigmatism, should be corrected. He had seen the best results from the weakest cylinders. An ocular error in the weak was capable of originating or keeping up a vicious circle of disturbance that would have no positive effect on the robust. There was no uniformity in symptoms due to eyestrain. They found hyperemia, conjunctival irritation of the eyelids, chalazia, blepharitis, photophobia, twitching of eyelids, etc. Again they met with patients who apparently had eye symptoms, but only suffered from headaches, or were nervous without any apparent cause; others were only troubled when they traveled by train, or were present at a ball game, or in the theater, or influenced by the moving effects of the cinematograph. Patients with high degrees of refractive errors soon learned their ocular limitations, and thereby avoided eyestrain; this was not the case in persons with medium or slight amounts. School children were not infrequently punished or regarded as stupid because of ocular conditions beyond their control.

Progressive Curvature of the Radius (Madelung's Deformity).—Dr. HENRY LING TAYLOR of New York read this paper. (See page 752.)

Dr. A. JACOBI of New York, president of the American Medical Association, thanked the members for their kind and warm reception. When the Medical Society of the State of New York resolved upon an innovation establishing the district societies it did a great deal toward the uplifting of the profession, bringing in contact a number of men who ordinarily did not meet one another. There was added a great influence to the various county societies. There was no more forlorn condition to be noted than that of a doctor living alone, a hermit's life. There was no more forlorn hermit than the doctor who meant to be a doctor day and night. That was one reason why the county societies were doing so much good; the district societies were doing more good; the State societies even more good than the county and district societies. And this was why the American Medical Association comprising 34,000 to 35,000 physicians in the United States gave an unusual advantage not only to the societies but to the in-

dividual members of these societies. Dr. Jacobi said that he was always instructed when he attended county or district societies; at these meetings he always learned something. All who joined these societies had the same advantage he had. This was why he always answered one who asked what he should do after having passed his examination—"Join your county society." He believed that he had every reason to congratulate himself because this district branch had invited him to be present and join in their proceedings. Yet there was much for them to do. In the State of New York there were between 13,000 and 14,000 physicians, while in the State Society there were only about 7,000 members. Of these 7,000 only about 3,450 belonged to the American Medical Association. He asked why were there not more members?

Dr. JOHN CALHOUN OTIS of Poughkeepsie expressed his appreciation of having been nominated and elected the presiding officer for the coming year; he also appreciated the responsibilities of having to preside over the First District Branch. Incidentally he said that no colleges in the world gave better instruction to their students than those in America and no better service was given than in the American hospitals. There was a great field in preventive medicine, particularly in diseases afflicting the kidney, in cancer, etc. In many diseases there was much to be done and it behooved the first district branch to take up a consideration of the diseases about which they knew so little.

Pyloric Stenosis in Infants.—Dr. CHARLES GILMORE KERLEY of New York read this paper. That true pyloric stenosis was a congenital condition was accepted by most authors. There were three types of this disease in infants, the spasmodic, the hypertrophic, and the combined type, Pfaundler noted that the first vomiting, or onset of the disease, was between the fourth and fourteenth days in 50 per cent. of the cases; from the second to the third week in 25 per cent.; and from the third to the sixth week in 25 per cent. According to Ibrahim's investigations of 206 cases there was a rapidly ascending curve in the first month and a reduced frequency with advancing age. According to Ibrahim males were affected about four times as often as females. Pyloric stenosis was one of the diseases upon which a great deal of theorizing had been done. Prominent and among the most universally recognized theories up to 1897 were those of Hirschprung and John Thomson. According to the former there was a congenital defect, a primary pathologically increased quantitative development of the pyloric wall which constricted the lumen, while Thomson contended that the essential lesion was not muscular but primarily a nervous one. There was to date no convincing evidence that the spasm was set up by erroneous finding or by hyperacidity. In hypertrophic stenosis hyperacidity was often the case. During recent years most authorities considered the condition as primarily spasmodic; by some this condition was considered a primary hypertrophy with a secondary spasmodic element added. The findings at post mortem were remarkably uniform. The alimentary canal below the pylorus was perfectly normal. The esophagus was sometimes noticeably dilated, sometimes of normal caliber. The stomach was usually much dilated. Finkelstein reported a case in which the thickening was due to an increase in the longitudinal fibers. The lumen varied in size, sometimes so small as barely to admit a fine probe. The test of functional potency by hydrostatic pressure was fallacious for the redundant folds of mucous membrane might act as valves. Vomiting was usually the only active symptom of the stenosis whether spasmodic or due to stricture. The vomiting had never, in his experience, appeared before the second week except in spasmodic cases in which it appeared at birth, or after the eighth week. The stools were normal and there was no suggestion of gastric disturbance. The vomiting might occur after each feeding but more frequently two or three feedings were retained and then a large amount was ejected. The vomiting was forcible in character. With the vomiting there was an associated constipation, loss in weight, and a voracious appetite. The child did not appear ill except for the wasting and moderate prostration. In all young infants that developed persistent vomiting with constipation or even without this latter symptom, stenosis of the pylorus should be looked for. As to the differential diagnosis between hypertrophic stenosis, pyloric spasm, and the combined type, it might be said that palpable pylorus might be looked upon as a hypertrophic pylorus and a pylorus that showed sufficient thickening to be palpable required operation. In the spasmodic cases there appeared to be vomiting periods. In some instances there would be no vomiting for a day or two. Cases of this type offered the best chance of cure without operation. In the combined type there was moderate hypertrophy and spasm; the stenosis might be intermittent and moderate in degree. It was possible for a considerable quantity of the stomach contents to pass into the intestine, if but small quantities of food were given at one time. The prognosis was dependent largely upon the type of the lesion. The age of the child, and the severe nature of the operation, meant that it would always show considerable mortality. Cases with palpable tumor should be given the advantage of immediate operation. There were comparatively few of the spasmodic pyloric cases without involvement of the muscular structure and in such cases the prognosis was good and all should recover. In the combined cases the prognosis was largely dependent upon the management. In the presence of tumor the treatment should be operation followed by breast milk feeding. Postoperative vomiting rarely caused trouble. Regurgitation might be obviated by bringing the force of gravity into play by placing the head and shoulders of the child on a high pillow. These children needed fluid badly and the Murphy drip should be used after the operation. Twelve hours after operation teaspoonful doses of water or breast milk might be given at one-half hour intervals. Later the amount of nourishment and the method of feeding must be determined in each case. The stomach should be washed out daily with 5 per cent. bicarbonate of soda solution. Where breast milk could not be obtained he had secured the best results by the use of fat-free cow's milk diluted with gruel or evaporated unsweetened condensed milk. The presence of fat and sugar in the stomach caused irritation. Dr. Kerley said he did not look with favor on opium or the bromides, and thought that little could be expected from them. When the vomiting continued and there was progressive loss of weight and strength operation should not be delayed. Rectal medication would be useful for a day or two only and should not be used oftener than twice in twenty-four hours. Local treatment was of little or no value.

A Consideration of Diet in Acute Diseases.—Dr. W. STANTON GLEASON of Newburgh read this paper. He said that the principles of food economics were by no means new and that even in the time of Moses certain laws were in force governing the use as food of the flesh of fish, meat, and fowl. These laws, although religious in character, carried an underlying hygienic truth and value. This early knowledge, although rudimentary, had its influence, but it has been left for this generation to perfect in detail the practical application of the value of foods, as to their quantity, quality and heat-producing elements as applied to the even sustenance of the individual. European investigators were the pioneers in this line. To-day, however, through the work of the United States Department of Agriculture, the Carnegie Nutrition Laboratory, and various educational institutions, they were well in the vanguard of progress. Dr. Gleason reviewed in a brief manner the general question of modern dietetics. He considered typhoid fever as a type in the application of modern diet in acute disease. This disease from its duration and consequent drain upon the body fluids and tissues with the accompanying perversion of the digestive and assimilative processes, imposed a special responsibility in making the proper adjustment of food to meet the varying changes produced by prolonged pyrexia. They had two conditions constantly present in typhoid fever, increased combustion and diminished assimilation. Their adaptation of nourishment must therefore be influenced by the age of the patient, the intensity of the fever, and the condition of the digestive and excretory organs. Each case should be carefully studied and individualized, and the physician should be as solicitous in regard to food requirements as in regard to symptoms. He believed that Coleman's plan of nourishing the patient in typhoid fever represented the modern trend in feeding. It was important to remember that the typhoid fever patient required about 35 calories per kilograms of weight, and in determining the exact amount of nourishment, it was only necessary to know the approximate weight of the individual. From his personal observation, all acute diseases responded well to the caloric standard of food requirements, applying judicious qualifications as the case demanded.

Urgent Surgery in Association with Uterine Fibroids.—Dr. JAMES E. SADLIER of Poughkeepsie read this paper. He reported several cases.

Gallstones.—Dr. PARKER SYMS of New York read this paper. He said that gallstones were of very common occurrence and though they gave rise to a distinct train of symptoms, their importance and significance were scarcely recognized. Gallstones were more common in women than in men. They were rare in youth, belonging particularly to the middle period of life. They seldom exhibited symptoms before the twenty-fifth year. They were always the result of infection, depending upon their formation on a

change in the character of the bile. They were frequently formed around a nucleus which might be merely a mass of thickened bile or a mass of mucus or some epithelium which had been shed during the process of inflammation. The infection might be due to one of a large variety of pathogenic bacteria, or there might occur a mixed infection. As in all infectious lesions of the alimentary tract, the colon bacillus played a very important part. This was also true of the bacillus of typhoid fever. The invasion of the biliary passages took place undoubtedly by one of three different routes: (1) by direct ascent from the duodenum through the common duct; (2) through the lymphatic system; (3) through the portal system, this being the most common. The mechanism of gallstone production was really dependent upon morbid changes in the character of the bile. They were dependent upon an inflammation of the mucous membrane, the result of infection. The very acute cases were not the ones that formed stones; it was the chronic, long-continued inflammation that produced gallstones. They might form in any part of the biliary system, but the majority found their origin in the gall-bladder. In studying the etiology of gallstones one should bear in mind the fact that there was a close association between the liver with the biliary system, the stomach, the intestines, and the pancreas. This was true embryologically, histologically, physiologically, and pathologically. Gallstones might produce infection and inflammation of the biliary tracts; they might produce infection of the liver; adhesions, involving any of the organs in this region, resulting in deformity, obstruction, and impaired function; they might produce pancreatitis or glycosuria, and, last but not least, they were the most potent cause of cancer of the biliary system. In fact gallstones were a pre-cancerous condition. While they were known to be caused by infection and inflammation it was equally true that they tended to provoke further infection and to keep up and produce inflammation. The so-called latent gallstone, doing no harm, did not exist. It produced at least a mild form of inflammation and irritation, and at any time might set up a most violent and destructive inflammatory process. Because of long irritation gallstones frequently caused cancer, and this was particularly true in cases of cancer of the gall-bladder; cancer of the gall-bladder was said to be preceded by gallstones in 95 per cent. of the cases. Gallstones might incite a chronic hepatitis, a form of cirrhosis, and frequently were the cause of a chronic pancreatitis. Infection might be transmitted to the pancreas from the bile-passages, and this was particularly liable to occur when a stone was impacted in the common duct. In the operative treatment of gallstones, pancreatitis as a complication should be borne in mind, for it rendered drainage essential to a complete cure. In discussing the diagnosis Dr. Syms said that it was unfortunate that the clear-cut classic picture of gallstone colic was rare rather than common. There had been a mistaken idea that in the majority of the cases gallstones did not cause symptoms; the fact that the symptoms were so frequently overlooked was owing to indifference on the part of the patients, or to ignorance on the part of their physicians. In the majority of the cases the gallstones were at rest and were not causing active and violent irritation; the gall-bladder and bile-ducts were chronically inflamed The symptoms would be those of a chronic inflammation, mostly those of a chronic dyspepsia, and the patients would have sour eructations, belching of gas, a sense of fullness, and tension after eating. They usually suffered from constipation. These were the cases in which the diagnosis was not easily made; they should be carefully watched. After considering the correlation of certain diseases of the stomach, the biliary tract, and the appendix, Dr. Syms considered the indications for operation. The mere diagnosis of gallstones alone was sufficient to warrant an operation. This opinion was based on the fact that all gallstones were doing more or less harm. If one operated during the early stages one should be able to accomplish the necessary object by means of a simple and a safe procedure and the chance of radical and permanent cure was much greater than it would be if one waited until complications had set in. Nearly all the complications were the result of delay. All things being equal, the death rate in biliary surgery bore a distinct relation to the period of the disease. Cancer resulted from delay because of the prolonged irritation. As all cases of gallstones were dependent upon infection, drainage was of the utmost importance and should be a routine procedure. For this reason the gall-bladder should be preserved unless there was some strong reason for its removal. Drainage should be continued until clear bile was flowing.

The Present Status of Medical Therapeutics.—Dr. Andrew Victor Jova of Newburgh said that to one who had followed the progress of medical science the vast improvements in many of its branches was certainly astonishing; but yet there was much to be desired in others. Modern medicine had been successful in many ways, but it had failed in its principal aim, the cure of disease. Many of our drugs employed relieved symptoms, but very few of them cured. Every ten years the pharmacopœia was revised, and a number of new remedies added to an already superabundant list until its products and preparations were now numbered by the thousands. Yet he asked, with all this array of medicines, how much had been accomplished. How many of the drugs had made good their pretensions of cure? The great majority of them, he believed, appeared to-day and were forgotten to-morrow. After many years of honest and arduous work drug therapy had been a failure, for we were to-day not far from where we began years ago. Materia medica, with its long list of drugs and preparations, had been a disappointment, and the newer remedies clothed in their long scientific names with the unpronounceable array of consonants a greater failure still. It might be argued that even though drugs cured but few diseases, yet they alleviated symptoms, relieved pain, and placed the patient in a more favorable condition for recovery; but we could not deny the fact that much was accomplished almost as well by the old practitioners when they had fewer drugs at their command. When we came to compare the value of the old and the new remedies we would realize how little progress had been made in drug therapy during the last century. The salicylates, opium, quinine, digitalis, iodide of potassium, the bromides, iron, and castor oil had found no successful competitor for their respective uses. We could draw but one conclusion, namely, that our present drug therapy, with few exceptions, had been a failure, and that conservatism in the administration of drugs should be exercised until a more satisfactory method had been found.

D. A. Jacobi of New York was of the opinion that those who refused to use drugs did not do their whole duty toward the profession or to the public; the older he got the more he used remedies. He, therefore, felt inclined to criticise the reader of the paper and hoped that he would mend his ways.

The Relation of Prolonged Pregnancies to Some Cerebral Lesions and the Backward Mental States.—Dr. Henry Lyle Winter of Cornwall said that it had taken him over fifteen years to collect 75 cases in which he could be sure of the duration of gestation, and of these 42 were idiots and 33 imbeciles. Inquiry among medical friends developed the fact that about 5 per cent. of all pregnancies were prolonged beyond the normal limit, but this was undoubtedly a movable percentage and it was, of course, absolutely impossible to even guess at the percentage of prolonged pregnancies which yielded mentally deficient children. In examining the histories of the mentally deficient which had come under his care he found that over 46 per cent. of the idiots, over 25 per cent. of the imbeciles, less than 5 per cent. of the feeble-minded and one-half of 1 per cent. of the backward children presented histories of abnormal births. The percentages he gave were worked out from the histories of 62 idiots, 105 imbeciles, 143 feeble-minded, and 400 backward children. Of the 75 cases in which the duration of pregnancy was reasonably certain 24 (32 per cent.) were instrumental births. Labor was normal in the others. In the 24 cases the cause might or might not have resulted during delivery. Dr. Winter presented a brain which was removed from a case of imbecility, one of the group of 75 presenting definite histories. This birth was normal. There was a cystic degeneration of the cortex where it apparently had its origin superficially. The brain presented was like several others which he had seen in similar cases. In all of the brains he had examined the lesions were over the parietal and occipital cortex. He thought that the figures be presented permitted the assumption that the fetal brain might be injured and probably by the maternal parts. Over-long pregnancies placed the infant brain in jeopardy in two ways through accident before birth and during birth. To avoid both of these dangers he urged the necessity of determining the date of the beginning of pregnancy in every case and the terminating it at term. He suggested that where choice was possible podalic version was less likely to result in an injury to the child's brain than a forceps delivery.

The Old Method of Treatment of Syphilis Versus the New.—Dr. Mihran B. Parounagian of New York read this paper. He said that it was not his purpose to cast any reflection upon salvarsan or to deprecate in a way the

marvels which he had seen it perform; indeed, the greatest skeptics were now convinced of its high efficiency. In his paper he compared the new with the old methods of treatment and presented what he considered the rational treatment of syphilis which was as follows: In the fresh case of syphilis in an adult, after demonstrating the presence of the spirochetes, (1) excision if possible of the primary sore, particularly before the eruptive stage, as this would remove an important focus of spirochetes. If the excision was not practical, inunctions of calomel ointment, 33 per cent., should be applied to the initial sore. (2) Injection (intravenous) of three or four doses of salvarsan, if possible in rapid succession, and then, notwithstanding the absence of clinical symptoms and a possible negative Wassermann reaction, the patient should be subjected to a vigorous course of mercury. For those having the advantages of large clinical and hospital facilities, and who could follow their patients for years, the treatment with salvarsan alone might suffice. But for the general practitioner, who saw his patients in a more transient way, the combination treatment should be employed. That was the patient should be given the chance of cure which salvarsan held out, but he should not be denied the benefits which followed the use of mercury. If for any reason it was incumbent upon the practitioner to choose between two remedies, in the light of the experimental stage of salvarsan at the present day, and in justice to the time-honored remedy, which had survived for four centuries, he believed mercury should be given the choice, at least for the present.

Election of Officers.—*President*, Dr. John Calhoun Otis, Poughkeepsie; *Vice-President*, Dr. Henry Lyle Winter, Cornwall; *Secretary*, Dr. Charles Ellery Denison, New York City; *Treasurer*, Dr. Nathan A. Warren, Yonkers.

Philadelphia Pediatric Society.

At a meeting held October 8 Dr. G. Victor Janvier exhibited "A Girl of Six Years with Diabetes." The patient was an emaciated, pallid child, with excessive appetite and thirst, passing large amounts of urine containing a high percentage of sugar. There was no history of traumatism and no family history of diabetes, and no other etiological factor could be elicited. Owing to the indifference of the mother and the inability to restrain the child treatment had yielded no special result. Dr. Horace J. Williams demonstrated "A Case of Abdominal Tuberculosis." The patient was a girl, between 3 and 4 years old, with a number of nodular masses in the abdomen and also yielding a positive cutaneous reaction to the tuberculin. There were occasional irregular elevations of temperature, and at one time symptoms of intestinal obstruction developed, but subsided after an enema of olive oil. Dr. W. Estell Lee exhibited "A Baby Aged Six Months Operated on for Intussusception Ten Days Ago." The little patient was at first seized with symptoms of intestinal obstruction, associated with discharge of blood and mucus from the bowel, but without the presence of an appreciable abdominal tumor. After two days the symptoms subsided suddenly, and the child appeared well. After a brief interval, however, there was a recurrence of the symptoms, and now a mass could be palpated in the right upper quadrant of the abdomen. The abdomen was opened and an intussusception of the ascending colon found. The abnormal condition was corrected, a retaining suture introduced in the cecum, and the abdominal wall closed. Recovery ensued without complication. Dr. Marina Taylor demonstrated "A Case of Alopecia Areata." The patient was a boy, about six years of age, who had fallen and injured the back of his head, lacerating the scalp. From this point as a center the hair began to fall out and the process continued until the entire scalp was denuded and even the eyebrows had fallen out. Under treatment with electricity and tonics great improvement took place, but at a later date the morbid process renewed its appearance, and under treatment with cantharides, chrysarobin, and other measures there appeared to be promise of restoration of the hair. The disorder was thought to be a trophoneurosis originating from possible injury to nerves in connection with the laceration of the scalp. No other member of the family presented a similar or analogous condition. Dr. John F. Sinclair exhibited "A Case of Enteritis with Interesting Complications." The patient was an infant, five or six weeks old, admitted to the Babies' Hospital with symptoms of ileocolitis. While under observation it developed bronchopneumonia and later cellulitis of the scalp. On quite a number of occasions the temperature fell below the 93° level, but eventually the child recovered, although at times it appeared moribund.

Pathological Society of Philadelphia.

At a stated meeting held October 10 Dr. R. M. Keilty demonstrated a specimen of "Intestinal Intussusception," illustrating an interesting factor in the development of this condition. As had already been pointed out by Dr. Allen J. Smith it was found that both the serous and mucous surfaces of the internal portion of the intussuscepting bowel were thrown into numerous small folds apparently as a resulting contraction of the interlying muscular coat. The appearance suggested that the intussuscepting portion of the bowel played an active part in drawing the intussuscepted portion within the lumen of the bowel. Dr. Kenneth M. Lynch exhibited on behalf of Dr. B. C. Hirst and himself specimens of "Congenital Cystic Kidneys Interfering with Delivery." The lower extremities of the fetus had been torn off in the efforts to effect delivery, and cesarean section was necessary to extract the remainder of the body. The obstruction to labor was found to be due to greatly enlarged cystic kidneys. Dr. Lynch exhibited also specimens of "Cystic Kidneys and Cystic Liver." These were obtained from a man, about 53 years old, who presented a mass in each flank and hypochondrium, made up of fluctuating nodules, and who died of uremia. At one time there had been hematuria, but secretion of urine went on almost to the last. There was some elevation of temperature, with chills. After death, the diagnosis of cystic kidneys was confirmed, and in addition a number of cysts were found in the liver. The gall-bladder contained calculi and the common duct was obstructed by a stone. Multiple abscesses also were present in the liver. Dr. Paul A. Lewis presented a communication entitled "The Bacteriological Examination of Selected Cases of Tuberculosis." He reported the results of a careful bacteriological study of glands removed from the neck of a girl about 20 years old. In section, in culture and in subculture only human tubercle bacilli were found. In a second case, a man formerly engaged as a butcher, and suffering with cough, presented a tubercle on one of his fingers, together with evidences of tuberculosis of the lungs. In this instance bovine tubercle bacilli were found in sections of the tissue from the finger and in cultures, while human tubercle bacilli were found in the sputum and in cultures. Drs. W. H. F. Addison and Leo Loeb presented a communication entitled "Regeneration of the Epithelium in Guinea-pig and Pigeon." They found marked differences between the normal epidemics of these two animals, that of the guinea pig containing more layers of cells, and the cells being larger, containing larger nuclei and exhibiting more mitoses. Precisely similar conditions were observed in the same animals during the process of regeneration in artificially induced wounds. That the conditions noted were inherent in the tissues of the respective animals was shown by the fact that they were present also when portions of epidermis were excised and transplanted to subcutaneous pockets in animals of the same kind. Dr. Karl F. Meyer presented a communication entitled "Hemorrhagic Septicemia of Cattle in Pennsylvania." He reported the results of a study of a number of cases of this disease observed during the past summer, in all of which the specific bipolar bacillus was found as the causative agent. The symptomatology and pathology of the disorder were described by Dr. Crawford.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Pennsylvania State Board of Medical Examiners.

December, 1911.

ANATOMY.

1. Give the external landmarks of the palmar and plantar arches.
2. What is meant by the portal circulation? Describe the same.
3. Describe the male bladder and its relations.
4. Describe the general distribution of the veins of the leg.
5. Describe the spermatic cord, giving its relations to other anatomical structures.
6. Describe the medulla oblongata.
7. Describe the wrist joint.
8. Give the anatomical relations of the axillary artery.
9. Give the external landmarks of the cerebral sinuses.
10. Give the form, position, and relations of the right kidney.

PHYSIOLOGY.

1. State the source of urea. Where is it formed, and what is the amount normally eliminated in 24 hours?
2. Discuss the factors entering into the formation of the first and second sounds of the normal heart.
3. Discuss in detail the physiological functions of the Eustachian tubes.
4. Give the physiology of digestion—(*a*) in the mouth; (*b*) in the stomach.
5. Describe the mechanism of contraction of the pupil

MATERIA MEDICA.

1. Write three prescriptions each containing a drug of the following classes: (*a*) Carminative; (*b*) Diuretic; (*c*) Stimulant.
2. Name the preparations of hyoscyamus and their doses
3. Name a drug obtained from an animal; from an insect.
4. Give the doses of the following: (*a*) Tinctura aconiti radicis; (*b*) Corrosive sublimate; (*c*) Amyl nitrite; (*d*) Silver nitrate.
5. Give the official name of nux vomica; name its preparations, and give the dose of each.

CHEMISTRY.

1. Give a method of conducting a test for the detection of free hydrochloric acid in the stomach.
2. Give a brief description of a test for blood in the feces.
3. Describe a test for arsenic in the tissues.
4. Describe Fehling's test for sugar in the urine and state how you would determine whether the reaction is that of sugar or some other reducing agent.
5. What is cholesterin? Give a test for its presence in urine.

PATHOLOGY.

1. Describe the gross and microscopic appearance of epithelioma of the lip.
2. Describe the pathology of (*a*) a furuncle; (*b*) a carbuncle.
3. Define and describe necrosis of bone.
4. Give the pathological changes which are characteristic of round ulcer of the stomach.
5. Describe the tissue changes in suppurative peritonsillitis (quinsy).

DIAGNOSIS.

1. What systemic diseases can be differentiated by the use of the ophthalmoscope?
2. Diagnose glaucoma from cataract.
3. Diagnose paralysis agitans, differentiating multiple sclerosis and senile tremor.
4. Diagnose progressive pernicious anemia.
5. Differentiate erysipelas, eczema, and tinea circinata.

PRACTICE AND THERAPEUTICS

1. What are the symptoms of aneurysm of the arch of the aorta?
2. Under what circumstances would you perform a lumbar puncture?
3. Describe the method you would follow in using salvarsan in the treatment of tertiary syphilis.
4. What are the symptoms of syphilitic iritis and how would you treat it?
5. Outline the symptoms and treatment of a case of ulcerative stomatitis.
6. What are the symptoms of acute poisoning with corrosive sublimate (bichloride of mercury) and how would you treat it?
7. Outline the management and treatment of a case of diphtheria
8. Name the indications and contraindications in the use of the preparations of opium
9. Outline the treatment of a case of cardiac dropsy.
10. Under what circumstances are the following drugs indicated as cathartics? (*a*) Oleum tiglii (croton oil), (*b*) Oleum ricini (castor oil), (*c*) Hydrargyri chloridum mite (calomel).

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

PENNSYLVANIA STATE BOARD OF MEDICAL EXAMINERS

December, 1911.

ANATOMY.

1. *Palmar arches.* The line of the *superficial palmar arch* crosses the palm in a line with the thumb separated widely from the fingers. The *deep palmar arch* lies in a line half an inch nearer to the wrist than the superficial.

Plantar arteries. The course of the *external plantar artery* corresponds with a line drawn from the hollow behind the inner ankle obliquely across the sole nearly to the base of the fifth metatarsal bone; from thence the artery turns transversely across the foot, lying deeply near the bases of the metatarsal bones, till it inosculates with the dorsal artery of the foot in the first interosseous space. The course of the *internal plantar* corresponds with a line drawn from the inner side of the os calcis to the middle of the great toe. (From Holden's *Landmarks.*)

2. By the *portal circulation* is meant the capillary circulation of venous blood in the liver, between the portal and hepatic veins.

Portal circulation: "The hepatic artery and the portal vein convey blood to the liver. The artery carries arterial blood, and the vein food-laden venous blood from the walls of the alimentary canal, and from the spleen and pancreas. Both vessels enter the liver at the transverse fissure, and they ramify in its interior, breaking up into small terminal branches which run between the lobules and send fine capillary branches into their substance; from these latter branches the blood passes into the capillary tributaries of the intralobular veins, thence to the sublobular veins, and from the sublobular veins to the hepatic veins, which terminate on the posterior surface of the liver in the inferior vena cava." (Bain's *Medical Practice.*)

3. The *male bladder* is a musculo-membranous pouch, situated in the pelvis, behind the pubes and in front of the rectum. It has a superior surface, antero-inferior surface, two lateral surfaces, a base or fundus, and a summit or apex. It is retained in its place by the two anterior ligaments, two lateral ligaments, and the urachus; there are also five false ligaments formed by folds of the peritoneum. Internally, on the floor, is the trigone, between the openings of the two ureters and the urethra. The anterior part of the bladder is uncovered by peritoneum, and is in relation with the triangular ligament, the symphysis pubis, and the pubo-prostatic ligament. Above it is covered with peritoneum and is in relation with the rectum and small intestines. The base is in relation with the rectovesical pouch, vasa deferentia, and seminal vesicles, all of which separate it from the rectum. It is supplied by the superior, middle, and inferior vesical arteries; and the pelvic plexus of the sympathetic, and the third and fourth sacral nerves.

4. The veins of the leg comprise two sets: the superficial and deep. The superficial set is composed of the internal or long saphenous, and the external or short saphenous. The deep set contains the posterior tibial and the anterior tibial.

The *saphenous veins* are formed from the dorsal venous arch. The *internal saphenous* begins at the inner end of this arch, on the inner side of the foot; it passes upward in front of the internal malleolus, then upward and backward with the internal saphenous nerve, behind the internal condyle of the femur, then upward and outward to the inner side of front of thigh, through the saphenous opening, to empty into the femoral vein. The *external saphenous* begins at the outer end of the arch, on the outer side of the foot; it passes upward behind the external malleolus, up along the outer side of the tendo Achillis, with external saphenous nerve, to the popliteal space, where it enters the popliteal vein. The deep veins accompany the arteries; the posterior tibials receive the peroneal veins, and unite with the anterior tibials to form the popliteal.

5. The *spermatic cord* consists of the vas deferens with artery to the vas, spermatic artery, and pampiniform plexus of veins forming spermatic vein above, sympathetic nerves, the cremasteric artery, the genital branch of the genitocrural nerve, lymphatics, together with some areolar tissue; it extends from the internal abdominal ring to the testis, passing in its course along the inguinal canal, from which it emerges by the external abdominal ring, and thence in front of the pubes to the scrotum. The vas deferens is placed at the back of the cord. Its relations are those of the inguinal canal in which it lies. *Behind* Peritoneum, transversalis fascia, conjoined tendon, and triangular fascia. *In front:* Internal oblique, and aponeurosis of external oblique. *Below:* Poupart's ligament and transversalis fascia. *Above:* Internal oblique and transversalis.

6. The *medulla oblongata* is the lowest part of the encephalon, and is continuous below with the spinal cord. It extends from the lower margin of the pons to the lower margin of the foramen magnum. It lies in the basilar groove of the occipital bone; its dorsal surface is between the cerebellar hemispheres. It forms the lower part of the floor of the fourth ventricle. It is about one inch long, half inch wide, and half inch thick. It has anterior and

posterior median fissures, which are continuous with those of the spinal cord.

7. The *wrist-joint* is a condyloid joint, formed by the lower end of the radius and the triangular fibro-cartilage above; and by the scaphoid, semilunar, and cuneiform bones below. It is united by the following ligaments: External lateral, internal lateral, anterior, and posterior; it is lined by a synovial membrane. The joint is capable of flexion, extension, abduction, adduction, and circumduction.

8. Relations of Axillary Artery. *In front:* Skin; fascia; pectoralis major and minor; costo-coracoid membrane; external anterior thoracic, inner head of median and internal cutaneous nerves; cephalic and acromiothoracic veins. *Behind:* First intercostal, serratus magnus, subscapularis, and tendons of latissimus dorsi and teres major muscles; posterior thoracic, internal anterior thoracic, musculospiral, and circumflex nerves, also posterior cord of brachial plexus. *Outer side:* Coracobrachialis; brachial plexus, and median and musculocutaneous nerves. *Inner side:* Axillary vein; ulnar, lesser internal cutaneous, and internal anterior thoracic nerves, and inner cord of brachial plexus.

9. The *superior longitudinal sinus* is marked by a straight line drawn over the top of the scalp from the root of the nose to the external occipital protuberance. The *lateral sinuses*, by a line drawn from the external occipital protuberance to the base of the mastoid process, and thence to the tip of the mastoid process.

10. The *form* is that of a flattened bean. *Position:* It is situated in the back part of the abdomen, near the spinal column, behind the peritoneum, the top being on a level with the twelfth rib, and the lower end on a level with the third lumbar vertebra. *Relations of right kidney: In front*, right lobe of liver, duodenum, hepatic flexure of colon. *Behind*, diaphragm, quadratus lumborum, psoas, last dorsal and iliohypogastric and ilioinguinal nerves, pleura, last intercostal space, and twelfth rib.

PHYSIOLOGY.

1. *Urea* is derived from proteins in the body; it is formed in the liver. About 500 grains is normally eliminated in 24 hours.

2. There are two normal heart sounds which follow in quick succession, and are succeeded by a pause. The first, or systolic, sound is dull and somewhat prolonged; the second, or diastolic, sound is sharper and shorter. The *causes* producing the *first* sound of the heart are not definitely ascertained; the following are supposed to be causatory factors: (1) The vibration and closure of the auriculoventricular valves, (2) the muscular sound produced by the contraction of the ventricles, and (3) the cardiac impulse against the chest wall. The *second* sound is caused by the vibration due to the closure of the semilunar valves.

3. *The functions of the Eustachian tubes:* (1) To maintain equality of atmospheric pressure on each side of the tympanic membrane; (2) to prevent echo, by allowing sound waves to pass from the middle ear; (3) to act as a drainage canal for the middle ear.

4. Digestion. (1) *In the mouth* the food is crushed, mixed with saliva, and reduced to a pulp; a certain amount of starch converted into maltose and rendered slightly alkaline. Fats and proteids are unaltered. (2) *In the stomach*, the contents are rendered acid, conversion of starch into sugar ceases, connective tissue of fats is dissolved and fats are set free. Proteids are dissolved and peptones formed. The albuminous foods are dissolved for the most part, and a grumous mixture of peptones, liquid fats, and starches is formed, which is termed chyme, and is gradually passed through the pylorus into the intestine.

5. "In the changes which take place in the iris, two sets of nerves are involved: (1) Those of the third nerve or oculomotor, and (2) those of sympathetic origin. The third nerve supplies the circular fibers, and consequently section of this nerve paralyzes these fibers, and dilatation of the pupil occurs. When the third nerve is stimulated, the circular fibers contract, causing a diminution in the size of the pupil. The sympathetic supplies the radiating fibers and its section paralyzes those fibers, causing contraction of the pupil, while its stimulation produces dilatation. When light falls upon the retina this portion of the eye is stimulated, and the impression is carried by the optic nerve to the brain, and there motor impulses are generated which are transmitted through the third nerve to the sphincter of the iris, causing it to contract; this is, therefore, a reflex act" (Raymond's *Physiology.*)

MATERIA MEDICA.

1. *(a) Carminative.*

℞. Chloralis, gr. xvj.
Potassii bromidi, gr. xxxij.
Aquæ menthæ piperitæ, ℥ij. M.

Sig: One teaspoonful in warm water every four hours.

(b) Diuretic.

℞. Potassii acetatis.
Potassii bicarbonatis.
Potassii citratis, *aa*, ℥ij.
Aquæ destillatæ, q.s. ad ℥viij. M.

Sig: One tablespoonful in water after each meal.

(c) Stimulant.

℞. Ammonii carbonatis, ℥ijss.
Syrupi acaciæ, ℥jss.
Aqua destillatæ, q.s. ad ℥iij. M.

Sig: One teaspoonful every two hours.

2. Hyoscyamus, 4 grains; Extractum hyoscyami, 1 grain; Fluidextractum hyoscyami, 3 minims; Tinctura hyoscyami, 15 minims; Hyoscinæ hydrobromidum, 1/128 grain; Hyoscyaminæ hydrobromidum, 1/128 grain; Hyoscyaminæ sulphas, 1/128 grain.

3. *Drug obtained from an animal:* Pepsin; *from an insect:* Cantharides.

4. Tinctura aconiti, 10 minims; corrosive sublimate, 1/20 grain; amyl nitrite, 3 minims; silver nitrate, 1/5 grain.

5. Nux vomica. *Official name:* Nux vomica.. The *official preparations and doses* are: Nux vomica, one grain; extract of nux vomica, one-quarter of a grain; fluid extract of nux vomica, one minim; tincture of nux vomica, ten minims; strychnine, one-sixty-fourth of a grain; strychnine sulphate, one sixty-fourth of a grain; strychnine nitrate, one sixty-fourth of a grain.

CHEMISTRY.

1. *Test for free hydrochloric acid in the stomach:* Mix a few drops of the filtered gastric juice and Boas' reagent in a porcelain dish, and slowly evaporate to dryness. A rose red color, which fades on cooling, indicates the presence of free hydrochloric acid. (Boas' reagent consists of 5 parts of sublimed resorcinol and 3 of cane sugar in 100 of alcohol.)

2. *Test for blood in the feces:* "Mix fresh each time the following solution: Benzidine, amount that will stay on small end of penknife. Glacial acetic acid, 2 c.c.; hydrogen peroxide, 1 c.c. *If solid*, mix material to be examined with small amount of water. Put drop on slide and place cover slip over it. Allow few drops benzidine solution to flow around edge. Blue or green color will develop at line of contact in presence of blood. *For liquid.* If opaque, proceed as above; if translucent, place a few c.c. in a conical glass and allow benzidine solution to flow slowly down edge. A blue ring will develop in presence of blood." (Greene's *Medical Diagnosis.*)

3. *Test of arsenic:* Reinsch's test is as follows: To the suspected fluid add a little pure HCl; suspend in the fluid a small strip of bright copper foil, and boil. If a deposit forms on the copper, remove the copper, wash it with pure water, dry on filter paper, but be careful not to rub off the deposit. Coil up the copper, and put it into a clean dry glass tube, open at both ends, and apply heat at the part where the copper is. If arsenic is present there will appear in the cold part of the tube a mirror, which will be found on microscopical examination to consist of octahedral crystals of arsenic trioxide.

4. *Fehling's test:* Place in a test-tube a few c.c. of the liquid prepared as stated below, and boil; no reddish tinge should be observable, even after five minutes' repose. Add the liquid under examination gradually, and boil after each addition. In the presence of sugar a yellow or red precipitate is formed. In the presence of *traces* of glucose only a small amount of precipitate is produced, which adheres to the glass, and is best seen when the blue liquid is poured out.

[The reagent must be kept in two solutions, which are to be mixed immediately before use. Solution I consists of 34.653 gms. of crystallized $CuSO_4$, dissolved in water to 500 c.c; and Solution II of 130 gms. of Rochelle salt dissolved to 500 c.c. in NaHO solution of sp. gr. 1.12. When required for use equal volumes of the two solutions are mixed, and the mixture diluted with four volumes of water.]

If the test with Fehling's solution is positive another sample should be examined by the *fermentation test*, which is absolutely reliable, glucose being practically the only fermentable substance ever found in urine.

5. *Cholesterin* is an unsaturated monatomic alcohol, with the empirical formula $C_{27}H_{45}OH$, but of unknown con-

stitution. It is found chiefly in bile, but also in blood, nerve tissue, brain. The crystals may be found on microscopical examination; heat these on a slide with a drop of sulphuric acid and water, and the edges of the crystals become red.

PATHOLOGY.

1. An *epithelioma of the lip* is of the squamous variety. It is a nodular, wart-like elevation, tending to become ulcerated on the surface. "Histologically there are seen branching columns of epithelial cells extending downward from the papillæ of the skin into the deeper structures. These consist of large translucent squamous cells which show a tendency to arrange themselves in certain places concentrically to form epithelial *perles*. The latter frequently undergo a horny transformation and sometimes even calcareous change. Metastasis is frequently seen in the neighboring lymphatic glands." (Stengel's *Pathology.*)

2. "*Furuncles and carbuncles* result from infection with the *Staphylococcus aureus*, which enters the orifices of the ducts of the skin under the influence of friction and pressure. A *Furuncle* results when the infection is located in a hair follicle or sebaceous gland. A hard, painful, conical swelling develops, to which, so long as the skin retains its normal appearance, the term 'blind boil' is applied. Usually, however, the skin becomes red, and after a time breaks, giving exit to a drop or two of thick pus. After an interval of from six to ten days a soft white slough is discharged; this is known as the 'core,' and consists of the necrosed hair follicle or sebaceous gland. After the separation of the core the boil heals rapidly, leaving a small depressed scar. *Carbuncle* may be looked upon as an aggregation of boils, and is characterized by a densely hard base and a brownish-red discoloration of the skin. A carbuncle is usually about the size of a dollar-piece, but it may continue to enlarge until it attains the size of a dinner plate. As time goes on several points of suppuration appear, and when these burst there are formed a number of openings in the skin, giving it a cribriform appearance; these openings exude pus. The different openings ultimately fuse and a large adherent, grayish-white slough is exposed. The separation of this slough is a tedious process and the patient may become exhausted by pain, discharge, and septic absorption. When the slough is finally thrown off a deep gap is left, which takes a long time to heal." (Thomson and Miles' *Surgery.*)

3. "*Necrosis* refers to the destruction of large portions of bone, as a result of interference with the blood-supply or from the extension of disease from the periosteum or neighboring bone. The dead piece remains as a sequestrum; part having been absorbed, the rest remains in a cavity surrounded by granulation tissue and pus. It acts as a foreign body, and constantly keeps up a suppurative reaction in the adjacent structures. A fistulous opening or cloaca, communicating with the exterior, generally forms, and the pus continues to discharge through it. This may continue for years if the sequestrum is so large that it cannot pass through the opening. When it does escape or become absorbed, healing takes place." (McConnell's *Pathology.*)

4. *Round ulcer* "consists in a rapid localized destruction of the mucosa and submucosa, or sometimes of all the coats, with consequent perforation. It is single or multiple and has its most frequent seat on the posterior wall or on the lesser curvature near the pyloric end. The edges of the ulcer, which is nearly circular, are well defined as though punched out, and funnel-shaped, the wide orifice being at the mucosa. The size of the ulcer varies from 0.5 to 6 or 7 cm., but if perforation occurs the hole is generally quite small, not larger than a goose-quill. A patch of fibrinous lymph usually forms on the serous surface opposite the ulcer, which is thus often attached to neighboring structures, and so perforation is prevented, or if this event happen extravasation is limited. The ulcer in course of time heals, becoming permanently attached to a neighboring viscus, usually the liver, and its base covered with cicatricial tissue, but it is questionable whether the epithelium is regenerated over the area." (Hewlett's *Pathology.*)

5. There is a tonsillitis, in which the "tonsils are swollen and hyperemic, and there is abundant secretion of mucopus. The inflammation mainly affects the crypts, which become greatly swollen and filled with foul purulent material. From here the inflammation may extend into the substance of the organ leading to tonsillar abscess, and, as an after-result of the follicular disturbance, the contents of the crypts may become inspissated, cheesy, and intensely foul smelling; still later they may become the seat of calcareous deposits, forming concrements. Where there is abscess formation the process may infiltrate through the deeper tissue extending into the cellular tissue around about, with much inflammatory edema, setting up the condition known as quinsy, or it may be peritonsillar abscess." (Adami and McCrae's *Pathology.*)

DIAGNOSIS.

1. The *ophthalmoscope* may be of aid in diagnosing: Brain tumors, abscess of the brain, anemia of the brain, cerebral aneurysm, tabes dorsalis, multiple sclerosis, exophthalmic goiter, nephritis, diabetes, hypertrophy of the left ventricle of the heart, fatty degeneration of the heart, syphilis, alcoholic or tobacco poisoning.

2. *Glaucoma* is a diseased condition of the eye, produced by increased intraocular pressure and resulting in excavation and atrophy of the optic disc, and blindness. It is due to increase of the contents of the eye, hypersecretion, retention, old age, gout, rheumatism, nephritis. *Symptoms:* Visual disturbances, increased ocular tension, hazy and anesthetic cornea, sluggish and dilated pupil, shallow anterior chamber, ciliary neuralgia, cupping of optic disc, blindness.

Cataract is an opacity of the lens on its capsule, and is characterized by diminished acuteness of vision, the patient "sees spots" which occupy a fixed position in the field, diplopia, myopia; there are no inflammatory symptoms.

3. *Paralysis agitans* is diagnosed by the muscular rigidity, the slowness of movement, the characteristic festinating gait, expressionless face, and coarse vibratory tremor. *Multiple sclerosis* shows increased reflexes and intention tremor. *Senile tremor* usually attacks the head first, and the rigidity and facies of paralysis agitans are absent.

4. *Progressive pernicious anemia* is diagnosed by the great reduction in the number of the red corpuscles, the relatively high hemoglobin percentage, diminished leucocytes; every abnormality of the red cells may be present, such as poikilocytes, macrocytes, microcytes, and nucleated red cells (normoblasts and megaloblasts).

5.

ERYSIPELAS.	ECZEMA ERYTHEMATOSUM.
1. Sudden onset with chill and marked constitutional symptoms.	1. No constitutional symptoms.
2. Eruptions sharply marginated.	2. Fades into surrounding skin.
3. Glazed, shining surface; great edema.	3. Dull, scaly surface; slight infiltration.
4. Color, violaceous.	4. Color, bright or dull red.
5. Burning pain.	5. Itching more marked.
6. Occurrence of discrete vesicles or blebs.	6. Vesicles occur in patches if at all.
7. Progressive peripheral spreading.	7. Spreading irregular.
8. Runs an acute course.	8. Runs a chronic course.
9. Contagious.	9. Not contagious.

TINEA CIRCINATA.	ECZEMA SQUAMOSUM.
1. Contagious.	1. Noncontagious.
2. Patches circular.	2. Patches irregular.
3. Patches marginated.	3. Patches ill defined.
4. Patches ring-shaped; clear in center.	4. Patches not clear in center.
5. Eruption proceeds with uniform peripheral extension and central healing.	5. Irregular extension and healing.
6. Trichophyton fungus in scales.	6. Scales free from fungus.

(From *Cyclopedia of Medicine and Surgery.*)

PRACTICE AND THERAPEUTICS.

1. *Symptoms of aneurysm of the arch of the aorta.* "The onset is usually gradual, with evidences of arteriosclerosis and failing health. Pain, which may be paroxysmal or continuous, is a constant symptom. Dyspnea is also common and may be constant with acute exacerbations, or may be remittent. Occasionally dysphagia occurs. A slight cough from pressure on the recurrent laryngeal nerve, with more or less alterations in the voice, may be present. The pupils are dilated or contracted, or are irregular in some cases, due to pressure on the sympathetic nerve. There are disorders of the circulation, a gradual loss of flesh, and a careworn expression of the face." (Hughes' *Practice of Medicine.*)

2. *Lumbar puncture* may be performed for anesthesia, for diagnosis, and for treatment. It is used to diminish intracranial pressure as in tuberculous meningitis; in

uremic convulsions; to differentiate between epidemic cerebrospinal meningitis and anterior poliomyelitis; to administer antitetanic or antimeningococcic serum.

3. The method of giving salvarsan intravenously is thus described by Hirsch: "Two graduated glass containers of 250 c.c. capacity are used. Into one is poured 150 to 200 c.c. of sterile salvarsan solution. The other is filled with a like volume of sterile saline solution (made with sterile distilled water and chemically pure sodium chloride). The saline solution is allowed to flow out of the needle so as to expel all air from the tube. The stop-cock is now reversed, allowing the salvarsan solution to flow out of the needle, thereby expelling all air from its tubing. The stop-cock is now reversed to its former position until the saline solution is running in a slow, even stream from the needle. The desired site of puncture is selected on the arm or at the elbow, and the needle is gently pushed or thrust through the skin into the vein. Meanwhile the saline solution is continuously running from it. The needle is held at about an angle of 10 to 15 degrees to the skin surface, depending on the prominence and caliber of the vein. Care must be exercised not to push the needle through both walls of the vein. This can be avoided by not introducing too long a surface of the needle into the tissues. The patient's arm having been carefully cleansed, a ligature in the form of an ordinary soft rubber catheter or tubing is tied around the middle of the arm, above the selected site of puncture, and the patient is requested to tighten the fist so as to make the superficial veins more prominent. Some prefer to expose the vein in all cases. As soon as the needle has entered the vein the rubber ligature is released by an assistant, the stop-cock of the needle is reversed, and the salvarsan solution flows through the needle into the vein. Hence there is no danger of any salvarsan solution getting into the subcutaneous tissues. The intravenous injection must be given slowly, not less than ten minutes being spent in the process; and the solution must be quite warm when poured into the container so as to allow for its cooling when flowing into the apparatus; when it enters the vein the solution should be about the temperature of the blood. An ideal intravenous injection is painless."

4. Syphilitic iritis. The *symptoms* are intense pain in the forehead and face, lacrymation, photophobia, dimness of vision, pericorneal injection, loss of luster of the iris, and hazy, distorted, and immobile pupil. The course of the disease is from two to four weeks. Synechias often result.

Treatment: Atropine, dionine, the application of leeches to the temples, hot fomentations, absolute rest in bed, protection from the light, light diet, purgatives, abstinence from alcohol, avoidance of all use of the eyes for near work, constitutional treatment for the syphilis, and paracentesis, and iridectomy.

5. Ulcerative stomatitis. The *symptoms* include slight constitutional disturbances, reddened and swollen gums, pain and salivation, acrid, irritating, and offensive saliva, foul breath, hemorrhages from the mucous membrane on pressure, etc. The *treatment* should first be directed toward the diet and hygiene of the patient. Salicylate of soda, borax, or hydrogen dioxide may be used in mouth washes. Potassium chlorate should be administered internally (gr. 10-20 in 24 hours to child 1 year of age) and also should be used locally. (Pocket *Cyclopedia.*)

6. *Symptoms* of poisoning by corrosive sublimate are: A burning pain in the mouth, pharynx, and stomach; the mouth and tongue are white; the vomitus is white, with shreds of mucous membrane, and tinged with blood; there may be bloody stools, also salivation. *Treatment:* The antidote is white of egg, but too much must not be given at one time; this should be followed by an emetic.

7. In *diphtheria* the patient must be isolated for at least three weeks after the throat is free from bacteria or till discharge from mouth or throat has ceased. At the earliest period antitoxin must be used; dosage is about 2,000 to 8,000 units; strict antiseptic precautions must be observed. The throat and nasal fossæ may be irrigated with antiseptic solutions. Symptoms are treated as they arise; tonics are needed.

8. Opium. *Therapeutic uses:* As an anodyne, a hemostatic, in inflammations, as an expectorant, in diarrhea, in manias and diabetes, as an antispasmodic, in insomnia, as a diaphoretic, in many respiratory affections, and to prevent or lessen shock. *Contraindications:* In young children, also in excessive bronchial secretion in old people, in cerebral congestion, and in the second stage of lobar pneumonia.

9. *Cardiac dropsy* is treated by purgatives, stimulants, diuretics, diaphoretics, puncture or incision of the skin and connective tissues. Infusion of digitalis and caffeine, calomel, and squill are of service.

10. *Oleum tiglii* is used when prompt evacuation of the bowel is required; in intestinal obstruction from accumulated feces, and lead colic, and in apoplexy. *Oleum ricini* is indicated whenever a laxative is required; in dyspepsia, in constipation, for children, at the beginning of almost any disease. *Hydrargyri chloridum mite* is used in diarrhea, bilious attacks, hepatic congestion or cirrhosis.

(*To be concluded.*)

Books Received.

The Medical Record *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

Pathology of the Eye. By P. H. Adams, M.A., M.B., D.O. (Oxon.), F.R.C.S. 194 pages, with 43 illustrations; flexible cloth; price $1.50. Oxford University Press, Publishers, New York.

X-Ray Diagnosis and Treatment. By W. J. S. Bythell, B.A. (Cantab.), M.D. (Vict.), and A. E. Barclay, M.D. (Cantab.), M.R.C.S., L.R.C.P. 147 pages, with 118 illustrations; cloth; price $5.50. Oxford University Press, Publishers, New York.

The Pituitary Body and Its Disorders. By Harvey Cushing, M.D. 341 pages, with 319 illustrations; cloth; price $4.00. J. B. Lippincott Company, Publishers, Philadelphia, Pa.

Ueber Sauglingsernaehrung. By Dr. Ernst Schloss. 231 pages; paper; price 6 M. S. Karger, Publisher, Berlin.

The Pituitary Body and Its Disorders. By Harvey Cushing, M.D. 341 pages, with 319 illustrations. J. B. Lippincott Company, Publishers, Philadelphia.

Fresh Air and How to Use It. By Thomas Spees Carrington, M.D. 250 pages, with 150 illustrations; cloth; price $1.00. Published by the National Association for the Study and Prevention of Tuberculosis.

Medical, Surgical, and Obstetrical Report of the Emerson Hospital. 91 pages; paper. Published by the Emerson Hospital, Forest Hills, Boston.

Leitfaden der Praktischen Kriegschirurgie. By DeW. von Oettingen. 377 pages; price 9.50 M.; paper. Theodor Steinkopff, Publisher, Dresden, Germany.

Pharmacology and Therapeutics. By Horio C. Wood, Jr., M.D., 420 pages; cloth; price $4.00. J. B. Lippincott Company, Philadelphia, Pa.

Practical Anatomy. By John C. Heisler, M.D. 789 pages, 366 illustrations; cloth; price $4.50. J. B. Lippincott Company, Publishers, Philadelphia, Pa.

The Healthy Baby. By Roger H. Dennett, M.D. 235 pages; cloth; price $1.00 net. The Macmillan Company, Publishers, New York.

The Practical Medicine Series—Vol. III. The Eye, Ear, Nose, and Throat. Edited by Casey A. Wood, C.M., M.D., C.C.L., Albert H. Andrews, M.D., and Gustavus P. Head, M.D. 358 pages; illustrated; cloth; price $1.25. The Year Book Publishers, Chicago, Ill., Publishers.

Studies in Cancer and Allied Subjects.—Vol. II. Pathology. Conducted under the George Crocker Special Research Fund at Columbia University. 267 pages; illustrated; cloth. Columbia University Press, Publishers, New York.

Tuberculin Treatment. By Clive Riviere, M.D., F.R.C.P., and Egbert Morland, M.B., B.Sc., M.D. 277 pages; paper; price, $2.00. Oxford University Press, Publishers, New York.

Gonococcal Infections. By Major C. E. Pollock and Major L. W. Harrison. 222 pages; paper; price $2.00. Oxford University Press, Publishers, New York.

Kidney Diseases. By W. P. Herringham, M.D., F.R.C.P., and Herbert Williamson, M.D., F.R.C.P. 378 pages; illustrated; cloth; price $5.50. Oxford University Press, Publishers, New York.

Infant Mortality and Milk Stations. Edited by Philip Van Ingen and Paul Emmons Taylor. 176 pages; illustrated; paper; price $1.00. The New York Milk Committee, Publishers.

Bibliographische Monatsschrift. Internationale Zeitschraft für die Gesammte Literatur der Medizin. Vol. I. By H. Albert Hellmers. 108 pages; paper; price for 12 numbers 36 M. Rettig & Kollmorgen, Publishers, Hamburg.

Miscellany.

Cooperation Between Medical Men and Midwives.—In spite of the opinions of those idealists who believe that only skilled obstetricians should be permitted to manage a case of labor, there will be, at any rate for a long time to come, a demand for the trained and intelligent midwife. The masterly address of Dr. Jacobi at the last meeting of the American Medical Association brought out the important fact that the midwives serve faithfully a large proportion of child-bearing women. G. Ernest Herman, of London, in his book on "Difficult Labor," even advocates the cooperation between medical men and midwivese. He says: "Many women cannot afford the fee which a busy doctor requires for conducting the birth of a child, and they therefore engage midwives. The usual relation between midwife and doctor has been that the case was left entirely to the midwife until the patient asked for help of the doctor; and sometimes the midwife did not find out that there was anything wrong until the patient's state had become dangerous. Then sometimes the doctor arrived too late to save the patient. This was not using either midwife or doctor to the best advantage. The better course would be that the patient at the first indication of labor or on the day on which delivery is expected, should send for or go to the doctor. He should then examine the patient, ascertain the position of the child, measure the pelvis (unless previous deliveries have proved it to be normal), estimate the size of the child in relation to the pelvis, and see that the vagina and vulva are healthy. If everything is normal he can then leave the case to the midwife. She can watch the progress of labor, tie the cord, and press out the placenta, as well as the doctor. If there are any special features in the case he can instruct the midwife about them. If the case is so abnormal that operative delivery is plainly called for, the early discovery of the need for operation will enable it to be done in the best possible circumstances." The following narrative indicates the important place which the midwife filled at a time when it was considered almost a crime for a male physician to act the part of accoucheur.

An Old Midwife's Tale.—W. H. Allport presents an interesting account of Louise Bourgeois, the celebrated midwife at the court of Henry IV and Marie de Medici. The daughter of a middle-class family, the *sage femme jurée*, was born in the Faubourg St. Germaine, near Paris, in 1563. She married a barber surgeon named Martin Boursier, who was intimately associated with Ambrose Paré. Through the influence of the latter and because of her many personal and professional excellencies, Louise, at the age of thirty-six, was called to Fontainebleau to attend Marie de Medici. How she presided at the birth of a dauphin—the first for eighty years and the future King Louis XIII, who first saw the light at Fontainebleau, September 27, 1601, she describes in her own naive and archaic style:

"The night of the 26th of September, at midnight, the king sent for me to come to the queen, who was feeling ill. I was sleeping in the queen's dressing-room, where were also the ladies-in-waiting. These ladies, often finding me asleep, had previously played jokes on me by giving false alarms, and in such a manner that I thought this was one of the same. I heard myself called by some one named Pierrot, who did not give me time to fasten my clothes—he hurried me so! Entering the bed-chamber of the queen, the king asked me—'Is this the midwife?' 'Somebody said to him—'Yes'—and he said to me—'Come, come, midwife, my wife is ill—look and see if it is really her confinement—she is in great pain.' Having examined, I assured him that such was the case. At the same moment the king said to the queen—'My dear, do you remember what I have said to you a good many times about the necessity of having the princes of the blood at your accouchement (to prevent substitution)—I beg of you to permit it—it is for the future greatness of you and your child'—to which the queen replied that she had always resolved to do whatever would please him. 'I know well, my dear, that you wish to do all that I desire, but I know your nature, which is timid and embarrassed, so that I fear if you do not make a great resolution, seeing them may prevent your confinement. That is why I beg of you not to be shocked, because it is according to the custom which always takes place at the first confinement of queens.' The pains pressed the queen, and at each pain the king embraced her, and asked me if it was time to send for the princes, reiterating that I must warn him in time, as it was an affair of the greatest importance that they should be there. I told him I would not fail to do so when it was time.

"About an hour after midnight, the king, overcome with impatience, seeing the queen suffer, and thinking that she would give birth to the child and the princes would not have time to get there, sent to seek for them. They were Messieurs the princes de Conti, de Soissons, and de Montpensier. The king said, waiting for them: 'If ever any one has never seen three princes in deep trouble, one will soon see them now. These are three princes very full of pity and good nature, who, seeing my wife in labor, would give most of their possessions to be far away from here.' All three came before the two hours, and were there about half an hour. The king, having learned from me that the delivery was not very near, told them to hold themselves in readiness until he called. M. de la Riviere, first physician of the king; M. de Laurens, first of the queen; M. Herouard, also physician of the king, with M. Guillemeau, surgeon of the king, were called to see the queen, and also retired nearby. In the meanwhile the great bedroom of Fontainebleau, which is near the king's bedroom, was prepared for the confinement of the queen. In it there was a great bed of crimson red velvet, ornamented with gold, near the bed of accouchement. There were also two pavilions, large and small, attached to the floor. The large pavilion was stretched and fastened like a tent by its four corners with cords; it was of beautiful Holland linen, about twenty ells square. In the middle of the large tent there was a little one of the same linen, and under this was put the bed of accouchement. Here the queen was put to bed on coming out of her bedchamber. The ladies whom the king had desired especially called to the accouchement of the queen were summoned. There were carried under the pavilion a chair, some folding seats, and some stools for the king, madame his sister, and Madame de Nemours, to sit in. The obstetrical chair was also brought in; it was covered with crimson velvet. About 4 o'clock in the morning a great colic mingling itself among the travail of the queen gave

her terrible pain without helping her along. From time to time the king made one of the doctors come to see the queen and speak to me so that I might know what was taking place. The colic made the queen suffer more than the travail, and even kept her from it. The doctors asked me, 'If this were a woman and you were alone with the case what would you do?' I proposed to them some remedies, which they ordered at once from the apothecary, who proffered to them others in the Italian style, which he said in similar cases had done much good. There were also two old and wise Italian maiden ladies with the queen, who had assisted at the birth of many children and had attended many accouchements in their own country. The queen, to show her friendship for them, had wanted them at her confinement to serve her as lady's maids. The relics of Madame Sainte Marguerite were on the table in the bedroom, and two holy men from Saint-Germain-des-Prez prayed God without ceasing. The king said he did not wish any one to give any advice excepting the doctors, and that we should agree together, so that I can say I never saw anywhere such tranquillity and peaceful spirit because of the good order which the king brought there, and the assurances which the queen gave him.

"To combat the insupportable colic, it was necessary to use a great many remedies. The queen's sickness lasted twenty-two and one-fourth hours, and her courage was an admirable thing. She discerned clearly the first pains as well as those last ones when the terrible colic came. During all the time she was in travail the king never left her once, excepting when he went out for something to eat; then he sent constantly for news from her, and madame, his sister, did the same. When the remedies had driven away the colic and the queen's real labor commenced I saw that she restrained her cries. I begged of her not to suppress them for fear her throat would swell. The king said to her: 'My dear, do what your midwife tells you—cry, that your throat may not swell.' She desired to be confined in her chair, and being seated, the princes who were beneath the large pavilion sat face to face with her. I was on a little seat before the queen. I placed M. le Dauphin in his linen wrappings, so that no one knew, excepting myself, what sex the child was. I wrapped him up well—this I understood was what I had to do. The king came near to me. I looked closely at the face of the child and saw he looked very feeble because of the great pain which he had endured. I asked for some wine from M. de Lozeray, one of the first valets de chambre of the king. He brought a bottle—I asked him for a teaspoon—the king took the bottle, which he held. I said to him, 'Sire, if it was any other child I would put the wine in my mouth and give it to him that way, because of his great feebleness.' The king put the bottle against my mouth and said 'do to it as you would to another.' I filled my mouth with the wine and thus gave it to the child. At that instant he was conscious and tasted the wine which I had given him.

"The king then went over to impress the princes with the weakness of the queen, then opened the bedrooom door and invited in all the people that were out in the antechamber and the grand cabinet. I believe there were 200 persons, so that one could not move through the room to carry the queen to her bed. I was infinitely angry at seeing this. I said there was no reason for everyone coming in here; that the queen was not yet through with her confinement. The king heard me and tapped me on the shoulder and said, 'Keep still, keep still, midwife—don't be angry—this child belongs to the whole world, and everyone must rejoice over him.' It was half past 10 o'clock at night, Thursday, the 27th of September, 1601, day of Saint Cosme and Saint Damien, nine months and fourteen days after the marriage of the queen.

"The valets de la chambre of the king and queen were called. They carried the obstetrical chair near the bed and the queen was then moved. Something was administered to her for her weakness, and having given her the service which was necessary, I took charge of M. le Dauphin, whom Madame de Montglas gave back to me. M. Herouard commenced then to wait on the child. He bade me wash it entirely in wine and water, and to look it all over before I bandaged it. The king brought up the princes and several noblemen to see it; all those belonging to the household of the king and queen saw the child, and then made places for others. Everyone was so glad they could scarcely express themselves. They all embraced each other without regard to who they were; they were so transported with joy they did not know what they did. I was told that through the entire town all night there were bonfires and the noise of trumpets and drums. Casks of wine were broken open, to be drunk to the health of the king and queen and the dauphin, and the messengers were sent out post-haste to all foreign countries to carry the news, and through all the provinces and towns of France.

"The twenty-ninth of this same month I went to see M. le Dauphin; the page, Biri, opened the door for me. I saw the room full: the king, madame his sister, the princes and the princesses were there, because they were just going to baptize M. le Dauphin. I was about to retire, but the king saw me and said, 'Come in, come in, you need never stay out.' He then said to Madame and the princes: 'I have seen many persons, but I never have seen any so resolute, be it man or woman, in war or elsewhere, as is this woman here; she held my son in her lap and looked at the whole world with those eyes as cold as if she held nothing at all—instead of a dauphin, and it has been eighty years since one was born in France!' I replied to this, 'I have said to your majesty, Sire, that it was necessary for the health of the queen.' 'That is true,' said the king, 'and I did not tell it to my wife until it was all over, so that the joy would not upset her. Never a woman did better than you did; if you had done any different, my wife would have died. Hereafter, I shall always call you *Ma Résolue!*'

"The king did me the honor to ask if I wished to be the nurse of M. le Dauphin, and that I could have the same wages as the wet nurse. I begged his majesty to allow me to continue my profession, so that I would always be more capable of serving the queen, and so that he would always have near her an honest woman who understood her well. I remained near the queen to serve her in her bed one month, then eight days afterward, awaiting the return of his majesty from Paris, who had asked me to wait for him."—*American Journal of Obstetrics and Diseases of Women and Children*, May, 1912.

The Physician's Attitude of Compliance.—Benjamin Rush, in an address to students, once said that the physician should not oppose unnecessarily the simple whims and prescriptions of his patients. He should yield to them in matters of little consequence, but should at all times maintain an inflexible attitude over them in matters that are essential to life.

AN OPERATION FOR EXTREME CASES OF PROCIDENTIA, WITH RECTOCELE AND CYSTOCELE

BASED ON ANATOMICAL, PHYSIOLOGICAL, AND DYNAMIC PRINCIPLES, WITH REPORT OF CASES.*

BY J. RIDDLE GOFFE, M.D.,

NEW YORK.

PROFESSOR OF GYNECOLOGY AT THE NEW YORK POLYCLINIC AND DARTMOUTH COLLEGE MEDICAL SCHOOL; ATTENDING SURGEON TO THE WOMAN'S HOSPITAL; ATTENDING GYNECOLOGIST TO THE POLYCLINIC HOSPITAL; CONSULTING GYNECOLOGIST, N. Y. CITY HOSPITAL; MT. VERNON HOSPITAL; ST. JOSEPH'S HOSPITAL, YONKERS, AND THE LAWRENCE HOSPITAL, BRONXVILLE.

No more interesting subject nor one more heavily fraught with promise of far-reaching and most beneficial results has attracted the attention of abdominal and pelvic surgeons during recent years than the dynamics of the closed cavities of the body. Through these investigations we are beginning to get some light on the causes of ptoses and methods of cure. A knowledge of the cause, the etiology, of pathologic conditions is the first step in the solution of the problem. This holds throughout the whole realm of medicine and surgery, but nowhere does it apply more conspicuously than in the treatment and cure of organic displacements.

Immediately there looms up before us the subject of intra-abdominal pressure, and therein has lurked a great mystery.

The laws of hydrostatic pressure have been accepted by some as the key to the problem, and upon these laws have been constructed complete and elaborate theories which, at first blush, seem to be quite convincing. In the elaboration of the details of intraabdominal pressure, however, they fail to answer satisfactorily many important questions, and we are driven to the conclusion that fluids, either in equilibrium or under active pressure, do not tell the whole story. Careful investigation reveals many reasons for this. In studying this subject we must take into consideration the following facts: (1) The abdominal and pelvic cavities, whether considered individually or as one continuous chamber, have both elastic and inelastic walls; (2) that the interior conformation is most irregular and made up of reflecting planes of pressure at various and varying angles to each other; (3) that within these cavities are many organs of various shapes and density which transmit and reflect pressure with varying degrees of facility and speed; (4) that some of these identical organs at successive and alternating periods contain solids, liquids, and gases; (5) that these tissues are all vital tissues acting under physiological laws.

The dynamics, therefore, of the abdominal cavities are not restricted to hydraulics, and we must follow the ramifications of pressure when applied upon any part of the surface of the cavities guided by the laws of reflection and deflection, of transmission through vital tissue, and all constantly modified by psychological action.

Without dwelling upon pressure as relating to the abdominal cavity, our interest is more directly concerned in this discussion with conditions in the pelvis. In this cavity the application of pressure is psychologically directed toward expulsion of the contents either of the uterus, the bladder, or the bowel. Here is where we have the most striking illustration of the importance of deflecting planes in directing expulsive force into the axis of the pelvic outlet. This mechanism of deflection and the importance of understanding the action of the deflecting planes is pronouncedly exemplified in the corkscrew progress of the fetal head through the various straits of the pelvis. In this the bony planes play the most conspicuous part. In the evacuation of the bowels, however, we have the intraabdominal pressure coming down into the pelvis, which, to accomplish its desired result, must likewise be deflected into the axis of the pelvic outlet. Under these circumstances the resultant of these forces which finally determines their ultimate effect, and which we must follow if we wish to determine their action, exerts itself most directly upon the posterior face of the uterus and its broad ligaments. This plane of tissue is thereby forced down to a lower level in the pelvis until its progress is interrupted by the resistance of its ligaments, more especially the cardinal ligaments, and in extreme instances by the crest of the perineum. At this stage the longer arm of the uterine lever (*i. e.* fundus) is arrested by this resistance, while the posterior freepole of the uterus (*i. e.* the cervix) is forced further down, thus tilting up the fundus, thereby deflecting the pressure backward and downward upon the rectum in the axis of the outlet. As Sturmdorf says: "Were this pressure to continue without deflection, this upward tilt of the anterior arm of the uterus must continue, and, extending beyond the perpendicular, would retrovert the uterus and force its long axis into line with that of the vaginal outlet." The uterus in this position would fall into the direct axis of the expulsive planes, where it is subjected to such irresistible pressure that the ligaments give way and prolapsus uteri ensues, with its accompanying complications of rectocele and cystocele.

To my mind the importance of this deflecting plane of tissue represented by the uterus and its broad ligaments, in deflecting intraabdominal pressure, cannot be overestimated. It is undoubtedly true that the ligaments of the uterus would be incapable of resisting normal intraabdominal pressure were it continuously applied in the direction in which it first impinges upon it. By the resilience of its ligaments and their muscular contractions

* Read at the meeting of the American Gynecological Society, Baltimore, May 28, 1912.

this force is deflected and the uterus when relieved of this pressure is elevated to its normal topographical position by the ureterosacral and round ligaments. "It is a gross misconception of function," says Sturmdorf, "to attribute visceral support to textural strength of ligament or muscle; the muscle or ligament is not created that can permanently withstand the continuous force of intraabdominal pressure. These muscular and ligamentous elements serve to support the pelvic contents not by virtue of their *textural resistance* to displacement but by *deflecting* the displacing force of intraabdominal pressure." *

The failure of procedures for displacements of the uterus which involve fixation of that organ to the abdominal wall tends to confirm this principle and is a pertinent demonstration of the fallacy of substituting artificial for normal physiological support. The normal physiological support of the uterus resides in its ligaments. They are, therefore, the proper tissue to utilize in any operation for the restoration of the uterus to its normal position and physiologic function as a deflecting plane.

In determining the kind of operation that shall be employed for the relief of procidentia and its accompanying lesions, it is the universal custom to divide all cases into two classes, namely, cases in which the patients are in the child-bearing period, and those which are at or have passed the menopause.

In my operation the underlying motive is to restore not only anatomical structures, but also physiological function. In the first class of cases, after attending to any minor lesions, the uterus is restored to its normal position by shortening the round ligaments through the vagina, and in extreme cases the utero sacrals as well. This is done with the prominent idea in view of reconstructing the normal anatomical arrangement, and thereby re-establish the important function of the uterus and broad ligaments as a deflecting plane of intraabdominal pressure.

In dealing with the cystocele, the effort has been made to observe with scrupulous care also the anatomy function, and topographical position of the bladder. Kelly has graphically described the physiologic action of the bladder and its function of receiving and discharging the urine. Incidentally he speaks of the anatomic fixation of the trigone. I cannot give a clearer picture of this process than by quoting Kelly's own words: "As the bladder empties, the upper, more movable portion, covered with peritoneum, settles down into the lower and relatively more fixed portion, which lies in close relation to the vagina until it comes to lie within it as one saucer rests in another. During respiration the free upper half may be seen (through the cystoscope) moving on the lower half, as if hinged, and the line of demarcation between them may be distinctly made out. At the edges where the two saucers meet, three folds are formed—the right, left, and posterior. The posterior fold stretches from side to side in front of the uterus; it is gently convex forward, following the contour of the uterus and ends in front of each broad ligament, where each lateral fold begins and extends horizontally around toward the urethra. These folds represent the physiological hinges on which the bladder moves in expanding and collapsing. The apices, where the posterior fold joins the lateral folds in front of the broad ligaments, are called the right and left vesical cornua."

My operation restores with accuracy this anatomic arrangement. The trigone of the bladder is spread out and made fast to the anterior face of the uterus and broad ligaments, by carrying the base of the bladder up and stitching it at three points; one stitch at each cornu, and one in the median line at the center of the anterior face of the uterus. The utrovesical peritoneal fold is restored as well as the hinges on which the dome of the bladder moves in its function of receiving and discharging the urine. I take it that nature is not working without a purpose in giving fixation to the trigone. This gives a fixed point of exit for the urine and a rigid canal in the passage of the ureters through the wall of the bladder.

In the restoration of the floor of the pelvis I use the method of distinct isolation of the levator ani muscles and stitch them together with buried sutures. It is my conviction that this is the surest and most effective way to restore proper function to the floor of the pelvis. The muscles are thereby freed from cicatricial attachments which distort and limit their function and seems to make a new clean sheath for themselves in which they contract and slide easily and normally. I got my inspiration for adopting this procedure through an article by Dr. Arnold Sturmdorf of New York (MEDICAL RECORD, April 1, 1905), and which is the fullest and most satisfactory explanation that I have ever read on intraabdominal pressure, and the physiological action of deflecting planes of tissue both as retention and expulsive planes.

In the second class of cases, that is, in patients at, near, or beyond the menopause, my effort has been, and I think successfully, to retain as nearly as possible all these physiological functions following the plan as already described. Unless there is positive objection on the part of the patient the uterus is removed per vaginum. In order to restore the deflecting plant of tissue the broad ligaments are stitched together across the pelvis from the infundibulo pelvic and round ligaments down to cardinal ligaments. In this procedure a plane of tissue is restored in exactly the same situation and under control of the same ligaments as under normal conditions. This deflects from its posterior surface back into the pelvic outlet, the intraabdominal pressure, and thus physiologically takes place of the original structures. On its anterior face it also affords a surface on which to spread out and fix the trigone of the bladder, restoring its hinges and all its physiological functions. The floor of the pelvis is restored in the usual manner.

Occasionally there is such an extreme prolapse of the rectum that something more than the restoration of the levator ani muscle becomes necessary. In these cases I have obtained most satisfactory results by stripping the vaginal mucous membrane off from the anterior wall of the rectum, from the line of the peritoneal covering down to the fourchette and then plicating the wall of the rectum with buried catgut sutures. The sutures are passed up and down in the direction of its longitudinal axis; sometimes one line of sutures will suffice, but in ultra conditions two and even three lines of suture running across the rectum have been necessary to comfortably take in all the slack. These sutures, of course, do not enter the lumen of the gut.

In estimating the indications and the value of this operation many things must be taken into con-

* MEDICAL RECORD, April 1, 1905.

sideration. (1) The permanency of results; (2) the age of the patient, with reference to shock; (3) the character of the convalescence, whether stormy or smooth and comfortable; (4) the restoration of physiological functions.

For the purpose of this investigation I have written letters during the last month to forty-six patients. This list included all those upon whom I had performed this operation previous to two years ago, and whose addresses I have. Owing to the removal of the Polyclinic Hospital to its new quarters, and the confusion attending it, I was unable to secure access to the records there. I regret this exceedingly, for I have quite a series of cases in which this operation was done, and whose histories are there.

Of the 29 patients who reported, 24 came to the office for examination, the balance reported by letter. Of the 24 who presented themselves for examination there was not one that showed the slightest tendency to recurrence, and all gave most favorable reports of improvement not only in their local condition but in their general health. Of five who reported by letter, all gave most favorable accounts of the benefit received, with one exception. She wrote as follows: "My operation was not a success; my bladder dropped the last of May. I was operated on in December. I am going out dressmaking and I am very comfortable at present." This was a poorly nourished widow, aged fifty-seven years, who was suffering from an extreme procidentia and an irritating kraurosis vulvæ. To relieve this she was subjected, at the same sitting, to circumcision of the pudendum. I wrote at once to her family physician asking him to call and make an examination, but to date have received no response.

I cannot tell you how gratified I have been by these tested results. Some of the cases are of seven years' standing, others of four, and three, and the balance of over two years' standing. Two of the patients who came to my office had each borne a child two years after the operation. Both had normal labors, and in neither one was there the slightest lesion of any kind. All the different procedures in the operation had held perfectly.

In regard to the bladder, three who had had annoying incontinence previous to operation reported a cure; five reported slight irritability of the bladder, lasting from three to five months after the operation, but not present since.

In making my examinations I tested in all instances the contracting power of the levator ani muscles. It was most interesting, and I must say somewhat surprising to me to discover these muscles responded readily and powerfully under voluntary control.

In reference to the age of the patients, although my previous experience had demonstrated to me that elderly women bore vaginal operations surprisingly well, I was not prepared for such sturdy resistance as the elderly women exhibited in this somewhat exteme operation. Among my cases are 11 patients between fifty and sixty years of age, 4 between sixty and seventy, and 1 at the rare old age of seventy-five years at the time of operation. In not one of them was there sufficient reaction to demand any departure from the regular routine after-treatment. The old lady of seventy-five years is now seventy-nine years of age, and last week walked across the city from Tenth Avenue to my office, fully a mile, on the hottest day we have had this year. When I asked her how she felt she replied, "You have made a new woman of me." Another patient, aged sixty-three years, replied, "I feel as good as new."

Convalescence is surprisingly smooth. In not a single case has infection occurred. Catheterization, as a rule, is not continued beyond the second day. If prolonged, I have the patient out of bed and on the commode by the fifth day.

In response to the question regarding the action of the bowels, all expressed gratification at the ease with which defecation was accomplished. While much of this can be attributed to the restoration of the levator ani muscles, I am inclined to attribute no small part of it to the deflecting power of the broad ligaments.

I have been greatly interested in the reports of Dr. Osgood, the cystoscopist at the Woman's Hospital. He has kindly interested himself during the last year in cystoscoping the bladders of all patients subjected to this operation, both before and after operation. He reports complete restoration of normal conditions in the interior of the bladder. The mouths of the ureters are in normal position and relation and the interureteral ridge is readily distinguished and followed from side to side. As none of these cases come into this report on account of the time limit, I shall hope to report at some future time the result of this feature of the investigation.

I have had a somewhat unique experience in three cases. They were patients who had hysterectomies done two, three, and four years previously, one of them a case of my own, in which, however, I did not apply my procedure of stitching together the broad ligaments. In all of them there was marked rectocele and cystocele. In these three cases I had the satisfaction of opening the head of the vagina through the original scar, picking up the broad ligaments, stitching them together across the pelvis, and then utilizing them as a plane upon which to spread out the bladder. These operations have all been done within the last six months, and so do not fall within the time limit prescribed for the report of cases at this time. In all these cases I was able to secure the infundibulo pelvic ligament and cardinal ligaments, and in two of them the round ligaments as well. In the third case the round ligaments had retracted so far that I was unable to recognize them. In this case there were many resisting cobweb adhesions to deal with in all directions.

In all operations upon the human subject it must be borne in mind that we are dealing with vitalized tissue. And the nearer the operation comes to restoring each and every physiologic function is the measure of success in reaching for the ideal. It is not sufficient to say that the result accomplishes a reasonable purpose as long as something more perfect is within our grasp. In the language of one of our distinguished colleagues, Dr. Polk: "The basis of our art being in reality science, and this branch of science dealing with life and its efficiency as developed chiefly in the human race, the sacredness of our trust compels at our hands the highest conceptions and the most skillful execution of such conceptions that human effort is capable of."

The detailed report of cases follows:

Mrs. G., Elmira, N. Y., aged thirty-four years; married twelve years, four children. Previous operation for trachelorrhaphy and perineorrhaphy, both operations failures. Diagnosis: procidentia of second degree; rectocele and cystocele; umbilical hernia; hemorrhoids. Operation January 30, 1905. All lesions repaired; Goffe operation for cystocele. Last seen, 1907. Result: cure.

Mrs. W., Mt. Vernon, N. Y., aged forty-six years; married twenty-five years; four children; last child six years ago; since birth of last child, menses excessive and too frequent. Diagnosis: large retroflexed uterus; large diseased cervix; lacerated perineum; marked cystocele and rectocele. Operation, March 10, 1905. Dilatation of cervix, curettage; amputation of cervix; interposition of fundus; perineorrhaphy. Result: convalescence uneventful; she gradually recovered strength and nerve, but complained of constant discomfort in the pelvis; uterus failed to involute; sensitive on pressure; slight leucorhea. Operation, February 15, 1906. Abdominal hysterectomy; bladder stitched to broad ligaments; health restored. Last seen May 20, 1912. Has not had such good health since marriage as since the operation. Examination: satisfactory. Levator works well.

Mrs. W., New York City, aged thirty-eight years; married seventeen years; seven children. Diagnosis: lacerated perineum; extensive cystocele and rectocele. Operation, December 19, 1906. Goffe operation for cystocele. Last seen May 23, 1912. "No more drag." Examination: uterus in normal position; everything satisfactory; levators stong under voluntary control.

Mrs. D., Mt. Vernon, N. Y., aged fifty-one years; married twenty-one years; three children; menopause one year; lacerated cervix and perineum; rectocele and cystocele. Operation, February 13, 1907. Hysterectomy; Goffe operation for cystocele. Last seen May 17, 1912. No unpleasant symptoms. Examination: satisfactory. Result: perfect.

Mrs. D., New York City, aged thirty-six years; married seventeen years; eight children. Diagnosis: complete rupture of perineum through sphincter; cystocele. Operation, March 12, 1907. Anterior colpotomy; perineorrhaphy. Last seen May 20, 1912. Had baby January, 1909; had postpartum hemorrhage and nearly lost her life; has slight leakage of the rectum occasionally. Examination: uterus and bladder satisfactory; levator strong; sphincter not quite tight enough.

Mrs. P., New York City, aged forty-eight years; married twenty-seven years; five children. Diagnosis: no control of bladder; extensive cystocele; lacerated perineum. Operation, July 1, 1907. Goffe operation for cystocele; uterus retained. Last seen May 18, 1912. Reports she has perfect control. Examination: perfect result.

Mrs. C., Mount Vernon, N. Y., aged fifty-seven years; married thirty-nine years; three children. Diagnosis; prolapsus; lacerated cervix and perineum; rectocele and cystocele. Operation, October 7, 1907. All lesions repaired. Goffe operation for cystocele; uterus retained. Last heard from in letters from daughter; report all satisfactory until time of death, December, 1911, from Bright's disease.

Mrs. S., Long Branch, N. J., aged fifty years; married twenty years; one child; menopause at thirty-five years. Diagnosis: procidentia, rectocele, and cystocele. Operation, October, 1907. Last seen May 14, 1912. Satisfactory, except slight hernia of bladder through vaginal sheath; upper end of vagina fast to broad ligaments; vagina proper length; perineum satisfactory; symptoms of return of bearing down feeling.

Mrs. W., New York City, aged forty-four years; married twenty-four years; four children. Diagnosis: lacerated perineum; rectocele. Operation, November 4, 1907. Plastic urethra; perineorrhaphy. Died March, 1908, from Bright's disease of kidney.

Mrs. C., White Plains, N. Y., aged fifty-seven years; married thirty-six years; four children. Menopause nine years ago. Diagnosis: prolapsus uteri; cystocele. Operation, December 20, 1907. Hysterectomy; Goffe's improved operation. Circumcision of pudendæ for kraurosis vulvæ. Result by letter, May 15, 1912. "My operation was not a success; my bladder dropped the last of May. I was operated on in December."

1908.—Mrs. M., Chester, N. Y., aged sixty-two years; married forty-two years; eight children. Diagnosis: procidentia; rectocele and cystocele; local relief perfect. Hysterectomy; Goffe operation; caruncle destroyed by actual cautery. Last heard from by letter from Pasadena, Cal., May 20, 1912: "Never was an operation more successful, and I see no reason why it should not remain permanent."

Mrs. P., New York City, aged thirty-three years; married twelve years; three children. Diagnosis: lacerated perineum and cervix; prolapsus uteri; rectocele and cystocele. Operation, January 15, 1908. All lesions repaired; Goffe operation for cystocele; uterus retained. Last seen May 15, 1912. Had a baby two years after operation weighing eleven pounds at birth; all parts in perfect condition, not even a nick in the perineum; surprisingly good in every particular.

Mrs. B., Mt. Vernon, N. Y., aged thirty-seven years; married thirteen years; three children. Diagnosis: complete procidentia; rectocele and cystocele; lacerated cervix and perineum. Operation, January 29, 1908. All lesions repaired; Goffe operation for cystocele; uterus retained. Last seen May 18, 1912. Reports great improvement in general health and local relief perfect. "Rolls sixteen pound ball down bowling alley every Tuesday night." Examination, result perfect.

Mrs. D., Bronx, aged fifty-one years; married; four children. Diagnosis: procidentia; cystocele. Operation, March 10, 1908. Writes, May 19, 1912: "Your operation made a new woman of me—a great success."

Mrs. Y., Glenridge, N. J., aged thirty-four years; married; one child stillborn ten years ago. Seven years ago applied for relief of prolapsus; had only escaped with her life after terrible forceps case three years previously; was told she could never be delivered. After measurements I reassured her and advised repair and try again. Operation: trachelorrhaphy; shortening of round ligaments vaginally and colporrhaphy; she conceived, and four years ago I delivered her of living child with high forceps; extensive laceration of cervix; immediate repair. Diagnosis: procidentia complete; rectocele and cystocele. Operation, April, 1908. Hysterectomy; Goffe operation for cystocele. Last seen May, 1910, satisfactory. Letter from Evanston, Ill., May 20, 1912: "I am glad to speak for the wonderful effect of your operation. I have been perfectly well ever since."

1909.—Mrs. Van V., Brooklyn, N. Y., aged seventy-five years; married. Diagnosis: procidentia, rectocele and cystocele. Operation, February 13, 1909. Hysterectomy; Goffe operation for cystocele. Last seen May 24, 1912. Result: "You made a new woman of me." Examination: nothing better to be desired.

Mrs. H., Brooklyn, N. Y., aged sixty-three years;

married forty-six years; two children. Diagnosis: extreme procidentia; rectocele and cystocele. Operation, February, 1909. Hysterectomy; Goffe operation for cystocele and rectocele. Last seen October, 1911: "Entirely relieved." Examination entirely satisfactory.

Mrs. B., New York City, aged fifty-seven years; married thirty-four years; fourteen children. Diagnosis: complete procidentia uteri. Operation, March 20, 1909. Vaginal hysterectomy; plastic for cystocele and rectocele; perineorrhaphy, Goffe method. Returned to hospital February 3, 1910. Diagnosis: rectocele; Goffe operation for rectocele; plication. Last seen December, 1912, satisfactory.

Mrs. S., New York City, aged forty-eight years; married; four children. Diagnosis: procidentia uteri, cystocele. Operation, April 21, 1909. Plastic for cystocele; perineorrhaphy; Goffe operation. Last seen May 20, 1912. Says she feels all right. Examination: large, stout woman; runs lunch counter and works in garden. Result: satisfactory; levator works perfectly.

Mrs. W., New York City, aged fifty years; married thirty-two years; two children. Diagnosis: procidentia; rectocele and cystocele. Operation, May 10, 1909. Hysterectomy; all lesions repaired; Goffe operation for cystocele. Last seen May, 1912. Result: perfect; health restored.

Mrs. R., Mt. Vernon, N. Y., aged sixty-three years; married thirty-five years; three children. Diagnosis: procidentia; cystocele and rectocele. Operation, June 5, 1909. All lesions repaired; hysterectomy. Last seen May 16, 1912. Result: perfect. "Feels as good as new."

Mrs. C., New York City, aged fifty-three years; married thirty-three years; two children. Diagnosis: procidentia rectocele, and cystocele. Operation, October 19, 1909. Hysterectomy; Goffe operation for cystocele. Last seen May 23, 1912. Result: "Entirely relieved." Examination: satisfactory; levators strong and under voluntary control. Satisfactory in every particular.

Mrs. F., Newburg, N. Y., aged thirty-two years; married six years; one child. Diagnosis: cystocele and rectocele; relaxed urethra. Operation, December, 1909. Goffe operation for cystocele; uterus retained. Last seen May 20, 1912. Feels all right; has slight leakage from urethra on exertion, but usually under good control.

1910.—Mrs. R., New York City, aged forty-nine years; married; six children. Diagnosis: procidentia, rectocele, and cystocele. Operation, February 16, 1910. Vaginal hysterectomy; perineorrhaphy; Goffe operation for cystocele. Last seen May 20, 1912. Has frequent micturition, otherwise satisfactory. Nothing to be desired.

Mrs. W., New York City, aged fifty-one years; married; nine children. Diagnosis: rectocele and cystocele following vaginal hysterectomy three years ago. Operation, March 10, 1910. Colpotomy; picked up the broad ligaments, stitched them together, and completed Goffe operation for cystocele; rectal wall plicated and perineorrhaphy, stitching separately the levators. Last heard from May 21, 1912, by letter: "Operation a decided success."

Mrs. C., New York City, aged thirty-nine years; married seven years; one child. One year ago had operation in Cleveland, Ohio, for falling of the womb, which at that time came outside the vulva. Diagnosis: recurrent cystocele; erosion of cervix, uterus in normal position, and well restored perineum. Operation, March 15, 1910. Goffe operation for cystocele; uterus retained. Last seen May 18, 1912. Result: satisfactory.

Mrs. D., New York City, aged thirty-four years; married fifteen years; four children. Diagnosis: lacerated cervix and perineum; retroversion; rectocele and cystocele. Operation, October 14, 1910. All lesions repaired; round ligaments shortened; Goffe operation for cystocele; uterus retained. Last seen May 20, 1912. Menstruates from rectum clots. Examination: nothing to be desired.

Mrs. G., New York City, aged thirty-six years; married twelve years; three children. Diagnosis: procidentia; rectocele, and cystocele. Operation, November 4, 1910. All lesions repaired; Goffe operation for cystocele. Last seen May 12, 1912. Result: satisfactory; uterus in good position; also bladder and perineum.

616 Madison Avenue.

SOME PRACTICAL POINTS IN THE INTERPRETATION AND MANAGEMENT OF HIGH BLOOD PRESSURE.

By EDWARD E. CORNWALL, M.D.,

BROOKLYN, N. Y.

ATTENDING PHYSICIAN TO THE WILLIAMSBURGH AND NORWEGIAN HOSPITALS; CONSULTING PHYSICIAN TO THE BETHANY HOSPITAL.

In order to know what constitutes high blood pressure we must first know what is the normal blood pressure. That is not as easy as might be supposed, for the normal blood pressure varies considerably at different ages and in different conditions of life and activity, and these variations as observed in apparent health are often so great as to require differentiation from disease symptoms. In fact, the interpretation of blood pressure findings calls for the exercise of a highly cultivated clinical judgment. But it is necessary to have some general statement for a guide, and the following will serve that purpose, with due reservation for exceptions.

We can omit consideration of the blood pressure in infants and children, because variations in their blood pressure rarely have serious significance. In young adults the normal systolic blood pressure ordinarily ranges between 110 and 130 mm. Hg. A large proportion of young adults show a pressure of 120 to 125 mm. Hg. In people of middle age the pressure is usually about ten points higher than in young adults, and in elderly people it may be twenty or thirty points higher. In young and middle-aged adults a pressure of 140 mm. Hg is often found without seeming to indicate disease; and elderly people who appear perfectly well sometimes show a pressure no higher than that of middle-aged adults, though failure to show increased pressure with advancing age is often an indication of myocardial degeneration.

The disatolic pressure in most healthy adults is usually 25 to 45 mm. Hg. lower than the systolic. In conditions of myocardial weakness and simple hypertrophy of the heart the difference may be greater. In aortic incompetence the difference may be as much as 100 mm. Hg., and in chronic nephritis with high tension it is often 60 to 80 mm. Hg. or more. In most cases of high tension the diastolic pressure does not rise *pari passu* with the systolic.

We distinguish between transient and persistent high blood pressure. The former is produced by any sudden and extraordinary demand made on the circulation and passes away with the cessation of the demand, and does not necessarily possess pathological significance. It is persistent hypertension,

that is, elevation of the blood pressure which lasts for a considerable time, to which pathological interest attaches and to which discussion is confined in this paper.

The general causes of persistent hypertension are these: Long continued functional abuse of the circulatory apparatus, mechanical obstruction of the circulation, toxemia, and neurotic states. These causes frequently coexist and cooperate and even produce each other.

Functional abuse of the circulation is brought about by physical and mental overwork, excitement, worry, and overeating. If a man lives a strenuous or a dissipated life, he compels his circulation for long periods to maintain an intra-articular pressure considerably higher than his arteries were meant to sustain. If troubles come on him and he worries about them, the worry keeps up an abnormally high arterial tension. If while leading a strenuous or a dissipated or a worried life, he eats too much or eats food which overtaxes his antitoxic or eliminative organs, whose efficiency has already been impaired by the disturbance of the circulation, a further demand is made for high arterial tension, and another factor, toxemia, is admitted. Overeating habitually indulged in can be a primary cause of hypertension, and after it has produced insufficiency of the protective and eliminative organs, it brings in the toxemic factor.

Hypertension resulting from functional abuse of the circulatory apparatus invites structural changes in that apparatus, viz., cardiac hypertrophy, myocardial degeneration, arteriosclerosis, and chronic nephritis. It may, however, continue for a considerable time before these changes develop to a serious extent; and it is during this premonitory or incipient stage of cardiovascular disease that treatment can be most effective.

Mechanical obstruction of the circulation is produced by arteriosclerosis, cirrhosis of the kidneys and other organs, and pressure of outside masses on the arteries. Arteriosclerosis may exhibit a pure obstruction, though sooner or later nephritis complicates the picture. As a result of mechanical obstruction anywhere in the system of tubes, permanently increased blood pressure is required to maintain adequate circulation through the tissues, and stiffening and deformity of arteries whose distribution is limited to a small region of the body may compel this increased pressure. For example, a rigid and thickened coronary artery causes increase of the general blood pressure in order to provide nourishment for the muscle of the heart, which requires to be fed first so that it can serve the rest of the body. Similarly, cerebral, renal, or splanchnic arteriosclerosis, in order to supply local requirements, compels general hypertension. The general response of the blood pressure to localized arteriosclerosis varies much with the importance of the anatomical region in which the circulation is impeded. When the obstruction of the arteries threatens a vital region with starvation, high blood pressure comes quickly to the rescue, but when the thickened arteries supply tissues of only secondary importance, the increase in blood pressure may be comparatively small.

Chronic nephritis, particularly chronic interstitial nephritis, is generally considered second only to arteriosclerosis as a cause of persistent high blood pressure. It may compel high blood pressure by the obstruction to the circulation in the hardened kidneys, but a large, possibly the major part of the increased tension is undoubtedly due to retained toxins.

Compression of the brain by a clot of blood or other mass regularly raises the blood pressure, and it may do so to a very high point. I have seen a pressure of over 300 mm. Hg. accompany an attack of cerebral apoplexy. Abdominal tumors and distention of the abdomen by gas or fluid sometimes cause hypertension by pressure on the arteries.

Toxemias cause high blood pressure directly, and perhaps indirectly also, by the demand which they make for increased elimination. Of the toxemias, the most extensively operative in these directions is probably chronic putrefaction toxemia of intestinal origin.

The putrefaction toxins when present in the blood in relatively excessive quantity seem to be powerful exciters of high blood pressure, and it is possible that they are also directly effective in producing degenerative changes in the walls of the arteries as well as in the tissues of the kidneys and liver. The proposition that putrefaction toxins directly raise the blood pressure has received positive support from recent experiments by Dale, who found that a rise of pressure from 110 to 260 mm. Hg. followed intravenous injection of parahydroxyphenylethylamine, a substance chemically somewhat similar to adrenalin, which Beyer isolated from putrid meat. Some toxins also lower blood pressure, and putrefaction toxemia is often observed without hypertension.

The toxemia of pregnancy, which seems to be a mixed toxemia, due chiefly to renal and hepatic insufficiency, is usually attended by considerable hypertension; less frequently the rise of blood pressure is only moderate; occasionally the blood pressure is low.

Alcohol produces, as an immediate effect, lowering of the blood pressure, but continued use of it may bring about degenerative changes in the heart, arteries, and liver. It is highly probable that it regularly disturbs the liver functions, and by so doing lessens the ability of that organ to protect the body from the putrefaction and other toxins which are brought to it by the portal vein; and in that way it may indirectly raise the blood pressure. The relationship which alcohol seems to bear to putrefaction toxemia through its effect on the liver, throws a new light on the symptoms and pathology of alcoholism.

Tobacco regularly raises the blood pressure, and in a healthy young man a single cigar may cause a rise of 15 or 20 mm. Hg.; but in habitual smokers, young, middle-aged, and old, I have seen excessive use of tobacco cause a slow, low tension pulse, which became normal after abstention from the drug for a few days.

Coffee directly raises the blood pressure, and if taken to excess may put the cardiovascular system in an irritable state which manifests itself by prolonged high tension; but the more common effects of coffee seem to be functional disturbances of the heart, which, however, if long continued, may produce cardiac hypertrophy and its consequences. It is possible that coffee, like alcohol, may increase putrefaction toxemia through its disturbing effect on the liver.

Some neurotic states cause hypertension. This has been observed in epilepsy during the attacks, though after the paroxysm the pressure regularly falls. In melancholia there is usually hypertension, but not in mania. In neurasthenia the blood pressure may be high or low.

Valvular diseases *per se* do not cause high tension, with the exception of aortic incompetence, in which condition the systolic pressure is regularly high, though it is usually counterbalanced by an abnormally low diastolic pressure. In any case of valvular disease there are changes, particularly in the kidneys and liver, which may bring about high tension and a vicious circle.

The subjective symptoms of high blood pressure are often slight and not at all distinctive. The most frequently observed of these symptoms are a feeling of weakness, inability to do the ordinary amount of physical and mental work, more or less shortness of breath on exertion, headaches, dizziness, loss of appetite; sometimes cardiac unrest is a prominent symptom; the closing of the aortic valves may be distinctly audible to the patient, especially when lying with his right ear on a pillow, but this symptom may be entirely unnoticed, and it may be present without much hypertension. Symptoms of cardiac overaction manifest after going to bed are common, and the patient may be awakened by a violently beating heart; but these symptoms may be due to myocarditis or indigestion. Cramps in the muscles of the legs are frequent and occur usually in cases with arteriosclerosis or nephritis. Localized pains and peculiar feelings in the head and head noises are often complained of by patients with high blood pressure, but it is difficult to say in any case how much they are due to the high pressure and how much to arteriosclerosis.

In making the diagnosis in any case showing persistent high blood pressure, we should first try to find out to what extent disease of the arteries and kidneys exists. Such organic disease may be present without giving frank signs. If nephritis is present repeated examinations of the urine will usually reveal albumin or casts, or at least some insufficiency of the kidneys. The estimation of the urea excretion in the twenty-four hour specimen of the urine is the most important single urinary test that can be made in this condition. Of particular value in determining to what extent arterial or renal lesions exist in cases showing high blood pressure, is the rapidity and extent of the improvement that takes place under appropriate treatment.

The state of the myocardium may complicate the picture. Chronic myocarditis is usually accompanied by conditions which naturally cause hypertension; but we often find a relatively low blood pressure with such conditions; and in such cases we justly suspect the myocardium of being the seat of more than moderate degenerative changes. Myocardial failure is regularly a terminal occurrence in any case of high tension due to chronic nephritis or arteriosclerosis, and a fall in the pressure in these advanced cases is always an ominous sign.

High blood pressure is essentially a conservative process, and may be absolutely necessary for the proper performance of the vital functions, and should therefore not be lowered without due consideration of the physiological necessities of the case. In fact, *high blood pressure, except in certain conditions where its continuance threatens accidents to the cardiovascular apparatus, should be reduced only by removing as far as possible the cause.* I wish to emphasize this statement, not only because it epitomizes the treatment of this symptom, but because of the warning it conveys against the indiscriminate use of arteriodilators in conditions of high blood pressure, which is so common in present medical practice as to require this warning.

Among the removable factors which enter into the etiology of high blood pressure there is one which is present in nearly every case in greater or less degree. I refer to chronic putrefaction toxemia of intestinal origin. In many cases this toxemia is the principal factor, and its removal is sufficient to lower the blood pressure greatly and to bring about a marked change for the better in the clinical picture and the prognosis. Even in cases with considerable arteriosclerosis or nephritis, removal of this factor usually relieves the situation. It can be removed to a very great extent by an appropriate diet. The regulation of the diet for the removal of this factor is the most effective means which we have for the lowering of high blood pressure, and it is our most successful agent in the treatment of the extensive group of morbid conditions in which hypertension is a regular symptom; furthermore, we have the satisfaction of knowing that any reduction of high blood pressure which comes from regulation of the diet is beneficial and safe because it is due to the removal of a cause. I shall say no more here on this phase of the subject, as I have dwelt on it at some length elsewhere. (See MEDICAL RECORD, April 11, 1911, and December 23, 1911; *New York Medical Journal*, June 20, 1912, and *Archives of Diagnosis*, July, 1912.)

There are other causes of high blood pressure besides putrefaction toxemia of intestinal origin, notably overwork and dissipation, late hours and excessive indulgence in coffee, tobacco, and alcohol, which are under our control and which should be removed as far as possible as an essential part of the treatment.

Mechanical methods of treatment, such as massage and judiciously administered baths, have a place, though not as prominent a one as some think, among our therapeutic resources. A change of occupation, especially the substitution of a moderate amount of light physical work for exclusively mental work, is often good treatment.

It is claimed, with what truth I do not know, that electricity, particularly the high frequency current, can directly and materially reduce high blood pressure. If this is so, it should be employed with great caution if at all. Certainly in the arteriosclerotic, nephritic, and toxemic cases, which include nearly all, any agent may do serious harm which lowers high blood pressure without removing the factor which causes it or makes it necessary.

Keeping the minds of the patients at rest and quieting their apprehensions about themselves are important points in the treatment. Some patients come to us who have acquired undigested fragments of knowledge on the subject of high blood pressure which worry them. With such patients we should be careful not to make too much of our blood pressure examinations. In every case we should be as optimistic as circumstances permit, and sometimes it may be necessary to exceed the warrant of circumstances in our optimism.

Drugs are of very little value in the treatment of high blood pressure in most cases, but sometimes we find it necessary to use them. Of the drugs employed for this purpose the most important is nitroglycerin; and that drug is the only one of its class, with the exception of amyl nitrite, whose use is limited practically to attacks of angina pectoris, which need be kept on our list; certainly sodium nitrite and probably erythol tetranitrate are dangerous. The indications for the use of nitroglycerin are found almost exclusively in conditions of ar-

teriosclerosis with disturbance of local nutrition and without much involvement of the kidneys or much toxemia. It is particularly valuable in coronary sclerosis, arteriosclerotic headaches, and some cases with arteriosclerotic pains in the abdomen and legs. When there is much nephritis or toxemia it is generally contraindicated. It can be employed as a test to show whether a headache is of arteriosclerotic or toxemic origin; if the latter, it produces no improvement but rather aggravation, while if the former, its effect is usually strikingly beneficial.

Aconite and veratrum have a limited range of usefulness as vasodilators in high pressure cases, but they should be used with great caution if there is much disease of the myocardium. In eclampsia, chronic nephritis, and cerebral hemorrhage they can sometimes be used to avert or lessen damage to the cardiovascular apparatus.

Strychnine, though classed as a heart stimulant, and rightly so, does not seem to increase the blood pressure in arteriosclerosis, but, on the contrary, lowers it in certain cases, probably by improving the general tone and responsiveness and coordination of the vasomotor system.

Small doses of potassium or sodium iodide, long continued, may be used in cases of arteriosclerosis with hope, though not with expectation, of producing improvement, but they should not be given in cases with much nephritis or toxemia.

In bringing these scattering remarks to a close, I wish to refer briefly to a therapeutic point germane to the present discussion, and to which I have made reference in a recent paper, viz., the prophylactic treatment of cardiovascular disease, of which increased blood pressure is an early or premonitory symptom. When we discover moderately high tension in a patient whose family history shows apoplexy, Bright's disease, diabetes, obesity, chronic rheumatism, or heart disease, although in the patient himself no signs of organic change are found, we should treat him the same as we would if he already had evident cardiovascular disease, for it is a practical certainty that he will develop it. We can at least for a time postpone for him his evil days. And when we meet one whose family history or ways of life or both indicate that he is predestined to cardiovascular disease, even if he does not show any elevation of blood pressure, we should seriously warn him of his danger, and should teach him how to live so as to avoid, if possible, his fatal inheritance or destiny.

In these days of strenuous and rapid living, when the spirit of the times drives a large portion of mankind to prefer the pursuit of wealth, fame, power, or pleasure to that of contentment; and when even the making of a simple living, especially in the cities, too often requires an unhealthy amount of hustling, the wear and tear on the circulatory apparatus is excessive, and cardiovascular disease in consequence has become increasingly prevalent. It is not too much to say that cardiovascular disease has come to occupy relatively as important a place in the pathology of the latter half of life as do bacterial diseases in the first half; and the ideal of preventive medicine is as worthy of practical regard in relation to this condition as it is in relation to the diseases of bacterial origin. While showing our patients how to avoid dysentery, smallpox, and typhoid fever, we should not neglect to teach them how to act and eat so as to preserve as long as possible the efficiency of their arteries, kidneys, and heart.

1218 Pacific Street.

THE MODIFIED RADICAL MASTOID OPERATION FOR THE CURE OF OTITIS MEDIA PURULENTA CHRONICA.*

By W. SOHIER BRYANT, A.M., M.D.,

NEW YORK.

In otology, as in all other branches of medicine, it becomes constantly more important to consider the modification and adaptation of certain stereotyped operations according to the needs of the individual case. In this paper we are to consider certain deviations from the classical Schwartze-Stacke operation for chronic middle ear suppuration, that is, from the radical mastoid operation as generally understood. These modifications may be divided into two groups. The first group is the "conservative radical mastoid operation" group, which contains conservative operative procedures upon the tympanic walls and Eustachian tube but allows the loss of the major ossicles and the drum membranes. This group, however, does not concern this paper.

The second group, or modified radical mastoid operation group, includes the operations *which conserve the ossicles and drum membranes.* This type of operation is the subject of this paper.

The author applies the term *modified radical mastoid operation* to the operation which he uses in cases of chronic middle ear suppuration, where he invades the tympanum proper through the bone excavation of the mastoid process and where an attempt is made to close off the tympanic space from the meatus by regeneration of the tympanic membrane.

The distant aim in the performance of the *modified* radical mastoid operation is the retention of the drum membranes and ossicles.

In approaching the subject of the modification of a radical operation, we should keep constantly in mind that the *raison d'être* of the operation is to leave as serviceable an ear with as little hardship to the patient as possible. Stereotyped operations about the ear are even more objectionable than those on other parts of the body, for this kind of aural operation often requires the resection of structures that are not diseased. We should treat middle ear structures with as much consideration as intracranial structures because of their great importance to the individual. Varying conditions require different procedures, because in some cases more important structures can be saved than in others. In some cases, the drum membrane can be saved; in other cases, the membrane and ossicles.

Consider the progress made along the lines of conservation of parts in other branches of surgery. In gynecological operations, for instance, it was formerly considered scientifically necessary to remove many parts which are now allowed to remain, the idea now being that everything possible should be left intact. Should not this be the point of view in otology? An eye is not enucleated when there is a possibility of saving it. Why should an ear be treated with less consideration? In the case of an infected foot, the general surgeon is able to determine with a high degree of accuracy whether the phalanges, metatarsals or any part of the leg can be saved; he decides what portion must be amputated for the safety of the patient's life and conserves with care as much of the useful member as pos-

*Read before the Ninth International Otological Congress, Boston, August 12-17, 1912.

sible. When a surgeon operates for suppuration of the hand, he saves for the benefit of the patient every millimeter of this useful member that he possibly can. The surgeon who does a stereotyped operation regardless of the individual needs of his patient is like the practitioner who prescribes a remedy by the number, as, for example, No. 15 for faintness.

In order to give the best results under the existing conditions, there should be accurate and precise adaptation of the operation to the need of each individual case. When all cases are subjected to technically the same prescribed operation, it is not reasonable that the results can be the best possible in every case. It should be an axiom in performing a mastoid operation that the operative field must be extended according to the advances the disease has made and that the operative field must be curtailed in proportion to the extent of the healthy or redeemable tissues. This conservation is especially necessary with the important structures of the middle ear.

The pathological process in cases of chronic middle ear suppuration extends through many and varied gradations. These grades of the extension of the process pass imperceptibly from one to another. In the most favorable cases there is no tympanic loss of tissue except a small membranal perforation. In these cases the intermittent discharge is kept up by a granulating mucous membrane needing better drainage, and this drainage is provided by a wide U-shaped myringotomy. By imperceptible gradation, the process leads to the crucial condition, which is loss of tympanic structures and active destruction of the temporal bone extending through the mastoid region, zygomatic cells and the cells of the pyramid and invading even the labyrinth. This condition demands wide exenteration of the temporal bone, pyramid, and labyrinth.

Specific Indication for the Modified Radical Mastoid Operation.—The indication for this modified operation is operable chronic middle ear suppuration in the presence of any part of the membrana vibrans. However, the absence of any one or all of the ossicles is not a counter-indication. If there is no possibility of the reestablishment of the drum membranes by cicatrization, that is, if the attachments of the drum membranes are completely gone, this operation cannot be performed. In cases not showing the necessary tissue for a successful modified radical mastoid operation, namely, the drum membrane and the ossicles, the conservative radical mastoid operation is, I think, always indicated.

I originally intended my *modification* of the radical mastoid operation to apply only in cases that had good hearing a short time before the operation, but in practice, I have extended the operation to include all cases that showed a possibility of regeneration of a tympanic membrane, preferably, of course, with the malleus, incus, and stapes *in situ*.

Results.—This operation minimizes danger; it is practically devoid of all dangers. Added to this fact is the fact that all the dressings are absolutely painless.

The operation secures cessation of suppuration; the author has never had a case where the suppuration recurred after the operation wound had healed. As a rule, the suppuration does not even reappear in the convalescence.

This modified operation is followed by a rapid convalescence and by a regeneration of the tympanic membrane for the protection of the labyrinthine walls. No post-aural scar occurs.

The most valuable result of the operation is the preservation, because of the conserved drum membrane and ossicles, of the maximum amount of hearing. In favorable cases the hearing becomes normal. For the restoration of this normal hearing, the cochlear apparatus must be intact and the middle-ear mechanism must be restored to its normal function. In many cases the hearing capacity does not reach its maximum for some time, sometimes as long as a year.

Special Technique and After-Treatment of the Modified Radical Mastoid Operation.—The details of the technique in the operation must be subservient to the desired result. The operator should have two things constantly in mind—first, the individual needs and demands of the case, and second, the conservation of as much of the parts as possible. Sufficient drainage must be provided, though generally little is needed.

After proper sterilization of the field of operation (shaving is not necessary), the skin incision is made about 1 centimeter posterior to the fold of the auricle. The skin is separated from the periosteum, which is cut on a line parallel to the skin incision about 1 centimeter in front of the skin incision. The length of the skin incision and periosteal incision is about 4 centimeters. The periosteum is lifted in an unbroken sheet. The outer table is attacked with rongeurs at the posterior lip of the osseous meatus. If it is impossible to get a good grip with the rongeurs, a curette or a front bent gouge is used and the opening is enlarged until the rongeur can take hold again. I prefer to attack the mastoid cells with rongeurs and curette, as in acute mastoiditis, where I never use the mallet, the only difference in the mode being that in a chronic middle-ear suppuration without acute symptoms, it is rarely necessary to open all the cells and remove the entire mastoid process as it is in acute cases. Having separated the membranous canal from the upper and back wall of the osseous canal, the posterior bony wall of the canal is removed with a rongeur, as in acute cases. In acute cases I always remove the posterior bony wall of the external meatus to the annulus and often remove part of the attic wall. When the bone has been removed close up to the annulus tympanicus, the membranous canal is cut across and held downward and forward with a spatula probe.

The completion of the tympanic work requires strong reflected light. This unusually strong illumination does not delay the operation, but on the other hand, gives added assurance. The dissection should be as exquisitely and carefully done as if in a laboratory under perfect illumination. Enough of the bony canal should be removed to gain a satisfactory view of the tympanic cavity, and thus expose the region of the annulus and middle ear. If drainage requires it, a long U-shaped incision is made in the membrana tympani; the outer attic wall is attacked with a small curette and enough bone is removed to insure drainage of this space. The bone excavation may have to be extended to include part of the tympanic ring.

The tympanic walls may be granulating, and therefore may need some curettage. The tympanic structures must be conserved. Provided the attachment to the incus is preserved intact, the operative field may be extended far enough to loosen some of the attachment of the malleus.

With "conservation of parts" as the watchword in this modified radical operation, we must bear in mind that the tympanic structures must be preserved; that the incus must not be loosened at its attachment in the sella incudis; that the incudostapedial articulation must be preserved intact; that the oval pelvis should not be touched unless it is absolutely necessary to do so; and that the vestibular articulation of the stapes must be preserved with great care. The intra-tympanic muscles, especially the stapedius, and their attachments, should be preserved.

After a thorough curettage the wound is syringed out with normal salt solution. The membranous canal is slit along its floor, carrying the cut through the cartilaginous meatus and a short distance into the concha. The periosteum is sutured with catgut sutures.

The meatal flaps are distended with gauze packing lightly applied inside Cargile membrane, but more tightly packed at the external orifice of the canal. The skin wound is closed by metal clamps and the external parts are painted with a 5 per cent. tincture of iodin. Then an absorbent dressing is put on. On the day following the operation, the packing is removed from the canal, iodin is applied on the external parts and the packing is replaced more lightly.

On the second day after the operation, the packing is again changed, the metal clamps are removed from the external wound and the patient sits up. On the fourth to sixth day the packing is wholly omitted. The bandage is usually removed in less than a week. No suppuration is expected at any stage of the convalescence and no external scar remains.

In order to promote the functions of the Eustachian tube, the nasopharynx always needs attention. Tympanic inflation is begun on the second day. Valsalva's method is used when practicable. If this method does not inflate, Politzer's method is used, and in default of this method, Eustachian catheterization is employed. This tympanic inflation serves to prevent unnecessary tympanic adhesions and promotes drainage. Exuberant granulations rarely appear; if they do they can be wiped away with a cotton applicator.

The canal sometimes needs local applications in order to promote dermatization. Boric acid or xeroform powder may be used to assure cleanliness. Stimulation by nitrate of silver or scarlet red salve is sometimes used to hurry epidermization of cicatrices. The convalescence should be complete in from seven to fourteen days. The necessity of individual cases of course causes a variety in the technique.

It has always been my interest and endeavor in performing a mastoid operation to conserve as much of the parts as possible, so that the greatest amount of hearing may be preserved for the patient, and the convalescence shortened. My operations for chronic middle-ear suppuration became, therefore, gradually more conservative of the membranous lining of the external meatus, of the Eustachian tube, of the walls of the tympanic cavity, and finally, of the ossicles and drum membrane.

This operation was performed at the New York Eye and Ear Infirmary, July 27, 1905, and was reported in my paper, "A New Instrument for Mastoid Surgery" (Case 1), which was read at the meeting, and published in the Transactions of the Tenth Annual Meeting of the American Academy of Ophthalmology and Oto-Laryngology, Buffalo, September 14-16, 1905, Transactions 1905, p. 117. This paper was also published in the Laryngoscope, St. Louis, Vol. XV, No. 10, October, 1905, pp. 796-801. This is the first published record of an operation of this kind.

The patient you see had left-sided chronic otitis media suppurativa of the intermittent type complicated by suppurative mastoiditis with bone disintegration. Watch not heard in left ear. A complete mastoid operation was performed, invading attic and tympanum. Closed wound with blood clot. Temperature normal after operation. Third day: Middle ear dry and nearly all posterior wound closed by first intention. Tenth day: Middle ear healed and posterior wound healed. Sixteenth day: Watch heard 13 inches—A. S. No pus or discharge since operation. Seven years later. A. D. Watch heard 12 inches. Operated ear. A. S. Watch heard 24 inches.

41 East Thirty-Third Street.

PARINAUD'S CONJUNCTIVITIS.

By JOHN S. KIRKENDALL, M.D.,
AND
CLIFFORD P. FITCH, M.S., D.V.M.,
ITHACA, N. Y.

In 1889 Parinaud described a rare form of conjunctivitis to which is ascribed his name. The salient points of this disease are first, that it is probably infectious, ushered in with febrile symptoms and chills and accompanied by an enlargement of the preauricular and sublingual glands, and second, that it is of animal origin. At first granular in form this disease later takes on its characteristic appearance of yellowish vegetations, which are semitransparent, later becoming opaque and attaining the size of a large pin head. Between these vegetations are small yellowish granules which suggest tuberculosis of the conjunctiva. These are located in the retrotarsal fold, on the tarsus or the globe. The cornea is unaffected. Mucous secretions and deposits of fibrin are formed, but no suppuration occurs. The lids become swollen and hard to the touch, feeling as though chalaza was present. Occasionally the glands suppurate. The course of the disease is from six to eight weeks.

The literature shows a large bibliography of which the major portion is quoted from a case reported by G. F. Keiper, of LaFayette, Ind., and read before the American Academy of Ophthalmology and Oto-Laryngology in 1910, to which are added four cases reported by Arganaraz, of Buenos Ayres, and my own case which I shall report, together with a carefully prepared report by Dr. C. P. Fitch, of the Department of Pathology and Bacteriology, New York State Veterinary College, at Cornell University.

C. F. B., of Horseheads, Chemung Co., N. Y., was referred to me by Dr. Willis King, of Newfield, N. Y., with the following history: A farmer, aged 28, good family history. Patient never had syphilis and had always been extremely healthy and strong. Four days previous to this visit to me, which was on April 22, 1912, he had called to see his physician, and complained of his right eye scratching and feeling as if there were sand in it. The eye was red and angry at the time and Dr. King prescribed an antiseptic lotion and told the patient that if the eye did not get better to call again. On April 22 the patient called again and

was immediately referred to me, and arrived at my office about 4 P.M. I diagnosed the case immediately as one of Parinaud's conjunctivitis. The eyelids and surrounding integument were extremely swollen and edematous and there was eversion of the upper lid as the result of the chemosis simulating gonorrheal ophthalmia. There was more or less exudate of a fibrinopurulent character. It was impossible to evert the lid to get a view of the fornix. The cornea, which was clear and normal, could be seen at the bottom of the well-like opening, about one-fourth inch in diameter, made by the extreme chemosis. The temperature was 99.2° F. The preauricular gland was extremely tender and about the size of a chestnut; there was also swelling of the surrounding tissues. The submaxillary and sublingual glands felt like lima beans. These were also quite painful to pressure.

The patient was sent at once to the City Hospital where iced cloths were applied every alternate hour and the eye was kept clean with the aid of an eye cup filled with a weak solution of boracic acid and zinc. The fever gradually abated. The chemosis and swelling of the lids and the tenderness of the glands subsided. At the end of two weeks the eye became much better and the cornea which was normal could be plainly seen. An ulceration of the lower palpebral conjunctiva took place at its center or at the apex of the chemosis. This yielded to calomel, but left at the end of about three weeks' treatment a slight symblepheron. When I was able to evert the lids there could be seen the characteristic granulations or vegetations described by Parinaud. The patient when last seen had some conjunctivitis and irritation. This, however, was gradually receding; in fact, was practically well.

April 23, 1912, the day following the admission of the patient to the hospital, a careful bacteriological examination was made. Antiseptics had not been used on the affected eye for eight hours preceding this examination, it having been kept clean with sterile water during this time. A considerable amount of exudate could be collected from the eye on the platinum loop at this time. Cultures were made from this exudate on agar, serum agar, bouillon and blood serum. Anaërobic cultures were made in serum agar. In making these cultures care was taken to draw the sterilized loop over the swollen lid and not to inoculate the fibrinopurulent exudate collected at the inner canthus. Smears of the exudate were made on glass slides. The cultures were incubated at 37.5° C. Duplicates were likewise incubated at 20° C. After 24 hours the agar and blood serum cultures which were placed at the higher temperature showed several small round colonies which on microscopical examination proved to be micrococci. The cultures left at 20° C. showed nothing at this time. The anaërobic cultures were likewise negative. Continued incubation of the cultures developed nothing but micrococci. These were later identified as *Staphylococcus pyogenes aureus* and *albus*. The smears made directly from the exudate were stained in a variety of ways and examined microscopically. Those stained for tubercle bacteria failed to show any acid-fast organisms. Wright's, Jenner's, and Loeffler's alkaline methylene blue stains were likewise used on several smears, and when examined showed many leucocytes, some fibrin, and an occasional micrococcus. Organisms resembling the gonococcus were not observed.

These bacteriological findings agree with those reported in other cases of this rare and but little known disease. To quote from Keiper's paper: "To date the examination of tissue and discharge for a specific bacterium, as a probable cause has been fruitless; and, as Alt remarks after the examination of a case of Barck's, 'I was absolutely unable to stain any particular organism. If there is one it is too small to be seen by our present means.' Often the staphylococcus and *B. xerosis* are found. The streptococcus has been found by Rohmer and Villeneuve. Gifford reports that in an examination made in three of his cases nothing was found that was not of secondary importance. Stirling and McCrea report finding a bacillus resembling the Klebs-Loeffler bacillus. This was found for twenty-five days while the patient was under active treatment. The impression received by these investigators was that they were dealing with a less toxic form of the diphtheria bacillus or with a virulent form of the xerosis rosæ bacillus which is recognized as inoccuous to the eye. Kornel-Scholtz, reporting a case resembling this disease, isolated what he believes to be the specific organism. Cultures made from nodules showed a small bacillus four times from five cultures. It was from 0.5 to 1.5 microns long and in chains of fives and sixes. It was negative to Gram. He also found it in smears from the lymph glands, though he could not cultivate it on the various media. It was pathogenic for mice and chickens. The corneæ of guinea pigs inoculated with the germ showed a diffuse opacity which cleared up in a few days. According to Axenfeld, the bacillus was very like the *B. gallinarum*, and belonged to the group of the polar staining bacteria, like those of plague and hemorrhagic septicemia. Auerbach found the pneumococcus in the pus of a large preauricular gland. He considers infection from animals doubtful and regards the necrotic areas of Verhoeff and Derby, and the plasma cells of Matys of no special significance. Claiborne in the report of a case states that he could find only *Staphylococcus pyogenes aureus*.

"Inoculation experiments were made on rabbits by Gourfein, Sinclair, and Shennen with negative results. The staphylococcus was the only organism recognized. The same writers in reporting another case found two varieties of the white staphylococcus from the necrotic areas of the conjunctiva, while from the glands of the neck were isolated *Staphylococcus albus* and *aureus*. From a sinus was obtained the streptococcus. Barck reports a case seen December 21, 1908, the excised follicles and smears of which he submitted to miscroscopical examination. The results were negative in all respects as to the presence of any specific bacterium."

That this disease is infectious there can be no doubt. However, we must admit that as yet the nature of the contagion is unknown. Parinaud believed the disease to be of animal origin. It so happened that his first three cases had all come in contact with animals. The thesis of Sans and Dominique lent additional weight to this view, since in all but one of their cases a similar history was obtained. Gifford was the first to cast doubt upon it, animal contact in his four cases being practically excluded. However, Hoor, reporting forty-four cases, believes that in two-thirds of them there was an opportunity for animal contact. One of Barck's cases was a telegraph operator with no such opportunity for infection. Webster from his case, a young lady, does not believe the disease to be of an-

imal origin. Parinaud suggested foot and mouth disease as the source of the infection. Acting on this suggestion, Chaillons brought one of his cases, the history of which gave some evidence of animal contact, to the laboratory of M. Nocard in the veterinary school at Alfort. The lesions did not impress Dr. Nocard as resembling those of foot and mouth disease. Inoculations of scrapings from the conjunctiva were made upon the mucous membranes of young pigs which are susceptible to foot and mouth disease, but with negative results.

The history of the case here reported has a very interesting connection with the theory of animal origin. The patient reported that for several months previous and up to the time of his infection he had been treating horses with "pink eye," and that one of his cows and her calf had had "sore eyes" which he had "washed out." The disease here referred to as "pink eye" is known under various names, as influenza, horse distemper, shipping fever, epizootic catarrh, etc. It is an acute infectious disease characterized by a rise in temperature and a catarrhal condition of one or more of the mucous membranes, especially of the head. One or more of the internal organs may be affected. It is a disease of horses, although asses and mules are susceptible, and a few cases are reported of its being transmitted to man and dogs. At present influenza is restricted to groups of symptoms and lesions in the horse that are not very unlike those of *la grippe* in man. A severe affection of the eyes is quite a constant characteristic symptom of influenza. At first it consists chiefly of a catarrhal and later of a phlegmonous conjunctivitis with considerable swelling of the lids (chemosis) which may be followed by parenchymatous keratitis and possibly by an exudative or hemorrhagic iritis. *Usually both eyes are affected.* The mucous membrane of the eyelids is glassy, edematous, and often projects outward between the lids in the form of an orange-colored protuberance. Often these inflammatory changes of the eye disappear in a strikingly rapid manner. Often, however, they lead to the formation of catarrh and occasionally to blindness from the detachment of the retina and opacity of the vitreous humor. The etiology of influenza is still in doubt. A number of bacteriæ has been described as the probable cause, but thus far none of them has been found to be sufficiently constant to warrant its acceptance as the etiological factor.

It will be noted that Parinaud's disease and the so-called "pink eye" in animals have certain symptoms in common, but there are so many wide differences, as, for example, the binocular character of pink eye, the monocular infection of Parinaud's disease, and the severe sequellæ of "pink eye" that there is no good reason to consider them related. It is interesting to note that the etiological factor of each disease still remains undetermined. There is not, however, any good proof upon which to base the statement that Parinaud's disease is of animal origin. It would seem as if there were two possibilities as to the nature of this disease: first, that it is a specific infectious disease, the cause of which has not been discovered; second, that it is a simple pyogenic infection manifested by the previously described symptoms. There are several facts supporting this latter view, for example, its sporadic character and the bacteriological findings. However, much further study must be devoted to the disease before a positive opinion can be given.

Summary.—(1) Parinaud's disease may occur at any time in this country. (2) It is a disease the etiology of which is undetermined. (3) It responds readily to treatment and usually complete recovery takes place in from three to six months. (4) The theory of its animal origin seems to be supported on insufficient evidence. Taking into consideration the reported cases it must not, however, be entirely ignored.

Cornell University.

X-RAY THERAPY.*

By HOMER E. SMITH, M.D.,

NORWICH, N. Y.

It is an interesting speculation as to what is due the efficacy of the *x*-ray in the treatment of malignancy and other diseased conditions. One may go back to the ultimate origin of things for basis of a theory, and the working out of this will draw upon the physics of matter in all its relations. The subject is so interesting that I cannot forbear a few words before taking up the practical side of *x*-ray therapeutics. The modern definition of matter is "A vortex whorl in a perfectly elastic medium." Stripped of technicalities this means that all matter, organic or inorganic, solid, liquid, or gaseous, is simply the expression of molecular activity and that its form is dependent upon the mode of motion, its amplitude, and the rate of vibration. The properties of matter also, such as chemical, photic, actinic, electric, or magnetic, are simply the results of etheric vibration and any one may be converted into either of the others.

What we call life is a phenomenon of cellular activity and is not confined alone to what has been termed the organic. The vital tendency of the cells is infinite, of their aggregation the trend is somatic death, so whatever may be the nature of a malignancy, the cell itself reverts to the embryonal type of excessive proliferation, and somatic death occurs by the drain this makes on other vital processes or by the absorption of toxins from broken down tissues. It is most probable that all matter is simply the allotropic expression of one element and that the protomolecule is the union of the positively and negatively electrified etheric corpuscle.

Inasmuch as the living cell, regarded as matter, is simply a vibration, one can understand if for any reason its amplitude or form of motion were altered, then would ensue changes in its physical properties, and atrophy or hypertrophy result. The germ of the cancer cell has been sought in vain and while it is not unlikely that the virulency of malignant growths may be enhanced by adventitious germ infection, it is most probable that the disease is caused by alteration in the molecular activity of the cell and most probable also, it can be, that this is brought about by some chemical change in the blood plasma. Whether in malignancy there is an increase or a decrease in the normal rate of molecular vibration one can only surmise, but it is probably decreased, so that when subjected to the bombardment from the high speed and ionized corpuscles from the *x*-ray stream the cell takes up again its proper rate and returns to a normal condition. The small amount of scarring after cure by radiation would seem to support this view. It is a curious fact that the *x*-ray alone is the only definite agency that unquestionably produces cancer. If as some assert, malignancy is the return of the cell to the embryonal type, it would seem that corroboration of this assertion is furnished by such *x*-ray lesions and is contraevidence of its humoral or microbic origin.

In the earlier days of experimentation with the Röntgen ray, little was known of its baleful effects and much harm was done to both patient and operator. It was not understood that with varying technique and dosage one of several distinct therapeutic results followed: viz., sedative, stimulant, irritant, or escharotic, and that a method suitable to one condition could not be indiscriminately applied to all. A leucocytosis may be induced and an accompanying erythrocytosis as a primary stimulating effect from radiation, or under intensive treatments a leucopenia and poikilocytosis. One may destroy all the hair follicles by prolonged radiation and induce baldness or by stimulating doses produce hypertrichosis. There are four factors in continuous radiation, the sum of which constitutes a dose or treatment; these are the distance of tube from patient, the duration of exposure, the state of the vacuum in the tube, and the amount of current which flows into it. To measure this dosage by any means, photometric, electric, or chemical, has proven so far to be unsatisfactory, and such dosage is in consequence largely a matter for the judgment of each *x*-ray

*I am indebted to Drs. F. R. Cook, George Pfahler, and others as authorities for part of the statements made in this article.

worker. It is a matter of the greatest importance that the proper values be given to these factors. For instance, in superficial growths a soft tube at two inches is of service, at twenty is practically useless. With deep-seated growths a tube of higher vacuum is most efficient at twenty inches and of little or no use at the lesser distance. The duration of treatment must be carefully graded, as it must not be forgotten that the effects of the ray are cumulative. Enlarged tuberculous glands which do not yield after a certain period become more resistant and more apt to break down as the treatment is continued. In the treatment of deep-seated cancer there may be first an improvement and later a marked increase in the rapidity of the growth, due to the failure of the operator to discriminate between the radically different impressions which must be made upon the malignant and the environing normal cells. Totally opposite effects may also be obtained, depending upon whether the rays are continuously applied or given by interrupted flashes. With the one we may get inhibition or destruction of cellular activity, with the other stimulation and regeneration. The regenerative effect is both local and general, and is accomplished largely through its action on the blood vessels. These flashes dilate the arteries and induce a natural and active hyperemia. They stimulate cellular metabolism without exhaustion and each subsequent stimulation is followed by an improvement in cellular vitality, a stepping up process as it were, made manifest in regeneration of tissue. This phenomenon has been accomplished in bone, nerve, muscle, glandular, vascular, and epithelial structures. In the eye it can be obtained in the cornea, lens, iris, chorioid, retina and optic nerve.

The local hyperemia induced by powerful *x*-ray flashes is too constant and too manifest to be open to doubt and explains the local regenerative action in diseases of chronic degeneration. With a high tube focussed over the chest and abdomen the pulse rate has been lowered ten beats and the blood pressure 10 mm. with a single instantaneous flash, with sixty such flashes a fall of 60 mm. and thirty-five in the pulse rate in a minute and twenty seconds.

In fatty degenerations and infiltrations a regenerative action is obtained. Lipomata have disappeared and cystic growths cured by their action. In the degenerations leading to fibrosis this regenerative action has been observed in many and varied conditions. The rapidity with which recent scar tissue becomes permeated with new blood vessels is at times almost incredible. In the treatment of chronic skin diseases intermittent rays often possess an advantage over the continuous application, and in tuberculous glands this form of treatment gives better satisfaction. An active hyperemia is first induced and then the treatment is suspended until this subsides. Following this line of treatment the glands do not break down or become unyielding, because there is no impairment or destruction of normal tissues. When we consider that practically every therapeutic effect which one may require in systemic or local action may be obtained by radiotherapy, it simply resolves itself into the selection of the modality and its intelligent application.

When we come to specific Röntgen therapy it is easier and better that we classify diseases suitable for such treatment under various headings. First, malignant growths. Here perhaps is the largest field of usefulness, and here must be reiterated that technique is everything. In general it may be said that superficial malignant growths are curable in 98 per cent. of the cases. In recent deep-seated cancer where surgery can reach it, a previous radiation to destroy outlying cells, operation, and postoperative radiation to prevent recurrence seems to be the best practice. As a primary method of treatment it is of doubtful expediency except when operation is refused, or is contraindicated, or when better cosmetic results may be obtained, when life is not threatened by delay or when the disease is already inoperable. Dr. Boggs of Pittsburgh has very recently reported twenty cases of inoperable carcinoma of the breast with an apparent cure in five. This is a result which will compare favorably even with operative and surgical cases. Dr. Bulkley of New York, in reporting on 400 cases of epithelioma, says in his conclusions, "By the proper use of *x*-rays we have a safe and, in cases that have not been grossly neglected or maltreated, a sure method of cure with the least amount of deformity." Again should be repeated, what is proper treatment for epithelioma is wrong for sarcoma or carcinoma, and what is right for either of the latter two is wrong for the other.

In gynecology its sphere of usefulness covers one of several conditions, such as the production of an artificial menopause and the application of this procedure in the treatment of uterine hemorrhage incident to the presence of myomata, and the so-called fibroid tumors of the uterine body. From radiation we may expect certain definite changes, as follows: The cessation of menstruation, a reduction in the myoma mass, the disappearance of the menstrual or intermenstrual bleeding, and the relief of pain. In cases where there is postclimacteric hemorrhage without the presence of myomata or intrauterine polypi relief also may be expected. In the matter of uterine carcinoma, it is not a rational procedure to use radiation as a primary measure.

These cases are purely surgical, but where a neglected case has become inoperable or there is extensive postoperative recurrence, then can pain and hemorrhage be partly controlled, life prolonged, and the patient given a larger measure of comfort.

Evidence in abundance has been published of the atrophic action of the *x*-ray upon the testicle and ovary, and there can result sterility without impotence. Therefore such radiation should be very guardedly used in young women or at any time when the question of continued fecundity is of importance. In the treatment of Basedow's disease (exophthalmic goiter) and in hyperthyroidism without exophthalmus much may be accomplished by proper Röntgen therapy and especially in those cases where there is marked hypersecretion without much enlargement of the gland itself.

The status lymphaticus, a condition of infancy, belongs in the same class of diseases as the above, namely, a hyperactivity of the ductless glands—in this instance, the thymus. These cases are characterized by enlargements of the lymphatics, with usually enlarged tonsils and adenoids, the thymus may be palpable, but its increase in size may certainly be outlined by percussion. These little patients are also feeble in constitution and have little strength. The spleen is enlarged. They have cough, stridor, and asthma. The diagnosis is complete when the blood

count is taken, for there is always a marked lymphocytosis. These patients take anesthetics very badly and most cases of death under anesthesia, induced for the removal of adenoids, are due to this status lymphaticus. The rapid disappearance of all symptoms under *x*-radiation is remarkable. The condition is comparatively rare, but this brief outline may be of help in the matter of diagnosis and to remind you that a blood count should be made before undertaking an adenoid operation in the very young.

Under the heading of dyscrasias of obscure etiology come two diseases in which *x*-ray therapy offers practically the only hope of amelioration or cure; these are leucemia and pseudoleucemia, or Hodgkin's disease. In the latter the outlook for a cure is better, and in the former certainly an improvement and prolongation of life. It would almost seem that the reason why cure is not effected lies in the technique, for all the symptoms can be made to disappear for a time and the blood picture returns to normal. Unfortunately after a period of apparent return to health a relapse usually occurs and death follows very soon; nevertheless, the patient can be given months of comfort and prolongation of life.

In tuberculous conditions success wholly depends upon the site of the invasion. In pulmonary tuberculosis and in this disease of the bones and joints little or no benefits have followed *x*-radiation. In tuberculous cervical adenitis it is practically a specific, providing treatment begins early and before there has been any breaking down in the glands. In the cutaneous tuberculides either the papular or ulcerative types or in the two forms of lupus, squamous and erythematous, it is practically certain of cure and is quicker and surer than the Finsen light. In diseases of the skin the parasitic types are very amenable to *x*-ray treatment. Tinea sycosis and tinea circinata yield readily, but there is a decided danger of producing a permanent alopecia. In blastomycotic infections it is of great assistance in the cure, but should be supplemented by the administration internally of potassium iodide in large doses. Psoriasis yields readily to *x*-radiation, but the various forms of eczema are not materially benefited. Perhaps no form of skin disease is so distressing to the patient as is the various types of acne, and here fortunately the *x*-ray is often curative and, best of all, the cure may be effected without scarring.

In conclusion, *x*-ray therapy is practically a specific in many chronic and inflammatory diseases of the skin. It is curative in 98 per cent. of all malignant and semi-malignant superficial growths. In the deep-seated sarcomatous or carcinomatous growths it may sometimes be curative. It is always palliative, it relieves pain; it is the handmaid of surgery where this is indicated, and should be used before and after operation. It is capable of inducing constructive metabolism and bringing about a return to health in many systemic conditions. It can lower the blood pressure, slow the pulse rate, and modify for good the cellular elements of the blood. These and many other properties it possesses, and when we consider that with it we may induce stimulation, sedation, inhibition, or destruction of cellular activity, we realize that its potentialities are many and beneficent. Nevertheless there lurks behind all these potentialities for good the constant element of danger, and only he who has mastered the intricate technique of *x*-ray therapy should be trusted with this subtle and potent agent.

THE SIGNIFICANCE OF SOME URINARY CONSTITUENTS.*

By J. BERGEN OGDEN, M.D.,

NEW YORK.

ASSISTANT MEDICAL DIRECTOR, METROPOLITAN LIFE INSURANCE COMPANY OF NEW YORK CITY.

It is my purpose to-day to discuss a number of subjects in connection with the urine, and in particular to point out to you the relative significance of some of the constituents of the urine which may have been considered of pathological importance, or the cause of some confusion in making decisions upon applications for insurance.

There is still a deeper purpose in giving you this paper and that is, that it may lead to a better understanding between the medical representatives of different insurance companies in deciding as to the fitness of an applicant for a policy.

We will first consider nucleoalbumin and some of the allied substances, and then devote some time to the consideration of albumin and casts. No pretense has been made to deal with any one of these subjects in its entirety, but I have endeavored rather to interpret in a brief way the meaning of a few of the substances which are not infrequently met with in the urine.

Nucleoalbumin.—It was only a very few years ago that nucleoalbumin was the cause of considerable confusion among insurance men. This confusion appeared to result partly because of the possibility of mistaking it for serum-albumin, and partly to a fear that it might have important pathological significance. When we consider that the urinary tract is a mucous surface and that every mucous membrane is capable of giving off its own secretion, and that such secretion is one of the forms of proteid, we can understand how a urine may contain proteid, either in soluble or insoluble form, which may not have pathological significance.

Nucleoalbumin is one of the nucleoproteids which is essentially a normal urinary constituent. When the mucous surface of the urinary tract is in a healthy state, the quantity present is extremely small, but if the mucous membranes are stimulated or irritated, the amount of nucleoalbumin is somewhat larger, but even then it is present only in very small quantity. We have no experimental or chemical data to show us that the nucleoalbumin of an irritated mucous membrane differs in any way from that of a perfectly healthy mucous surface, except in quantity.

Nucleoalbumin is apt to be much more apparent in the urine of a female than in the male, because of the mucous surfaces of the genitalia with which the urine often comes in contact. It is found also in larger quantities than normal in the urine of the new-born; in the urine after overexertion; after chloroform inhalations, and after injury to the kidneys and other parts of the urinary tract.

There should be no confusion between nucleoalbumin and serum-albumin. We know that nucleoalbumin can be separated from the urine by acetic acid only after getting rid of some of the urinary salts, particularly sodium chloride; in other words, as long as we have in the urine an excess of sodium chloride, there is no danger of getting a reaction for nucleoalbumin in the heat test for serum-albumin. Thus it is that we so strongly encourage

*Read at the 23d Annual Meeting of the Association of Life Insurance Medical Directors of America, held in New York October 9 and 10, 1912.

salting every urine with one-sixth of its volume of a saturated solution of sodium chloride before applying the heat test.

As to the pathological importance of nucleoalbumin, we believe that it has none. We cannot lose sight of the fact, however, that there are a number of other nucleoproteids that may get into the urine and which some day may be found to have some significance. At the present time, however, we need not concern ourselves with such substances as chondroproteids, phosphoglucoproteids and others.

Mucoids.—While there is a similarity between true mucin and nucleoalbumin, there is a chemical difference; in other words, when these two substances are broken up different products result. We are in the habit of using the term mucin in connection with shreds found in the urine, but these would better be termed mucoids or nucleoalbumin, for true mucin is a rare urinary constituent. The shreds and threads of varying size so commonly found in the urine in catarrhal conditions of the urethra and bladder, are, therefore, in all probability nucleoalbumin in an insoluble form, and they have no further significance than that they represent a hypersecretion of the mucous surface involved. These nucleoalbumin threads are most prominent in the urinary sediment during the late stages of gonorrheal urethritis, catarrhal disturbances of the bladder, and in the urine of a female who has a leucorrhea or some mild inflammatory condition in the genital tract.

Cylindroids.—In the urinary sediment we not infrequently come across cylindrical bodies with one or both ends rounded, which at first sight might be called casts, but upon close study will be found to be of varying diameter and to have fine lines running through them. Rarely these bodies may be formed in the kidney, but they are more commonly found coming from the prostatic ducts. The chief point about them is to distinguish them from true casts which form in the kidneys, and this can generally be done by careful focussing and by varying the light of the microscopic field. Occasionally it is necessary to let the body pass as questionable and be governed chiefly by the accompanying elements; for example, if true renal casts are found and no undoubted mucoid threads are present, the doubtful body may be a renal cast, but if no true casts are detected and there is evidence of irritation or disturbance in the prostatic region, the questionable body is what is generally termed a cylindroid. These cylindroids are in reality mucoids or nucleoalbumin in insoluble form and do not differ from the mucoid threads above referred to as coming from the urethra or bladder.

I am personally not in favor of the use of the term cylindroid, but rather to call them mucoid shreds, since they represent only the hypersecretion of a stimulated or irritated mucous membrane, whether in the kidney, the prostatic ducts, or some other part of the genitourinary system. These mucoid bodies in themselves have no special significance, for they may exist in the urine without accompanying elements and be found when the urinary mucous membranes are stimulated but otherwise in a healthy condition. When, however, they are present in large numbers they are usually accompanied by evidences of irritation or inflammation. Probably their most common occurrence is in very mild catarrhal conditions of the neck of the bladder and then they are usually accompanied by an excess of leucocytes and an occasional free red cell.

Those of you who have followed closely the developments in connection with urinary work in the past ten or fifteen years have no doubt been impressed with the refinements in technique and in urinary tests that have taken place and how the confusion that was once so apparent has largely disappeared. It is safe to assert that we are to-day getting into a frame of mind which permits us to take a sane view of our findings in the urine, and to interpret them with some degree of confidence. I regret to say, however, that there are some who are inclined to hold up their hands in horror at the sight of the word albumin. I cannot help feeling, and I believe that we shall soon have statistics which will bear me out in saying, that such an attitude is largely the result of prejudice, and to some extent fear.

Albumin.—Let us consider for a time the subject of albumin and its significance in the urine. I shall confine my remarks about albumin to the very small amounts and what I am personally in the habit of terming the "slightest possible trace." This amount of albumin is what the careful examiner in the field will report to you as a minute trace or a small trace; or he may use the word trace, but whatever the nomenclature it is the faint reaction that he obtains when he uses the methods and the technique prescribed by our Association.

We can all agree that the presence of serum-albumin in the urine is a danger signal, but we seem to differ as to its importance. Given a urine containing albumin it is expedient for us to find out to what it is due, and this is best accomplished by a careful microscopic examination of the urinary sediment.

For convenience we can divide the causes of slight albuminuria into two classes, viz.: (1) disturbances below the kidneys, and (2) disturbances or diseases of the kidneys.

By far the most frequent causes of a small amount of albumin in the urine of a male in the first class are very slight irritation in the urethra, at the neck of the bladder and in the bladder, such as may be seen many months or years after a gonorrheal infection, and after the elimination of a highly concentrated urine for several days. In the female, the presence of vaginal secretion in which there is almost always a small amount of free blood may lead to the presence of a small amount of albumin in the urine.

I do not believe that anyone would for a moment consider that the disturbances that I have just recited would in any way effect longevity, and yet those very conditions comprise nearly 70 per cent. of all urinary troubles found in applicants for insurance.

As to disturbance and disease of the kidneys, there may be some ground for apprehension. It is my firm belief, however, that by close study of the urine together with the clinical picture of a case, it is possible to distinguish between harmless renal disturbance and important renal disease. For example: A young man of good habits with a clean clinical and family history, an unobjectionable occupation, an average normal blood pressure, and of good average weight, applies for a policy. In his urine we find a normal specific gravity, relatively normal solids, an absence of sugar, a minute trace of albumin, and in the sediment rarely a cast of either the hyaline or granular variety or both, rarely a renal cell, and altered blood globule. This condition is evidently a slight temporary renal irrita-

tion or active hyperemia and of no more importance than a headache due to a temporary constipation. If subsequent urinary examinations are made it will be found that the casts have disappeared in the great majority of instances. Such an individual is, I believe, entitled to some form of insurance policy.

Casts. There is apparently a belief that a distinction should be made between the hyaline and the granular varieties of casts; that the hyaline casts indicate a grave condition in the kidneys, while the granular casts signify a less serious condition; or there may be those who contend that granular casts have much greater importance than those of the hyaline variety. After many years of close observation I am convinced that one variety has no more pathological significance than the other, except when there is a great predominance of casts of the hyaline variety.

The basis of all casts is a hyaline material having its origin in the tubules of the kidney, and when a hyaline cylinder is without adherent or imbedded granules, it is, of course, a pure hyaline cast, but most of the hyaline bodies that we find in the urinary sediment have a greater or smaller number of granules imbedded, when they must be considered either mixed hyaline and granular, or granular casts. Pure hyaline, mixed hyaline and granular, and granular casts are found in nearly every disease and disturbance of the kidneys and in varying numbers of each. When, however, the number of casts present is rather large and there is a great predominance of those of the hyaline variety, we may then suspect a chronic interstitial nephritis, a marked chronic passive renal congestion such as may be seen in extensive cardiac disease without compensation, or an amyloid degeneration of the kidneys. In the urine of the average person the presence of a pure hyaline cast or two has no more pathological importance than a like number of granular casts.

In conclusion I wish to enter a plea in behalf of the applicant for insurance. He has been refused a policy because of albuminuria. The question naturally arises what is the cause of the albumin in the urine and is the condition temporary or is it due to a long-standing process in some part of the urinary tract? In fairness to the applicant the nature of the urinary process should be determined in every instance and if, by studying his case for a time, the trouble has been found to have greatly improved or entirely disappeared, he ought to receive insurance. I refer particularly to those cases in which the urinary abnormality is the only impairment. I cannot help feeling that our medical discrimination in many of these cases of urinary difficulty has in the past been unfair to the applicant and I feel safe in predicting that, as a result of statistical data, the time is coming when we shall be willing to issue insurance to a large number of those who have had or still have slight urinary impairment.

Case of Fixation of the Left Half of the Larynx in a Woman.—H. F. Powell and L. Colledge report the case of a married woman, aged 58, who complained of hoarseness, which she had noticed for about seven weeks and which had not been getting better or worse. She had no pain nor other symptom. Her general health was good, with the exception that she had a cough. The left half of the larynx was quite immobile. The left vocal cord was a little red and swollen compared with the right. The pupils were active to light and accommodation, but the left was much smaller than the right. Examination of the chest revealed nothing abnormal.—*Proceedings of the Royal Society of Medicine.*

CONGENITAL STRICTURE OF THE URETER, PRODUCING PYONEPHROSIS; NEPHRECTOMY.

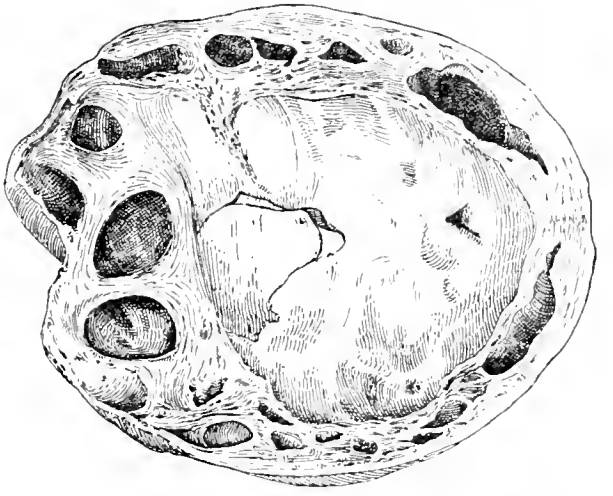
By L. MILLER KAHN, M.D.,

NEW YORK.

ASSISTANT SURGEON, LEBANON HOSPITAL.

Congenital stricture of the ureter producing hydronephrosis is of sufficient rarity to warrant the publication of a case in which the chief clinical picture was that of ileus due to an enormous pyonephrotic sac. In a scholarly paper by Bottomley (*Annals of Surgery*, November, 1910) there were reported but 58 cases, after a search of the literature. Of these cases there are but three, including the author's own case, "in which a successful removal of both cause and effect was possible." The case reported below permitted of the successful removal of both the strictured ureter and the pyonephrotic kidney.

Case No. 29441. B. I., aged 4½ years; admitted to Lebanon Hospital, service of Dr. Henry Roth, May 3, 1910; discharged cured July 10, 1910. Previous history: "Pneumonia and typhoid" two years ago, followed by limping in the left leg; this



Pyonephrosis of the kidney, produced by a congenital stricture of the ureter, in a child of four and one-half years.

limping was painless. Abdomen became prominent at that time and he has remained slightly "pot-bellied" since. Patient was in bed for four weeks at that time. Has limped slightly ever since. Bowels have been irregular.

Present illness: Two weeks before admission patient complained of pain in the left leg. Three days before admission complained of colicky pain in the abdomen and was put to bed. Next day vomited after taking castor oil. Catharsis was not effected. The pain continued and an enema was given which was also ineffectual. Abdominal enlargement was now noticed and the abdomen seemed to the mother to be hard. The child was at this time in great distress and was sent to the hospital.

Physical Examination: Child of normal height, fair color; poorly developed. Thorax normal. Lungs and heart normal. A mass is visible in the left iliac region and may also be felt in the left iliac region running up into the lumbar and left hypochrondiac areas. This is a large rounded firm mass occupying the greater part of the left side of the abdomen. In the right lower side a mass the size of an orange may be made out. All these are

immovable and do not change position on inspiration. There is no rigidity present, but the entire abdomen is markedly distended. Some limitation of motion in the left hip. Left leg slightly shorter than right. On rectal palpation a mass can be felt pressing down on the rectum. The rectum is empty. Blood count shows 36,600 white blood cells; 89 per cent. polymorphonucleus and 11 per cent. lymphocytes. Urine acid, sp. gr. 1010. Negative for albumen and sugar. Temperature 102° F., respirations 44, pulse 140.

An enema which was given soon after admission produced only partly satisfactory results, the fluid returning discolored and the patient expelling more or less flatus.

An operation was decided upon and was performed on the day of admission. Ether anesthesia. An incision was made in the outer side of the left rectus. On opening the abdomen I found a large mass, retroperitoneal, extending from well down in the left side of the pelvis up to the spleen and far over to the right side above, pushing the intestines into small space in the lower abdomen and pelvis. The mass was tense and the peritoneum smooth. It was decided, on account of the condition of the patient, to open into the mass in the quickest way, and the peritoneum covering the tumor was fastened to the anterior parietal peritoneum, thus shutting off the general peritoneal cavity. The posterior layer was now incised and the pelvis of the kidney opened, and about 1 quart of fluid was evacuated. The circular suture uniting the two layers of peritoneum was of Pagenstecher linen. The fluid, at first clear, became cloudy at the last with large flocculi. A finger in the kidney pelvis now palpated a very large cavity with what was felt to be trabeculæ at one side. Drainage tubes were inserted and the muscles and skin closed around them.

Examination of the fluid showed a large number of pus cells.

The recovery from the operation was prompt, the dressing becoming slightly saturated on the third day. Seven days after operation it was first noticed that the moisture on the dressing had a urinous odor. It was hoped that, if the fistulous opening were permitted to close, the urine would again be discharged into the bladder. On two occasions the drains were withdrawn, but the kidney pelvis filled again and the temperature rose to 102° F. This proving unavailing, nephrectomy was decided upon.

Operation June 22; ether anesthesia. An incision was made in the left loin, at the outer border of the quadratus lumborum, from the twelfth rib downward and outward to the crest of the ilium. A large adherent sac was found occupying the entire retroperitoneal area and extending far over to the right. The peritoneum was now opened purposely and an attempt was made to palpate the right kidney. This was unsuccessful. The opening in the peritoneum was now closed, but as it was necessary to establish the presence of the right kidney, an opening was made in the right loin, which exposed the right kidney, normal in appearance. This opening was closed in layers and dressed. The left kidney sac was now freed from adhesions, and the ureter and blood-vessels were tied separately with heavy catgut ligatures. The remaining end of the ureter was fastened in the lower angle of the wound. There remained only the fistulous opening in the anterior abdominal wall to be cut away, which was easily done from the posterior wound and the kidney sac was removed. A cigarette drain was inserted into the opening in front and passed into the retroperitoneal space. The posterior wound was closed in layers and a small cigarette drain placed in the lower angle. Recovery was uneventful, the drains being removed on the fifth day.

The patient was seen one year after leaving hospital and health continued good. The specimen removed showed an enormously dilated kidney pelvis. The normal conformation of the papillæ is flattened and the cortex as well as the medulla, while very thin, are burrowed in every direction by cavities which give the kidney substance a trabeculated appearance. At a distance of one inch below the junction of the pelvis with the kidney there is a narrowing in the ureter, which makes a distinct valve when seen from the inner side. On filling the pocket in the ureter above the obstruction with water none of the fluid passed the stricture. From the outside of the ureter the narrowing was restricted to the lower half of the circumference. There were no anomalous vessels observed, although they were looked for at the time. There were no bands outside the ureter to account for the valve formation. The infolding of the ureter at this point affected its entire thickness.

Comment.—The drainage of the pelvis of the kidney transperitoneally is not to be preferred, but its employment here served admirably and shortened the first operation by minutes when time was valuable. If the posterior peritoneal layer is made to adhere in a complete circle to the anterior layer, the retroperitoneal space may be safely explored or it may be drained by this route. This procedure added no difficulty to the subsequent operation of nephrectomy. No plastic work on the ureter was attempted as the kidney substance was destroyed.

The pyonephrosis is secondary to the congenital stricture of the ureter and the infection of the sac probably only took place at the time the child complained in its present illness. The previous illness, which resulted in a permanent limp, was probably poliomyelitis.

It is most necessary to be certain of the presence of a second kidney before removing one, no matter how diseased. Cystoscopy is usually sufficient, but in horseshoe kidney both ureters may come from the fused organ. Herringham (Kidney Diseases, London, 1912) shows a specimen from St. Bartholomew's Hospital Museum of a horseshoe kidney with two ureters. One-half of this specimen was hydronephrotic.

In the diagnosis, the history of intestinal obstruction confused the issue and megacolon had to be considered, as did tuberculous peritonitis. The urinary findings in ureteral obstruction may, as in this case, give no intimation of the condition present in the kidney. The absence of symptoms pointing to the ureter as the source of the trouble, particularly in an urgent case, makes a definite diagnosis of ureteral stricture before the operation extremely difficult. In the chronic cases the general employment of the cystoscopic examination and catheterization of the ureters, with collargol injection and *x*-ray plates, will aid in clearing up the diagnosis.

POISONING BY SCARLET RED.

By HENRY H. M. LYLE, M.D.,
NEW YORK.
ASSOCIATE SURGEON, ST. LUKE'S HOSPITAL.

The clinical use of the dye scarlet red has amply fulfilled the promises of its early sponsors and is to-day the best epithelial stimulant that we possess. A study of the German literature shows how firmly it is established in that country. In America its warmest advocate is Davis of Johns Hopkins, through whose able efforts scarlet red has become more widely used.

In rare instances scarlet red produces a local wound irritation, a discoloration of the urine, and possibly an albuminuria. It is said that workers in aniline dyes are subjected to bladder irritation and the possibility of the formation of epithelial tumors. Aside from these suggestive hints the literature regarding the general toxic effect of scarlet red is very meager. There is only one reported case, that of Gurbski's; to this case the author wishes to add a personal one.

Gurbski in 1910 published a report on the toxic effect of scarlet red ointment. A child, aged eleven years, was severely burnt by an explosion of turpentine. The burns which were of the second degree involved the lower two-thirds of the right thigh and the entire lower limb to the ankle. Gurbski applied Schmieden's 8 per cent. "amidoazotoluolsalbe." Fifteen hours after the application the patient complained of headache and dizziness. This was followed by violent vomiting and gastralgia, cyanosis of the lips, a low-tension pulse of 110, a temperature of 102.3° and an albuminuria. With the removal of the dressing and the placing of the patient on a milk diet the symptoms disappeared in a few hours. Eight days later the ointment was again employed and similar symptoms appeared with the exception of the albuminuria. Five days later a third dressing produced similar symptoms but the vomiting was less marked. Subsequently the ointment was applied to one-quarter of the wound at a time. No toxic symptoms developed and rapid epidermization followed. Gurbski considered that this case had an especial susceptibility for this preparation, and that the poisoning was due to the amido group in the amidoazotoluol.

The author's case was that of a woman, fifty years old, who was admitted to St. Luke's Hospital February 21, 1912, suffering from extensive burns of the anterior chest, both forearms, and wrists. The burns were caused by exploding benzine, and were treated by the dry method until the sloughs separated. A scarlet red ointment (8 per cent. scarlet red in U. S. P. boric acid ointment) was applied to a small portion of the granulated edges. As the wound reacted kindly the area of application was extended. On the sixteenth day of the employment of the scarlet red ointment the patient complained of headache, dizziness, and general faintness. The following morning she was seized with severe cramp-like pains in the epigastrium, was intensely nauseated, and vomited violently. The pain was accompanied by tenderness in the upper right quadrant of the abdomen, the maximum point being in the region of the pylorus: the temperature rose to 102°; the pulse to 120; the blood count showed a slight leucocytosis; urination was frequent and painful, the urine showing albuminuria but no casts. Despite gastric sedatives and lavage the nausea and vomiting persisted for ten hours. The violent onset coupled with the pain and tenderness in the upper abdomen, suggested the possibility of a duodenal perforation. However the low blood count, the lack of abdominal rigidity, and the peculiar intensity of the nausea pointed to some form of poisoning rather than to a perforation. After the discontinuance of the scarlet red and the employment of repeated stomach and colonic washes the symptoms gradually subsided.

One week later the scarlet red was again applied to a small area, and gradually increased until two-thirds of the circumference was covered. The same toxic symptoms appeared, but of a milder degree, and again disappeared on the withdrawal of the scarlet red. After a second interval of rest the scarlet ointment was applied in a 4 per cent. strength; no further toxic symptoms developed. Throughout the treatment there were no signs of local wound irritation. Four months after admission to the hospital the patient was discharged cured.

In both cases the burns were extensive. In the first case, that of a child, the ointment was applied to a fresh wound and the toxic symptoms developed within a few hours. In the second case the patient was fifty, the ointment was applied to a granulating surface, and the toxic symptoms did not develop until the sixteenth day. The marked features of both cases were the dizziness, the gastralgia, and the intense nausea and vomiting.

Schmieden, commenting on Gurbski's case, emphasized the fact that scarlet red should not be used in fresh wounds, and in large granulating wounds only a thin layer of the ointment should be painted on the edges.

THE PREGNANT WOMAN, TUBERCULOSIS, AND SAFETY.

By DOUGLAS H. STEWART, M.D.,
NEW YORK.

Scientific obstetricians, even if they allow theological teachings to influence their medical practice, will admit the fact that safety to the mother should preponderate against safety to the child, when it is possible to secure but one and that only at the expense of the other.

Suppose a consultation to be held and that two or three standpoints have been stoutly and rightly upheld. Suppose the standpoints to be religious, medical, and diplomatic and hopeless in argument. Is it not simple to cut the knot of this tied up consultation by quietly urging "safety" as the great factor in reaching a determination as to the proper course to be pursued? An appropriate remark might be: "Dr. A's idea of procrastination is 60 per cent. safe. Dr. B's plan is 65, but in Dr. C's plea for immediate

operation we have 70 per cent. of safety to the mother." This scheme or something similar will rarely fail to procure a good-humored and unanimous verdict, and the contestants part with the feeling that the plan adopted is the very best because it is the safest and any other way may or may not be equally sure. Should a woman suffering from tuberculosis become pregnant then a very easy emptying of the uterus would be 90 per cent. safe. On the other hand, allowing her to progress to full term always shortens her life. I would consider her 30 per cent. safe for her first labor, 20 for the second, and 10 for the third, giving figures based on my own experience; but Du Bois states that she "may bear her first child well, her second with difficulty, and the third never." While the 30 per cent. may be increased, but never to 90, because the latter is contingent on absence of demand and drain upon the mother's physical resources, the best we can do is to limit the damage and exhaustion arising from unavoidable conditions which no one may eliminate from the development of a child *in utero*.

It is a downhill road from emesis to delivery with the demand for twelve (or more) pounds of solid material, to be supplied to womb and contents, to be met on the journey. A hydremic or plethero-anemic woman may go the whole distance and endure the pain and strain of parturition at its terminus, but a tubercular anemic, not more anemic but less plethoric than the first, may pause to die because she has not the fee to pass some toll-gate. Her vital resources have been all paid out. I think we can make her safety, say, 60 per cent., but ninety as aforesaid is unattainable. It is just thirty years (Oct. 1, 1882) since I carried my first tuberculous patient to successful labor. Many of the suggestions here set forth were part of my student education; they have been tried and not found wanting, and I would be glad to give credit for them, but unfortunately that is now impossible. For instance, somebody told me if you "have a tuberculous patient, give him the gout." I think it was William Detmold, but am not sure. However, I will give experience and make no attempt at tracing derivations or sources. A Spanish physician told me of the "only wine which would make an appetite," and I do not even recall his name. From the above, it is evident that the rule for dieting the tuberculous mother is as simple as it is important. Make a composite list of the usual sheets for debility, for obesity, and for gout. From the second and third slips remove the word "not" so that the directions will read "Must take." Order the patient to eat anything on the three lists which seems to agree with her. Then make her so hungry that she is ashamed of her appetite, or, in other words, supernourish her.

If she is not prejudiced against wine, Manzanilla will make her hungry. It is a light, bitter sherry. It has proved successful only if bottled in Spain. Wine dealers all assure me that the same wine is imported in casks and bottled in America. It has failed me every time I have been persuaded to try it. Manzanilla is cheap, is also called the "tonic wine of Spain," and there seems to be no choice between different Spanish bottlings. This with creosote, with sulphur, with iodoform, and with ichthyol, in about that order, has always given satisfactory results.

Many experiments finally resulted in 1892 in the following formula: Lysol, one part; ichthyol, ten parts; glycerin, twenty parts, with the wine in addition. Lysol was adopted at first as a substitute for tar (see Ringer's "Therapeutics," 1883); later it was retained because of the enormous appetite which it created. The combination has been found fault with on chemical grounds, incompatibility, etc. It It may be condemned by the chemist, but the usual complaint of the patient is that it makes her eat like a truck-driver, and if she is pregnant and does not gain twenty ounces per week or non-pregnant and does not increase her weight by eight ounces, then I am both surprised and disappointed, and suspect late hours, disobedience of orders, or something similar, which so far has always materialized with cross-examination. The ichthyol was substituted for creosote. Some one told me that it might be so used diluted with equal parts of peppermint water. I have always been afraid that each new bottle opened might contain the irritating sort. But nothing untoward has ever occurred, possibly because I always made the mixture myself. The mixture may be given in drachm doses without fear if well diluted, but that is simply a waste of medicine, as the effect desired appears to be manifested quite as well by half-drachm dosage. The ideal mode of administration is to begin with one drop, increase one drop per dose until thirty drops are attained and hold it there. Drop it into a half-tumblerful of water and take just before each meal, when first sitting down to the table.

Important questions of fresh air, exercise and all expedients of value in tuberculous conditions are taken for granted and omitted from this paper, which deals with a valuable addition to any plan of treatment.

Summary.—The safest procedure is to empty the uterus at the earliest possible moment. If for any reason this must not be done and the child is to be carried to delivery, I have endeavored to show how it may be done. Not safely, no, but with a high percentage of safety.

Mode of Death of the Human Heart.—G. C. Robinson studied this subject by means of the electrocardiograph. He found that in acute infectious diseases cardiac activity sufficient to give a definite record with the electrocardiograph may continue in the human heart for some minutes after clinical death has occurred. In the seven cases described the cardiac activity continued from six to thirty-five minutes after all the usual clinical signs of death had occurred. In four cases the ventricular outlasted the auricular activity; in two cases this was reversed; and in one case the two parts of the heart seemed to cease synchronously. Marked slowing of the rate of cardiac activity always occurred and there was usually distinct delay in the conduction time between auricles and ventricles. Complete dissociation was seen in three cases. Ventricular fibrillation occurred in two cases, in one of which the ventricles again established a regular rhythm. Evidence of auricular fibrillation was never seen. Characteristic changes in the ventricular electrical complex occurred in all cases. They consisted of a decrease in the size of the R-wave and an increase in the size of the T-wave, and a tendency to a fusion of these waves. There was usually but little change in the duration of the ventricular complexes as the cardiac activity gradually ceased. The foregoing observations indicate that when death occurs from an acute infectious disease there is no one point in the human heart which may be considered as the "ultimum moriens."—*Journal of Experimental Medicine.*

MEDICAL RECORD.

THE PITUITARY BODY AND ITS DISORDERS.

THIS subject is one that possesses a peculiar interest. The remarkable additions to the knowledge of the functions of an organ sheltered in one of the most inaccessible parts of the body, and the recognition of its relationship to a large number of morbid conditions, constitute some of the most signal triumphs of modern research. Most wonderful of all is the demonstration of the success attending surgical access to this organ.

No one has made a more thorough study of the experimental and surgical problems associated with the hypophysis than has Harvey Cushing. For this reason the recent volume* in which this worker has set forth the present status of the hypophysis and of its derangements, is one that constitutes a unique addition to medical literature, and chiefly because it details the results of original observation. Few of the many volumes that are annually added to the shelves of the medical library will stand this acid test of originality.

The most remarkable fact about the hypophysis is the variety of avenues through which it has been investigated. The autopsy, the exploratory operation, the observation of cerebral manifestations due to an enlargement of the hypophysis, or to infiltrations of the brain associated with these enlargements, the recognition of the association between diseased conditions of the hypophysis and such clinical entities as gigantism, acromegaly, Fröhlich's syndrome, adiposity, and glycosuria; radiographic studies of the skull and of the acral extremities; and chemical analyses of the urine, the blood, and the cerebrospinal fluid; all these represent the lines of research converging on the hypophysis. It is quite probable, as Cushing points out, that clinically recognizable pituitary disease is at least as common as clinically recognizable thyroid disease, and that in the case of both organs there are low grade functional disorders that are usually unrecognized.

Considerable light is thrown upon the rather confusing subject of dyspituitarism by Cushing's classification of the latter into five clinical groups. The first group includes those cases "in which not only the signs indicating distortion of neighboring structures, but also the symptoms betraying the effects of altered glandular activity are outspoken." In the second group "the neighborhood manifestations are pronounced, but the glandular symptoms are absent or inconspicuous." In the third group are comprised those cases "in which neighborhood manifestations are absent or inconspicuous though glandular symptoms are pronounced and unmistakable." To the fourth group belong "cases in which obvious distant cerebral lesions are accompanied by symptomatic indications of secondary pituitary involvement." The fifth and last group includes those cases "with a polyglandular syndrome in which the functional disturbances on the part of the hypophysis are merely one and not a prominent feature of a general involvement of the ductless glands."

It is important to recognize the fact that deficient and excessive hypophyseal activity produces in each case different clinical manifestations depending on whether the causative condition occurs during childhood or during adult life. Thus, hyperpituitarism during childhood or before the epiphyses are ossified, causes gigantism; when hyperpituitarism occurs later it gives rise to acromegaly. Hypopituitarism occurring in childhood causes adiposity with a persistence of both skeletal and sexual infantilism —which combination is known as Fröhlich's syndrome. When hypopituitarism arises during adult life it causes adiposity with sexual infantilism of the reversive type. An individual may at one time exhibit symtoms of hyperpituitarism and later symptoms of hypopituitarism, and in the transition stage he may show symptoms of both states.

One of the most important recent contributions to the study of the hypophysis has been the discovery by Cushing and his co-workers that hypopituitarism is associated with an increased sugar tolerance. This fact furnishes a diagnostic sign of eminent significance, particularly in the recognition of the possible hypophyseal origin of certain obscure conditions, in the determination of whether or not an hypophyseal overgrowth has undergone involution, and in deciding upon the need of administering hypophysis extract.

Cushing calls attention to the fact that remote intracranial lesions may lead to secondary disturbances in the pituitary body. Thus hypopituitarism may result from the deformation of the pituitary caused by a congenital hydrocephalus. There is cited a case of acromegaly of a year's duration, in which a large unsuspected cerebellar cyst confused the clinical picture. In another case a large endothelioma of the right hemisphere caused hydrops of the right ventricle and hypopituitarism. In this connection the question is raised that some cases of epilepsy may be of hypophyseal origin. An insufficiency of the posterior lobe may cause an undue excitability of the cerebral cortex. In the author's series of forty-three cases there were thirteen patients with existent hypopituitarism who showed epileptiform tendencies. This percentage he regards as too large to be purely accidental. "Many

*"The Pituitary Body and Its Disorders; Clinical States Produced by Disorders of the Hypophysis Cerebri." By Harvey Cushing, M.D., Associate Professor of Surgery, The Johns Hopkins University; Professor of Surgery (Elect) Harvard University. An amplification of the Harvey Lecture for December, 1910. With 319 illustrations. Philadelphia & London: J. B. Lippincott Company, 1910.

individuals," says Cushing, "supposed to be suffering from so-called genuine or essential epilepsy, present manifestations of a nutritional disorder—a tendency to adiposity and a high sugar tolerance coupled with a lowered temperature and pulse rate—closely akin to the constitutional state which characterizes hypophyseal insufficiency. In some of these individuals the administration of hypophyseal extract has served to moderate the seizures from which they previously suffered."

There is nothing in all surgery that seems so forbidding as the operative approach to the pituitary, nevertheless the splendid results obtained by the pioneers in this field justify the more frequent intervention of the surgeon in the class of cases in which an operative procedure holds out some hope of relief. In Cushing's series of forty-three patients sixty-one operations were performed with an operative mortality of 10 per cent. for the entire series. The operation of choice is the transsphenoidal operation through a median inferior nasal opening, reached by a sublabial incision and a submucous resection of the vomer, the turbinates being flattened but not removed. The chief purpose of operation is to afford relief to neighborhood symptoms, to diminish the manifestations of increased intracranial pressure, and to extirpate part of the gland in states of hyperpituitarism. It is suggested that in states of profound hypopituitarism it may be possible to implant a gland from another source.

The work of Cushing upon this frontier of surgery is a rare example of the happy combination of animal experimentation, clinical investigation, and surgical enterprise.

INFANT CONSULTATIONS.

At the Congress on Hygiene and Demography held recently in Washington two important papers were read by Dr. Janet Lane-Claypon of London and Miss Ellen C. Babbitt of New York City respectively, dealing with the movement for the education of mothers in the feeding and caring for their infants, and these have since been supplemented by a paper contributed to the *American Practitioner*, October 15, by Dr. Eric Pritchard of London. Dr. Lane-Claypon is Dr. Pritchard's first assistant in carrying out the work in Marylebone, and her description of the *modus operandi* was excellently given. Miss Babbitt's paper dealt more especially with the care of the expectant mother, which also now comes within the scope of the infant-consultation work at Marylebone.

In the paper by Pritchard a full account is given of the initiation, development, and progress of infant consultations in Marylebone. It is pointed out that in England there are no national or concerted efforts to reduce the high mortality among infants, and the paper in question represents an account of an individual experiment which during the past ten years has been in progress right in the heart of London in one of its most active and thickly populated boroughs. Twelve years ago in Marylebone there was an infant mortality of 190 per thousand births. When Pritchard and his coadjutors began their really serious work the infantile death-rate was 121 per thousand births, reduced from 190 by sanitary reform and sanitary reform alone. In 1906 then "a system of voluntary service in a municipal setting" was inaugurated. At that time an "Infant Consultation" was an experiment in England, and in order that it might prove a success Pritchard visited some of the best-known institutions in Belgium and on the Continent, borrowing from them some of their best points, which he incorporated with a number of new ideas. It would be impossible within the limits of an editorial article to explain the working of the scheme in all its details. Suffice it to say that the system is well organized and comprises health visitors and inspectors, while an important feature of the work is that the history of the infant is closely followed. As for feeding, all methods are used impartially. Whole milk, citrated whole milk, carefully home-modified diluted milk, specially modified milk sold at special dairies, condensed milk, and dried milk are all used, and mothers are taught how to prepare the food extemporaneously. Careful records are kept of the results, but no analysis of these has been made as yet. Breast feeding is, of course, insisted upon whenever possible, and is conducted on the most up-to-date and approved lines. The health visitors always follow up the cases and by periodical visits to the home see that the physician's instructions are carried out.

Owing to the efforts of Dr. Lane-Claypon there has been founded recently in Marylebone an "Association of Infant Consultations and Schools for Mothers." These schools for mothers not only teach mothers how to care for their infants, but also teach mothers and expectant mothers how to care for themselves—a very essential part of the education. The work indeed is mainly educational. So far as Marylebone is concerned, many health visitors and a small number of medical men and women have been educated in the science and requirements of infant feeding, and some degree of instruction has been given to every mother who has given birth to a child in Marylebone and who has stood in need of such assistance.

Such teaching spreads quickly. As Pritchard says, "It becomes, as it were, highly infective." Infant Consultations and Schools for Mothers are springing up almost like mushrooms in all the great cities of Great Britain, with results that so far have been remarkable. As Miss Babbitt showed in her paper there is room for this kind of work in all the big cities of America, specially is instruction required for future mothers, together with insistence from the educational standpoint upon the necessity for breast feeding. The tendency of mothers the world over appears to be to avoid breast feeding, and the tendency is to some extent encouraged by the multiplicity of artificial foods and to a lesser extent by the opportunities afforded for obtaining modified milks. The first aim and main object of infant consultations and schools for mothers are to preach the gospel of breast feeding, and therefore both should enlist the earnest assistance of all those who have the welfare of the human race at heart. It is encouraging to learn from Miss Babbitt that the movement in this direction is rapid in many cities of this continent.

THE CHILD AND THE PUBLIC SCHOOL.

The hydra-headed evil of child labor, which thrives wherever human greed and human poverty furnish the necessary pabulum, still flourishes, though not to the extent of a former generation, in the factory, the mine, and the tenement workshop. But the rule of the rod and the other tyrannies of the classroom have given way before the spirit of enlightenment that characterizes modern public school education. Nevertheless in the very complexity of the educational curriculum that has been evolved to meet the demands of the present day, one perceives the growth of an element of danger in the excessive strain to which the young children in many schools are being subjected.

The large public school of our cities presents for solution some of the most perplexing problems. The housing within one building of sometimes as many as three thousand children and then providing for their various needs entails a host of difficulties, of whose magnitude the inexpert public can have but little comprehension. The main drawback of the simultaneous teaching of large groups of children is the fact that in many instances this practice operates as an injustice to the individual child. The latter is all but sacrificed to the complex mechanical needs of a system.

It must be admitted that the public schools have made vast strides within the past decade. The introduction of physical and of manual training; the increasing attention paid to studies that develop the appreciation for art, literature, and music; the recognition of the importance of detecting the physical defects of school children; the improvements in the mechanical features of school life; the inauguration of open-air classrooms, school lunches, and special classes for defective children—all these point to a phenomenal progress in public school methods. The three "R's" of the modern school make for reason, righteousness, and recreation. There can be little doubt that most children of to-day enjoy their schoolwork.

But every new addition to the scope and program of the school has increased certain dangers that have always been associated with public school education. The crowding of the school syllabus imposes upon the teachers the impossible task of accomplishing the work imposed by the supervising officers without overburdening their young charges. The result is that the entire system of teaching force and pupils is subjected to the blighting effects of the administrative machinery. Individuality is crushed, a premium is placed upon the numerical demonstration of results obtained, and the efficiency of the entire school system is apt to be gauged by its material resources and its demands upon the budget.

The chief danger of the complex elaboration of the modern school is that it overlooks the infinitely more complex organization of the pupil. It is solicitous about the child's tonsils and adenoids, but it is oblivious to the delicate texture of the immature nervous organism. It inaugurates fresh-air classrooms and instals complex ventilating systems, but it does not hesitate to overcrowd many rooms beyond the limits of respiratory safety. It is quick to point out the bad effects of malnutrition, but it does little to relieve the moral and emotional starvation that is so common among the children. It readily discerns the pallid cheek and the tired eye, but ignores the fact that in many instances these are the result of the assignment of excessive home lessons. School authorities are prone to shift the entire responsibility upon the supposedly neglectful parent, and seem to forget that many of the ailments of the child and adolescent are the direct or indirect result of the stresses of school life.

The priceless influence of personal contact between teacher and pupil has all but vanished in the complex superstructure of modern public education. The inexorable grind of daily school tasks eliminates the cultivation of those graces of manner and refinements of emotion that are no less indispensable than the purely formal attainments. "Sweetness and light," the criteria of culture, find little place among the maze of studies that must be mastered.

SOME THERAPEUTIC APPLICATIONS OF HEXAMETHYLENAMINE.

Formaldehyde has long been known as a most useful antiseptic, and it has been practically employed on a large scale for purposes of disinfection. In the form of hexamethylenamine it has been shown to exhibit a similar activity in the human body when administered both therapeutically and prophylactically. Thus employed hexamethylenamine is found within a short time in the form of its decomposition-product, formaldehyde, in almost all of the bodily fluids. Under such conditions it has been demonstrated in the urine, the bile, the pancreatic juice, the saliva, the milk, the cerebrospinal fluid, in synovial, pleural, and peritoneal effusions, and in the circulating blood. On the basis of this knowledge the drug has been employed as both a therapeutic and a prophylactic agent in a wide range or disorders, and the results are detailed in an interesting communication by Dr. S. J. Crowe (Bulletin of the Johns Hopkins Hospital, September, 1912), who has had a considerable experience, both experimental and clinical, along these lines.

With a view of preventing intracranial infection hexamethylenamine was administered in thirty-five consecutive cases of fracture at the base of the skull, and in none did such a complication arise, whereas among thirty-five earlier cases of similar character treated without this preparation meningeal infection of one kind or another developed in nine. Again, of twelve cases of fracture of the cranial vault treated with hexamethylenamine two terminated fatally from meningitis, and recovery ensued in ten, while of eight cases of similar character treated without the drug death occurred as a result of infection in four. The drug proved of service also in a series of forty cases of hypophysis-tumor in which incision of the dura covering the gland was undertaken through the nose and sphenoid sinus; in cases of cerebrospinal fistulæ, in the presence of infections of the ear and of the nose, and in cases of poliomy-

elitis. It has further been employed in the treatment of other disorders of the respiratory tract, and in cases of epidemic cerebrospinal meningitis and of experimental meningitis. As a rule, the drug can be administered to adults in amounts of from 60 to 120 grains and more daily for four or five days or longer, without fear of complication, provided it be given in divided doses at frequent intervals and well diluted; or it may be dissolved in salt solution and allowed slowly to flow into the bowel drop by drop. In susceptible persons, however, even small amounts may cause painful micturition and hematuria and perhaps a cutaneous eruption.

Rationale of the Action of Yohimbin.

This substance has now been in common use in both human and veterinary practice for many years, and although it is not a pharmacoplial remedy, it is not a secret remedy and there seems to be no reason why it should not receive recognition in time as an official drug. Numerous articles continue to appear in regard to its pharmacodynamics, indications, overaction, and collateral action. The view that it exerts a selective action on the lumbar cord has doubtless been abandoned, for it is much more likely that it is able to affect the tonus of the smooth muscle in some manner, something after the manner of ergot and pituitrin. In the *Deutsche medizinische Wochenschrift* for October 17, Fritsch, in a brief communication, expresses his conviction that in some subjects it acts directly upon the involuntary musculature of the genitourinary tract. Such influence as it may possess over *protentia cœundi* may be explained by a tonic action upon the bladder, prostate, and neighboring organs. The author has been testing it as a general nerve roborant, with especial reference to commencing senility. He warns that in one instance it appeared to determine cardiac oppresson, so that the doses should not be too large.

The Clinical Congress of Surgeons.

The third annual session of the Clinical Congress of Surgeons of North America, held in New York during the week just closing, was in every respect an unqualified success and will undoubtedly rank as one of the most important events in the medical year. The attendance was notable, not only for its size (over 2,600 having been registered up to Thursday of this week), but also for the high standing of those constituting it, and the enthusiasm was in proportion to the attendance. The amount of clinical work, including laboratory demonstrations, done during the week was enormous, and the papers read each evening, a full report of which is published elsewhere in this issue, were of a superior order. Seldom, if ever, has any organization established itself so firmly as a permanent institution in so short a time, and much credit is due those who conceived and have so triumphantly carried out this idea of a clinical surgical congress.

Modern Rifle Wounds.—Professor Jedlicka of the University of Prague recently lectured in Vienna on his experiences in the campaign in the Balkan Peninsula. He considers the modern rifle a weapon which disables but does not kill. Of 670 wounded whom he had treated only two suffered amputation, and the rapid healing of the wounds was very remarkable.

News of the Week.

Mental Hygiene Conference.—The opening session of the Conference on Mental Hygiene was held in the great hall of the College of the City of New York on November 8, President John Finley of the college welcoming the members. Addresses were made by Dr. Lewellys F. Barker of Johns Hopkins University, president of the National Committee for Mental Hygiene, on "Unsoundness of Mind: A National Handicap"; by Dr. James V. May of the New York State Hospital Commission, and by Dr. George Canfield of the State Charities Aid Association. The exhibit in connection with the conference was opened on November 9, and both it and the sessions of the conference were continued during the week.

Resignations from Fordham.—Dr. James J. Walsh, dean and professor of nervous diseases and the history of medicine in the Fordham University College of Medicine, New York, together with seven other members of the teaching staff, resigned from the school on November 8, the resignations being accepted by the president of the University. It is said that the resignations were due to the failure of the university authorities to comply with certain demands of the American Medical Association in order to keep the school in Class A of medical colleges. This, however, is in turn denied by the university authorities, who have appointed Dr. William P. Healy, clinical professor of surgery, to succeed Dr. Walsh as dean, and have declared their intention of carrying on the school on its present lines. Those who have resigned, in addition to Dr. Walsh, are the following: Dr. V. E. Sorapure, professor of clinical medicine; Dr. William J. M. A. Maloney, professor of nervous diseases and physician-in-chief of the neurological hospital; Dr. Isidor Abrahamson, clinical professor of neurology; Dr. Horatio Storer, consultant director of museums; Dr. Benjamin Tilton, clinical professor of surgery; Dr. Siegfried Wachsmann, clinical professor of medicine, and Dr. Charles A. Elsberg, professor of neurological surgery.

Public Clinics.—The Department of Public Charities of the City of New York has issued the following orders and has communicated them to the Academy of Medicine. That on and after October 1, 1912, all clinics held in the amphitheater and operating rooms of the hospitals of the Department of Public Charities shall be open to duly licensed graduates in medicine and to the students in all regularly organized medical schools and colleges, and that tickets shall be issued by the secretary of the Department of Public Charities for distribution by the secretaries of the several medical schools and societies of New York, which will entitle the registered holders thereof to admission to these clinics.

Personal.—Dr. S. Adolphus Knopf of New York has been elected honorary president of the Medical Board of the Bruchesi Institute of Tuberculosis of Montreal, Canada, and consulting physician to the Institute.

Dr. M. Neustaedter writes, referring to a recent statement in the Medical Record crediting Dr. Simon Flexner with the dust theory of the transmission of poliomyelitis, that he was the author of this theory and that it was accepted by Dr. Flexner only after Dr. Neustaedter had proved its correctness.

III International Congress of Diseases of Occupation.—Arrangements are being made for

holding the meetings of this congress in Vienna, Austria, during the autumn of 1914. The program is in the hands of Dr. L. Teleky, Wien IX, Türkenstrasse 23, from whom particulars may be obtained.

Memorial to Dr. Roosa.—At the New York Post-Graduate Medical School and Hospital, on the afternoon of November 7, a memorial to the late Dr. D. B. St. John Roosa was unveiled with appropriate ceremonies.

Public Health Course.—The University of Kansas School of Medicine announces a course in public health and preventive medicine which will be required of candidates for the degree of M.D. This is the first time such a course has been made obligatory in a medical school.

Public Mausoleum.—The trustees of Fairmount Cemetery, Newark, N. J., are considering the erection of a mausoleum large enough to hold 1,000 bodies, in which crypts and vaults will be sold to the public.

Plague in Venezuela.—The State Department at Washington received notice on November 4 of the occurrence of a case of bubonic plague at La Guayra, Venezuela.

Disease in Constantinople.—It is reported from Constantinople that typhus fever, smallpox, and Asiatic cholera are prevailing there to an alarming extent among the citizens, the refugees from outlying towns, and the returning soldiers, whose resistance has been broken down by misery, starvation, and the sting of defeat. Sanitary regulations are no longer enforced and there is every reason to fear that all three of these diseases will soon become epidemic.

Centenarian Dead.—Mrs. Emma Rock, a negress of Red Bank, N. J., died on November 4, at the age of 104 years.

Vital Statistics.—During the week ending November 2 there were in New York City only 222 deaths of children under one year of age, the lowest number recorded for any week so far this year. At the first of November the total number of deaths of infants during the year was 570 less than the total for the same period of 1911, according to the records of the Babies' Welfare Association.

In the State of New Jersey there were during the month ending October 10, a total for all ages of 2,990 deaths, of which 328 were due to tuberculosis. This total is 60 less than the total for the preceding month, and 98 less than the average number of deaths per month during the year.

Free Pulmotor Service.—The Consolidated Gas Company of New York has notified all the hospitals of Manhattan and the Bronx that its emergency ambulances equipped with pulmotors for resuscitating persons overcome by gas, smoke, or electric shock are at the disposal of physicians who wish to use them, and that calls sent to the stations where the apparatus is kept will be answered immediately.

Harvey Society Lecture.—The fourth lecture of the Harvey Society for 1912-1913 will be given by Prof. George Neil Stewart of the Department of Experimental Medicine, Western Reserve University, on November 23, at 8.30, at the New York Academy of Medicine. The subject will be: "The Rate of Blood Flow and the Vasomotor Reflexes in Disease.

Visiting Surgeons Entertained in Brooklyn.—The University Club of Brooklyn, N. Y., celebrated "Physicians' Night" on November 9, by entertaining 300 surgeons at dinner at its club house. The guests of honor were Dr. William J. Mayo of Rochester, Minn.; Dr. John B. Murphy of Chicago, Dr. Edward Martin of Philadelphia, Dr. George W. Crile of Cleveland, O.; Dr. Robert C. Coffey of Portland, Ore.; Dr. A. J. Ochsner of Chicago, and Dr. W. Arbuthnot Lane of London.

Dr. Jacobi Resigns.—After twenty-three years of continuous service Dr. Abraham Jacobi has offered his resignation as a trustee of the New York Academy of Medicine, and has insisted that it be accepted. Dr. Jacobi was elected to membership in the academy in June, 1857, served as president from 1885 to 1889, and has been a trustee ever since he retired from the presidency. His entire term of membership extends over fifty-six years and his services to the academy during that time are incalculable. Action on the resignation will be taken at a later meeting.

Associated Out-Patient Clinics.—The organization meeting of the twenty-eight dispensaries in New York, which have consented to join the Associated Out-Patient Clinics, will be held on Wednesday evening, November 20, at 8.15 in Room 21 of the Academy of Medicine.

Charitable Gifts.—By the will of the late Mrs. Melinda Hasbrouck of New York, a bequest of $10,000 is left to Stony Wold Sanatorium, Lake Kushaqua, N. Y.

Mt. Sinai Hospital, New York, receives $5,000 and the Montefiore Home $2,000 by the will of the late Nathan F. Straus of New York.

By the will of the late Mary Packer Cummings of Mauch Chunk, Pa., all the real estate owned by her at Sayre, Pa., is left to the Robert Packer Hospital of that place. In addition, the sum of $10,000 is bequeathed to the Protestant Episcopal Church of Delaware in trust for the benefit of St. Michael's Day Nursery and Hospital for Babies at Wilmington, and residuary bequests of $15,000 each are made to the Protestant Episcopal Hospital of Philadelphia and the Rush Hospital Consumptives of Philadelphia.

Northern Medical Society.—A meeting of this society will be held on Monday, November 18, in the Bronx Hospital Dispensary Building, 1385 Fulton Avenue, near 170th Street, New York. Papers will be presented by Drs. A. L. Soresi, William J. Robinson, Leo Buerger, and William S. Gottheil. The profession is cordially invited to attend.

American Sanatorium Association.—The next meeting of this Association will be held at the Montefiore Home Country Sanitarium, December 7, 1912.

Army Medical School.—Surgeon General Torney of the United States Army has submitted an estimate of $350,000 for the construction of buildings for the use of the Army Medical School, which now rents its quarters. It is proposed to place the school on the same tract of land with the Walter Reed General Hospital near Brightwood, in order that there may be a mutual exchange of advantages.

Kentucky State Medical Association.—At the annual meeting held in Louisville the election on October 31 resulted as follows: *President,* Dr. William Owen Roberts, Louisville; *Vice-Presidents,* Dr. J. H. Hendron, Cary; Dr. T. C. Holloway, Lexington; Dr. J. Paul Keith, Hopkinsville; *Secretary,* Dr. A. T. McCormack, Bowling Green; *Orator in Medicine,* Dr. T. Atchison Frazer, Marion; *Orator in Surgery,* Dr. Wilford E. Senour, Bellevue.

Ottawa (Can.) Medical Society.—At a meeting of this society held in St. Luke's Hospital on October 25, the following officers were elected for

the coming year: *President*, Dr. Charles W. Gorrell; *Vice-Presidents*, Dr. Campbell Laidlaw and Dr. Neil McLeod; *Secretary*, Dr. A. F. McLaren; *Treasurer*, Dr. J. Harold Alford.

Washington Parish (La.) Medical Society.—The organization of this society was perfected recently by the election of the following officers: *President*, Dr. Herbert Claiborne Cole, Bogalusa; *Secretary*, Dr. Joseph Latamore Brock, Franklinton.

Washington County (Ia.) Medical Society.—At the annual meeting held in Washington on October 25, the following officers were elected for the ensuing year: *President*, Dr. James C. Boice, Washington; *Vice-President*, Dr. William Henry McLaughlin, Riverside; *Secretary*, Dr. Clyde A. Boice, Washington; *Censor*, Dr. Henry C. Hull, Washington.

American Association of Clinical Research.—The fourth annual meeting of this association was held in New York on November 10, when the following officers were elected: *President*, Dr. Frank H. Blackmarr, Chicago; *Vice-Presidents*, Dr. Leonard K. Hirshberg, Baltimore, and Dr. Alice Conklin, Chicago; *Secretary*, Dr. James Krauss, Boston; *Registrar*, Dr. S. R. Klein, New York.

Obituary Notes.—Dr. William Frederick Rex of Brooklyn, a graduate of the New York College of Pharmacy and of the Long Island College Hospital, Brooklyn, in 1905, a member of the New York State and Kings County Medical Societies, and of the American Medical Association, and assistant surgeon to the Williamsburg Hospital, and the Bushwick and East Brooklyn Dispensaries, died at his home on November 1, aged 31 years.

Dr. Samuel Charles Emley of Kansas City, Mo., a graduate of the Rush College, Chicago, in 1902, a member of the American Medical Association and of the Missouri State and Jackson County Medical Societies, associate professor of pathology and bacteriology in the University of Kansas School of Medicine since 1905, and formerly in charge of the tuberculosis exhibit of the Missouri State Board of Health, died at his home on October 16, after a long illness, aged 38 years.

Dr. Joseph F. Land of New York, a graduate of the Dartmouth Medical School, Hanover, N. H. in 1876, a veteran of the Civil War, and a member of the American Institute of Homeopathy, the New York State Homeopathic Medical Society, and the Academy of Pathological Science, died at the home of his son in Erie, Pa., on October 29, aged 74 years.

Dr. William Henry Harlin, retired, of Oceanport, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1862, and a veteran of the Civil War, having been present at the attack of Fort Sumter, died at his home on October 27, aged 72 years.

Dr. Erastus M. Ward of Rosedale, Mo., a graduate of the College of Physicians and Surgeons, Keokuk, in 1877, died recently at his home, aged 70 years.

Dr. George W. Nuckolls, retired, of Minneapolis, Minn., a graduate of the Rush Medical College, Chicago, in 1881, died at his home after a long illness on October 19, aged 69 years.

Dr. William H. George, retired, of McPherson, Kansas, a graduate of the University of Michigan, Department of Medicine and Surgery, in 1869, died in the McPherson Hospital following an operation for appendicitis, on October 19, aged 67 years.

Dr. William Jones of Portlaand, Ore., a graduate of the Cooper Medical College, San Francisco, San Francisco, in 1878, a meember of the Oregon State and Multnomah County Medical Societies, and a former president of each, senior surgeon at St. Vincent's Hospital, Portland, and emeritus professor of clinical surgery in the Medical Department of the University of Oregon, died at his home after a brief illness, on October 20, aged 59 years.

Dr. Joseph Pfeiffer of New York, a graduate of the University of Giessen, Germany, in 1853, and a member of the New York State and County Medical Societies, died at his home on October 31, aged 85 years.

Dr. Lewis J. Davis of Watertown, N. Y., a graduate of the University and Bellevue Hospital Medical College, New York, in 1899, died suddenly in New York City on November 3, aged 45 years.

Dr. Marietta H. C. Woodruff of Boonton, N. J., a graduate of the New York Medical College and Hospital for Women in 1874, died at her home on November 6.

Dr. David H. Agan of New York, a graduate of the Bellevue Hospital Medical College in 1879 and a member of the New York State and County Medical Societies, died at his home on November 4, aged 64 years.

Dr. Clarence A. Baker of Yaphank, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1885, a member of the Association of Railroad Surgeons of New York and New England, and of the Associated Physicians of Long Island, health officer of the town of Brookhaven, and county physician, died at his home on November 8, aged 50 years.

Dr. Henry G. Small of Brooklyn, N. Y., a graduate of the College of Physicians and Surgeons, New York, in 1874, died at his home on November 8, aged 60 years.

Dr. Joseph C. Pickard of Chicago, Ill., a graduate of the Rush Medical College, Chicago, in 1887, and a member of the Illinois State and Cook County Medical Societies, died at his home on October 31, aged 70 years.

Dr. Charles W. Oviatt of Oshkosh, Wis., a graduate of the University of Illinois, College of Medicine, in 1887, and a member of the American Medical Association, the Wisconsin State and Winnebago County Medical Societies, the American Surgical Association, and the Western Surgical Association, died at his home on November 1, aged 67 years.

Correspondence.

A SUBSTITUTE FOR FRESH AIR.

To the Editor of the Medical Record:

Sir:—To offer a substitute for fresh air would indicate the height of temerity; it would seem as absurd as to propose a substitute for food. The report of the Practitioners' Society in Medical Record of November 2 contains a paper by Dr. John W. Brannan on the "Prophylactic and Therapeutic Value of Fresh Air in Schools and Hospitals." It reproduces fully many valuable data and the logical deductions which the doctor's fine opportunity for observations have enabled him to make. The most obvious facts are often the most neglected, as I have had cause to realize in connection with my propaganda for Hydrotherapy and Public Cleansing Baths. That the latter are now recognized universally and adopted at great finan-

cial outlay, while the former still requires constant effort to overcome prejudice, simply demonstrates that medical men are *sui generis* in their moss-grown, falsely termed, Conservatism. As a remedial agent water arose coeval with bloodletting and is to-day used in most German clinics and taught more or less in all medical schools, while bloodletting is barely mentioned, despite the fact that it was the ruling remedy for 2,000 years during which water slumbered and almost died. This therapeutic agent though everywhere obtainable is neglected, while polypharmacy is now rampant and new drugs are taken up with an avidity unsurpassed in the history of Medicine. Strange disregard of the teachings of History! It is hoped that Dr. Brannan's paper will be widely read and that fresh air may become a universal remedial agent, despite its familiarity and accessibility.

This much to defend myself against any possible charge that I would counsel the abandonment of this agent which like water surpasses most renowned drugs. On occasion, when owing to prejudice, fear of taking cold, or lack of facilities, the proposed substitute is advised. In this matter clinical observation has preceded theoretical, scientific explanation of its rationale, as it has done with water and with cinchona, digitalis, and others. The improvement of patients exposed to the action of fresh air is very properly ascribed to stimulation of the vasomotor centers on the skin of the face and the mucous membrane of the nose. I may be permitted to add that this is precisely the action of fresh water.

Hitherto it would almost have been heresy to have claimed that the benefit from fresh air for healthy and sick people is due to anything else but the increased amount of oxygen in the "pure air." In an excellent paper on "the unknown factors in the ill effects of bad ventilation," read at the Congress on Hygiene, Dr. Yandell Henderson said positively that "the ill effects of bad ventilation cannot be due to lack of oxygen. It is probable they are not due to any considerable degree of excess of CO_2. The idea that they are due to some poisonous substance contained in the expired air has in recent years been regarded as untenable. The recent investigations of Hill in England and Fluegge in Germany make it highly probable that the effects of fresh air or vitiated air are brought about not by direct aciton upon the lungs but *indirectly through the skin.* It appears probable that the temperature and moisture of the air surrounding the body are the essential elements. The condition of the skin exerts a potent influence upon the lungs. This may be in part a vasomotor reflex acting upon the pulmonary circulation. The evidence accumulated during recent years indicates that that the lungs are not mere passive organs through which gases diffuse as through nonliving membranes—under certain conditions they secrete oxygen into the blood. The evidence available, although still far from complete, suggests that *these pulmonary activities are indirectly but powerfully influenced through conditions affecting the skin, and that it is in this manner that ventilation influences both.*"

The practical application of these views may be of great value in therapeutics. The experiment of Fluegge were made on himself and seven students in a properly constructed room three meters square. Three electric fans were secured to the ceiling and an electric stove to raise the temperature. It was found that when the temperature of the room was raised to 82° the experimenters began to suffer the usual ill effects of rebreathed air; when these effects could no longer be borne the fans were turned on with relief from all symptoms that were formerly regarded as due to increase of CO_2. Hill's experiment with himself and another person confirmed Fluegge's result: he also had a bag containing CO_2 emptied into the room, without an appreciable increase of the distressing effects. The fans removed the latter.

Now these observations would serve as a lesson to teach us to compensate for air vitiation by promoting the circulation of the air in rooms to which fresh air cannot be admitted in sufficient quantities. I have already advised this process in a room which is frequented by many and in which the air "feels close," despite the fact that artificial ventilation supplies thorough "fresh air renewal," according to the engineer in charge. It is found that whenever the fans are turned on the air "feels fresh" for some time; when they are quiet the room feels stuffy. *This experience proves that it is not the absence of fresh air which causes unpleasant effects but the absence of air currents.*

The introduction of fans, which are now so easily obtained, would be a great improvement in hospital and schoolroom construction, as well as in private houses, especially in rooms used for patients suffering from infectious diseases. It would be wise to make control experiments to ascertain the effect of outdoor treatment compared to indoor treatment with fans. Theoretically the substitution of the former by the latter is sound. I would not wish, however, to be understood as advocating this procedure when an ample supply of fresh air is available. And even under these conditions I should favor the addition of fans to enhance the refreshing action. In my lectures on the physiology of the skin I have laid stress upon this newly discovered action of air currents as vasomotor stimulants, and cite them as being analogous to the vasomotor action of water below skin temperature, which, being applied to much larger surfaces, is far more powerful, especially since water conveys temperature to the skin twenty-seven times more rapidly than air. As this may be regarded as a theoretical statement, I would suggest to any doubter to arrange the temperature of the bathroom at 70° F., and to fill the bathtub with water of precisely the same temperature. The air at 70° would be found comfortable by the nude skin, while the water of 70° will be found cool and soon chilliness will ensue. There is a rational basis for hydrotherapy as there is now found to be of aerotherapy. Both are based upon vasomotor action, but water acts upon larger areas of nerve terminals. Tuberculosis specialists and others may well hearken to the suggestions given in the MEDICAL RECORD of July 17, 1912—"The External Use of Water for Enhancing Resistance in Tuberculosis"—and accept the wise dictum of Adolphus Knopf, "Hydrotherapy comes next to Aerotherapy."

SIMON BARUCH, M.D.

51 WEST SEVENTIETH STREET, November 1, 1912.

AGAR TUBES IN THE DETERMINATION OF THE PANCREATIC FERMENTS.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In my recent paper on agar tubes for the determination of the pancreatic ferments, published in the MEDICAL RECORD, October 12, 1912, I mentioned

the desirability of having a specific indicator for the steapsin which would not be influenced by alkaline solutions. Nile blue sulphate (diethyldiamidonaphthophenazoxonium sulphate) has been used lately by Lohrisch (*Archiv. f. Verdauungskr.*, 1912, p. 636) as a specific stain for fat in examination of feces and gastric contents; neutral fats assume a red color, while fatty acids become blue.

This statement I can fully corroborate. The Nile blue sulphate I now employ for the steapsin determination of pancreatic fluids by the agar tube method. The agar mass for filling the tubes is prepared as follows:

Olive oil.....25 gm.
Agar-agar .....2 gm.
Solution Nile blue sulphate (1 -:- 2000), ad. 100 gm.

The olive oil Nile blue tube, which has a violet tint, becomes blue at the end when steapsin is present, otherwise it remains unchanged or becomes slightly purple. The amount of the agar column in millimeters turning blue represents the approximate quantity of the fat-splitting ferment. The agar tubes for the estimation of the pancreatic ferments can be made in the laboratory or obtained from Eimer & Amend, New York.

MAX EINHORN, M.D.
20 EAST SIXTY-THIRD STREET.

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

THE PLAGUE—MOSQUITOS—MALARIA—A VICTORY OF SANITATION—PERSONAL.

MANILA, P. I., September 28, 1912.

THE plague situation in the Philippine Islands remains but little changed. An additional case occurred at Iloilo on September 15 in a person who is believed to have been in close contact with the inmates of the house in which five cases have already occurred. This makes a total of 8 cases with 8 deaths at Iloilo. On September 23 another case was found in Manila, this being the first since August 22. This last case occurred in the person of a Filipino, a cochero (coachman), who lived in the loft of a stable located in a lumber yard at the corner of Calles Magdalena and Salazar. There are probably forty or fifty other persons who live in this same lumber yard, under similarly poor conditions, but none of these, so far, have shown any evidence of plague. The neighbors report that the rats in the lumber yard are very numerous, but no dead rats have been found and careful laboratory examinations made of about 500 rats caught in the yard and vicinity during the past week have failed to show any evidence of plague among them. This case occurred in the same general section of the city as the cases heretofore reported, being some five blocks removed from the case on Calle Poblete. The neighborhood is a particularly insanitary one, owing to its being in a lumber and mill section, and inhabited by persons who live under most primitive conditions, and among whom it is most difficult to enforce garbage regulations. Guards have been placed all through this neighborhood and especial pains have been taken to insist upon the use of garbage cans so that the rats will be compelled to come to the rat-traps and rat-bane for their food.

Soon after the onset of the rains, in July, there was a rapid diminution in the number of mosquitos which afflict man, in Manila and vicinity. As the measures for eradicating mosquitos are the same now as they were immediately preceding the period in July that the large increase in their number took place, it will be seen that the theory that the unusually high June tides were responsible, by causing the innumerable salt-water pockets, was probably the correct one. Ordinarily, the salt-water mosquitos in Manila do not attack man, but this increased number of breeding places produced mosquitos in such numbers that, in order to obtain food, they did attack man. At all events, Manila is practically free at the present time from biting mosquitos, and it is possible to sit on verandas almost anywhere in the city without being annoyed.

A perusal of the statistics of the Bureau of Health for the fiscal year ended June 30, 1912, showed that in twenty-nine provinces there were 24,339 deaths attributed to malarial fever. A determined effort is being made to reduce the incidence of this disease in the future by the free distribution of enormous quantities of quinine and by educational campaigns carried out principally through schools in the provinces. The constant extension of commercial enterprises throughout the Islands is also becoming an important factor; not only in the spread of malaria, but also upon its successful control will largely depend the success of some of these commercial ventures. For instance, there has been a very extensive outbreak of malarial fever among the employees of the company engaged in the production of sugar on the San Jose Estate and vicinity, in Mindoro. At first there was a marked disinclination on the part of those in charge of these companies to take adequate sanitary measures to control the malaria. This caused many of those sick with malaria to leave and return to their homes, and, in many instances, they infected regions heretofore free from the disease.

Just what it is possible for modern sanitation to accomplish in this direction is well shown by the success which has attended the Government's efforts at the Iwahig Penal Colony on the Island of Palawan. At the time that the Penal Colony was begun this was notoriously one of the most insalubrious sections of the Islands; a death rate of over 200 per thousand occurred soon after the first prisoners were sent there. Before American occupation several Spanish sugar companies met financial ruin owing to the laborers dying of malaria. Quinine was distributed, in prophylactic doses, to all inmates, and steps were taken to drain or fill lowlands, the use of mosquito nets was insisted upon, and grass and other foliage which formed harboring places in the vicinity of houses was removed. Upon completion of these measures the death rate fell to approximately 16 per thousand, which is a rate which will compare favorably with the most healthy sections of the Philippine Islands, and perhaps even with those in temperate zones.

Mr. Edouard Nyssans, Administrator of Civil Hospitals of Belgium, has been a visitor in the city of Manila, and among other things has made an inspection of the new Philippine General Hospital and has expressed his high approval of the type of construction and the method of administration.

Dr. W. E. Musgrave, who recently went to Japan for his health, has returned, recovered, and has again resumed his duties as dean of the College of Medicine and Surgery.

Dr. H. E. Stafford, one of the oldest practising physicians in the Philippines, was recently stricken with appendicitis, from which he is now well on the road to recovery.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

MEETING OF THE ROYAL INSTITUTE OF PUBLIC HEALTH—GOVERNMENTAL MEASURES FOR RESEARCH IN INFECTIOUS DISEASES—INFECTIOUS DISEASES AND THEIR CONTROL IN LONDON—A CENTRAL BUREAU FOR MEDICAL LITERATURE—MODES OF LITERARY RESEARCH.

BERLIN, September 15, 1912.

A SPECTACLE quite unusual even to the learned classes of Berlin was presented in the large auditorium of the upper house of parliament on July 25. Brilliant academic gowns were worn by the distinguished men who came from far and wide to attend the annual meeting of the Royal Institute of Public Health, which parted from its former custom in holding the meeting this year in Berlin. The object was to acquire first hand information of the public hygienic measures of Germany and also to bring into closer personal relationship the public health workers of both countries. The different sections were as follows: (1) State medicine under the presidency of Sir T. Clifford Allbut; (2) bacteriology and comparative pathology, presided over by Prof. Sims Woodhead of Cambridge; (3) the hygiene of childhood and of the school, presided over by Sir James Crichton-Browne of Edinburgh; (4) marine, military, and tropical hygiene, under the presidency of Sir Ronald Ross; (5) municipal hygiene and hygienic technique, under the presidency of P. C. Cowan. There were read 150 papers, among which were many contributed by German authors; many hygienic establishments, particularly hospitals and sanatoria, were visited, and many social functions tended to knit the bonds of good-fellowship between the English and the German members.

The opening address was delivered by the president of the society, Earl Beauchamp, Minister of Public Works in London. The governmental regulations for the investigation and experimental control of the infectious diseases are much better in Germany than in England, but in the practical campaign against the infectious diseases England is ahead of Germany. London has for this purpose fourteen hospitals, containing a total of 8,568 beds. The mortality from scarlet fever has fallen from 13.5 to 1.9 per cent.; the mortality from diphtheria has fallen from 40.7 to 8.44 per cent.; the typhoid fever mortality has fallen from 21.3 to 14.3 per cent.; while that from smallpox has fallen from 20.8 to 15.7 per cent. All these figures pertain to a period of about forty years. Ten years ago of every 10,000 inhabitants of London there were 4 cases of scarlet fever; in 1911 there were 2.3 cases. The morbidity from diphtheria fell from 2.6 to 1.6, and that from typhoid fever fell from 0.7 to 0.23. In 1884 there were provided floating hospitals at some distance from London. In these all cases of smallpox were isolated. Since that year the incidence of smallpox diminished; during the past four years there has not been a single fatality from this disease. For the forty-seven years preceding the period of isolation away from the city there occurred annually an average of 1,045 cases.

The ambulance service of London is now entirely provided for by means of automobiles. For the transportation of acute cases there are 35 ambulances, of which 16 are provided with 21 beds. Ten ambulances are set aside for the conveyance of convalescents and discharged patients. The speaker next alluded to the government's provisions for the sanatorium treatment of tuberculosis, and to the various English institutions for the study of tropical diseases, and closed with a eulogy of the great German hygienists, Koch and Pettenkofer.

A short time ago there was established in Berlin a central bureau for research in medical literature. It is supervised by Chief of Staff Dr. Beyer, and a number of physicians who look after the special subjects. The mode and purpose of the organization are described by the director as follows: The modern enormous expansion of medican literature makes it impossible for the general practitioner, except in certain rare instances, to keep in touch with the latest contributions to medical science. The time has arrived when the investigator, the clinician, and the practising physician should avail themselves of the services of a literary expert. The objection may be urged that the latter may not be able to meet in every instance the requirements of the author of a theme, but as the work goes on the two may cooperate to produce a satisfactory result. The desultory reading of the novice should be replaced by the methodical work of the literary bureau. Older and busier practitioners will appreciate the services of the latter institution by being provided with those articles which are of special interest to them.

The routine work of the literary worker comprises the following three divisions: (1) The preparation of reports for publication, with reference to new contributions, bibliographies and abstracts. (2) The preparation of reports for individual physicians, including résumé's and surveys. (3) The preparation of translations, tables, indices, and the making of corrections, and other special phases of literary assistance. The medicoliterary bureau of Berlin at Friedenau has as yet undertaken only the first division of this work, in a manner that has aroused universal approval among the profession. An extension of this work is being projected. The plan of the larger bureau is as follows: It should be under the directorship of a physician, with two physicians in charge of each division. One of these will be on the premises, while the other will be in charge of extramural investigations, such as at various libraries and other institutions. An ample compensation is urged for these workers.

2. Prostatic Obstruction.—A. L. Chute believes that the mortality in operations for the relief of prostatic obstruction depends largely on the condition of the kidneys, and that urinary back pressure and the damage and embarrassment this inflicts on the kidneys is the commonest form of renal danger in prostatics. Its importance lies in the fact that a patient may be very near the uremic state without this being evident. The functional tests do not give absolutely definite information as to how near the

uremic state a patient is. The most accurate idea of this is obtained from the symptoms of general toxemia that these patients show; these symptoms are referred to the digestive tract most often, less frequently to the nervous system. What the author terms the "element of embarrassment" in these patients, the element that depends on back pressure alone, is capable of relief. This relief by proper preliminary treatment may be enough to determine the success or failure of operation. The endeavor in these patients should be to relieve the back pressure without infecting the urinary tract or with the minimum of infection. In the aseptic cases this is best accomplished by a preliminary suprapubic cystotomy under local anesthesia; in the infected cases the use of an inlying catheter is usually sufficient.

3. **Artificial Pneumothorax in Advanced Pulmonary Tuberculosis.**—E. O. Otis notes that the conditions which warrant a recourse to artificial pneumothorax are an advanced or advancing case of pulmonary tuberculosis the disease being principally unilateral. After a careful physical and *x*-ray examination, the spot which appears to be free from adhesions is selected, and, by careful manipulation, a needle similar to an aspirating needle is inserted between the two layers of the pleura and through it nitrogen gas is slowly injected under slight pressure. Only a certain amount of the gas is allowed to flow in at the first attempt, depending upon individual conditions, and the procedure is repeated, if all goes well, at frequent intervals until the lung is tightly compressed, as shown by the physical examination and *x*-ray picture. When this has been accomplished, the subsequent injections are given at longer intervals, sufficient to maintain the compression.

2. **Ecchymotic Skin Reaction.**—W. M. Barton states that during the past few years a few cases have come under his observation in which comparatively slight digital or other pressure has produced a local ecchymotic cutaneous reaction. Two cases have occurred in women during or after the menopause. In a recent article Sicard and Gutman report two cases of a similar kind, one in a female and one in a male, in both of which there occurred cutaneous ecchymoses as a result of slight digital compression. Are these similar cases and to be regarded as true acquired hemophilia? If any defect of coagulability of the blood is to be taken as a criterion, the answer is no. In none of the four cases reported was there any delay in coagulation time. In one case no examination was made to determine this point, but the patient had never had a hemorrhage of any severity. It would appear more reasonable to suppose that cases in which the ecchymotic skin reaction is observed, spontaneously or upon slight pressure, are not cases of true hemophilia. It would be interesting to examine the condition of the vascular walls in these cases. In some cases of true hemophilia changes have been observed in the smaller vessels; but in others no pathological alterations have been found. Perhaps the condition of acute ecchymotic skin reaction may be found associated with, and dependent upon an abnormal fragility of the capillary wall and this upon a generalized capillosclerosis.

4. **Infected Rooms and Fomites in the Transmission of Infectious Diseases.**—By A. H. Doty. (See MEDICAL RECORD, September 28, 1912, page 580.)

7. **Implantation of Fat into Tenon's Capsule after Enucleation.**—W. B. Weidler states that the ophthalmic surgeon has for the past twenty-five years tried many forms of enucleation and implantation into Tenon's capsule and the orbital tissues of different materials, with the hope of securing a more freely movable stump for a glass eye. So far these efforts have been successful to a moderate degree only. Before this time it had been thought sufficient if the ophthalmic surgeon removed the diseased or disfiguring eye without giving any special thought to the after appearances or the movements of the artificial eye. The author mentions some of the many things that have been tried from time to time to secure a more movable stump for the glass eye. Mules used the glass ball and Fox suggested the gold ball; others have tried celluloid, sponge, peat, fresh or decalcified bone, agaragar, petrolatum, rubber, wire, silk, catgut, rabbit's eyes, and fat from the gluteal region. The author calls attention to the use of fat as an implant. This is not a new operation, as it was first tried by Barrequier fifteen years ago and has been performed by many ophthalmic surgeons with varying degrees of success. The operation is comparatively simple and is not attended with any danger to the patient.

1. **Gallstones Coincident with Other Surgical Lesions.**—J. G. Clark concludes that gallstones give rise to symptoms in a much larger proportion of cases than is commonly supposed. Many cases heretofore diagnosticated and treated as chronic indigestion and other vague stomach disorders are in reality cases of cholelithiasis. Gallstones are not necessarily innocuous when they are producing no symptoms, but may produce fatal lesions while their presence is unsuspected. Unless contraindicated, the gall-bladder as well as the appendix should be examined in all cases of celiotomy, and gallstones, if present, should be removed whether they offend or not, provided the patient's local and general condition are favorable.

3. **Ovarian Dermoids.**—A. C. Martin, after reporting a case of dermoid of the ovary, discusses the cases of malignancy in these growths and emphasizes the necessity of submitting the tumors to a careful microscopical analysis in every instance. In the case he reports there was a suspicion of malignancy in the somewhat too numerous cells and their atypical arrangement. Undoubtedly simple dermoids are benign, but there is a possibility of malignancy in those that approach the teratoma type. Another characteristic of the ovarian dermoid which calls for men-

tion in this connection is the peritoneal metastasis, in which the peritoneum is dotted with minute knots, each furnished with a small tuft of hair. Bland Sutton does not consider these malignant, and this opinion seems to be borne out by the usual history of these growths. The author presents a summary of the reported cases of malignant complications of ovarian dermoid, and concludes that primary conservation of the ovary, if technically possible and otherwise desirable, is the operation of choice in dealing with ovarian dermoids which give no evidence of malignancy in the gross or on the immediate examination of a frozen section. The excised tissue should invariably be examined subsequently with the utmost detail for microscopical evidence of the threefold possibilities of malignancy, each of which, fortunately, is rare. In young women, a radical operation is imperative only if demanded by positive pathological findings.

9. **Multiple Sclerosis.**—L. H. Mettler states that the literature of multiple sclerosis is full of contradictions. The disease has been called in Europe one of the most common of the organic nervous affections, and in America one of the rarest. The author introduces his discussion of the subject with the histories of three cases, which indicate that quite dissimilar troubles may be classed under this head. One was a typical case with marked neuropathic heredity; the second was less clear, both etiologically and clinically; the third was a pure case of cerebrospinal syphilis with merely a remote resemblance to multiple sclerosis. The symptoms of multiple sclerosis are not uniformly distinctive and diagnostic errors are far too common. No two investigators seem to agree on the physical basis or pathophysiology. The crux of the whole matter is the plaque or sclerotic patch. This is fairly distinctive, and if agreement could be reached as to its origin and essential constitution one might have a basis for statistics. Differences of opinion prevail as to their relationship to the blood-vessels. Most pathologists do not believe that the plaques are limited to this disease. Multiple sclerosis of the typical Charcot type, with marked neuropathy in the ancestry, is a very rare disease.

11. **Experimental Ileus.**—A. McLean and R. C. Andries conclude that death in ileus is not due to a toxemia, *i.e.* it is due neither to the absorption of bacteria or their toxins, nor to the absorption of some altered physiological secretion. A depletion of the vascular and lymph-system, causing a grave disturbance in the circulation, especially in the cerebral circulation, is a prime factor in the causation of death. A pathological change in the sympathetic nervous system, a loss of sympathetic control, is probably contributory. Treatment must, first of all, relieve distention and secondly, refill the depleted vessels.

8. The Practical Use of Vaccine Treatment in Pulmonary Tuberculosis. B. Hudson.

1. **The Passing of Morbid Anatomy.**—Sir James F. Goodhart points out that all of the changes and shiftings of ground in the development of modern pathology suggest the existence of a struggle on the part of the pathologist to find out some morbid change for every disease, and it is indeed admitted that the pathologist has been ever more and more reducing function to terms of structural change. But the time has come when it seems worth while to insist that all this work upon the foundation—whether it be anatomical, histological, chemical, physical—has, unconsciously perhaps, but none the less inevitably, been ushering in another point of view, and the latest phase of pathology is the more intricate one that concerns itself primarily with the investigation of function.

2. **Mental Disorders.**—Sir George H. Savage states that so-called mental disorder is gauged in relationship to conduct, and that certain disorders depend more on the surroundings of the patient than on the patient himself. The author has long been in the habit of referring to the social misfits which depend on the surroundings rather than on the patient. Social and mental disorders are nearly related, and one of the most difficult problems is to decide where badness ends and madness begins. There are many mental disorders which deserve the name functional in so far as they are not represented by any material change in the central nervous tissues. Nature provides the iron, but man makes the horse-shoe for service. In considering heredity too much stress should not be laid on the existence of some forms of mental disorder in the family. Insanity, like genius, may be an accident. It is certain that some families in which every form of neurosis has been represented have succeeded in breeding out of the tendency. It is interesting to note in some members of a family eccentricities or tricks of manner, insanity in one generation being followed by musical or other aptitude in the next, while in the third generation, or in some members of the second generation, beside the normal members there were some with tricks, such as the faculty, untrained, of mirror writing. One should not believe too much in what Maudsley has called the tyranny of the organism. That external conditions have very much to do with the production of attacks of insanity the author has no doubt. One of his favorite similes in teaching on the question of heredity was to compare it with the mycelium of the mushroom. This spreads far and wide, and is not recognized till suitable conditions lead to the mushroom which comes to the surface. So the neurotic inheritance spreads far and wide and is deeply seated, but the occasion for its development may be wanting.

3. **Industrial Mercurial Poisoning.**—By F. E. Tylecote. (See MEDICAL RECORD, October 19, 1912, page 716.)

6. **A Case of Sulphemoglobinemia.**—H. Davis reports the case of a woman, 27 years of age, whose face had a remarkable color, being stained a deep slate blue, almost a blue-black. This hue prevailed all over the face and scalp and over the exposed part of the neck, but it could not be observed anywhere else except at the bases of the finger-nails. The bases of the toe-nails were of the normal color. The mucous membranes were unstained. On the face the color was most marked over the nose, but it was quite obvious in the sclerotics; the cheeks and forehead were also affected, but the ears to a slightly less degree than other parts. The color could not be dispersed by pressure. The patient's face had assumed its peculiar tint eleven years previously, when the patient was 16 years old, and had not changed since that time. When the patient was admitted to the hospital she had been suffering from a certain amount of digestive disturbance, of which the chief sign was pain after meals; this symptom had lasted for three months. She was also subject to headache, dyspnea, and sweating on exertion, with occasional palpitation and giddiness. Her general nutrition was good. Nothing abnormal was discovered in the lungs. The apex-beat was in the fifth intercostal space in the nipple-line, and there was a slight systolic bruit in the mitral area. Otherwise the heart sounds were normal. There was no clubbing of the fingers. The tongue was furred and the teeth were bad. There was no enlargement of the liver or spleen. The urine was straw-colored, and acid in reaction; no abnormal constituent was discovered, and the specific gravity was 1007. There was thus no sign of

alkaptonuria. The blood count showed red cells 5,280,000, white cells 6,000, percentage of hemoglobin 98, index 0.9. The differential count showed polymorphonuclear leucocytes 76 per cent., lymphocytes 20 per cent., transitional cells 2 per cent., and eosinophile cells 2 per cent. The diagnosis of this case was difficult. The possibilities which presented themselves were argyria, ochronosis, hemachromatosis, methemoglobinemia, and sulphemoglobinemia. The general appearance of the patient was very suggestive of argyria. A specimen of the patient's blood showed the characteristic absorption band of sulphemoglobinemia in the red end of the spectrum.

8. Vaccine Treatment in Pulmonary Tuberculosis.—B. Hudson has found that in certain cases of pulmonary tuberculosis a course of vaccine treatment is of great benefit. There is, however, always a large amount of uncertainty, owing to the difficulty of isolating the causal organism; but even if the vaccine does no good, it at any rate never seems to do any permanent damage and is worth trying. The treatment may be used in conjunction with tuberculin. It must be carefully borne in mind that any injection or other treatment is only an adjunct, and that the general hygiene, open-air, climatic and tonic treatment, systematic rest, and good feeding should be always strictly enforced.

1. The Passing of Morbid Anatomy. Sir James Goodhart.
2. Pellagra in the British Islands. L. W. Sambon and A. J. Chalmers.
3. Mitral Stenosis: Peripheral Emboli Causing Partial Monoplegia with Symptoms Simulating Cerebral Embolism. G. G. Alderson.
4. On the Presence of Sugar in the Cerebrospinal Fluid from Cases of Meningitis. F. H. Jacob.

1. The Passing of Morbid Anatomy.—By Sir James Goodhart. (See page —.)

2. Pellagra in the British Islands.—L. W. Sambon and A. J. Chalmers present the evidence which proves that for an undetermined but long time pellagra has endemically prevailed in parts of the United Kingdom, and that, notwithstanding the recognition and publication of two grave typical cases, the disease has been generally overlooked in its milder and more obscure forms. The presence of pellagra in the British Islands is of geographical interest, because hitherto the disease was believed to be limited northwards by the forty-fifth parallel. Etiologically, its presence in the United Kingdom is of importance, because here its causation cannot be reasonably explained by the consumption of either sound or bad maize, and its topographical distribution shows that here, as elsewhere, it is linked to the swift-flowing, Simulium-infected streams. Sociologically, the disease calls for the most urgent attention. Pellagra is an insidious disease, either of a rapidly fatal or of a long intermittent course, leading to insanity. The pellagrous psychical disturbances are as many-sided and as obscure as the somatic manifestations of the disease, but the salient feature is an intermittent and progressive amentia, often assuming a semblance of melancholia and exhibiting from time to time regular outbursts of maniacal excitement. In some cases there may be all the appearances of progressive paralysis. Dementia is the invariable termination, unless the patient be cured, or carried off sooner by some intercurrent disease or mere exhaustion of the vital powers.

3. Mitral Stenosis with Peripheral Emboli.—G. G. Alderson reports the case of a woman aged 42 years who had mitral stenosis following an attack of rheumatic fever six years previously. This case is of interest because on two occasions on which embolism occurred in a limb artery the attendant symptoms accurately simulated those associated with cerebral embolism. Thus, on each occasion the patient was the subject of partial monoplegia, with attendant nausea and giddiness. Additional interest is afforded by the fact that death was absolutely sudden, and was found to be due to the presence of a ball thrombus in the right auricle.

4. Sugar in the Cerebrospinal Fluid in Cases of Meningitis.—F. H. Jacob concludes that in pyogenic meningitis, whether caused by the pneumococcus or streptococcus, or by a mixed infection, sugar is invariably absent. In cerebrospinal meningitis sugar is absent in the acute stage, but may return in some degree as the infection recedes. In tuberculous meningitis sugar is present, except in very rare cases shortly before death, in which stage a difficulty in diagnosis rarely exists. In poliomyelitis sugar is present. These findings seem sufficiently definite to be of real value.

Berliner klinische Wochenschrift.

October 21, 1912.

Angiosclerosis of the Intestinal Arteries with Intermittent Limp.—Friedmann of New York relates the case of a syphilitic man aged 46 who suffered from severe crises of intestinal colic. Various affections like gastric and duodenal ulcer, gallstones, tabes, etc., could be excluded. The attacks set in instantaneously. As intermittent limp developed later a diagnosis was made of angiosclerosis of the superior mesentery artery. The patient was placed upon the antisyphilitic regimen (no salvarsan) and within a short time the limp had permanently vanished. It is impossible to state whether the paroxysms of colic have been removed. The patient later received salvarsan in the further hope of a permanent cure.

Therapeutic Action of Metals Upon Cancer.—Gaylord of the Buffalo Cancer Institute began to test various metallic salts in mammalian cancer, notably halogens, long before 1908, and no less than 250 distinct substances have been employed for this purpose. It was not until long afterwards that the Berlin results were published. During the same period the subject of goiter and cancer of the thyroid in certain fishes (Salmonidæ) was likewise investigated. It was learned that if the water was impregnated with a little iodine this condition could be controlled. It has since been learned that mercury and arsenic exert the same curative power as iodine. The fact that infinitesimal quantities of metal can affect fish cancer so favorably will lead to a reduction of the doses in cancer in mammals.

Necrotic Cyanotic Liver with Icterus.—Oertel of the Sage Pathologic Institute, New York, believes that he has discovered a new and peculiar lesion of the liver which is non-inflammatory in origin, being determined by extreme venous stasis. He has published several papers on the subject, the first in 1904, and has now five cases recorded, each of which is given in detail. He also knows of other material. The last case may be briefly reproduced here: patient, a man aged 25, had typical initial stenosis. Among other results of stasis pulsating liver developed with icterus. Leucocyte count showed absence of infection. The icterus increased and acute hemorrhagic diathesis began to be in evidence. Death supervened without any temperature rise. Section showed the usual phenomena of venous stasis. The state of the liver, however, differed radically from the ordinary red atrophy. The organ was smooth and of a uniform green color. The microscope showed irregular streaks of necrosis with hemorrhagic extravasations. The picture was quite unlike that of ordinary parenchymatous degeneration.

Dysbasia Arteriosclerotica and Flat Foot.—Brandenstein calls attention to the comparative frequency of this association. Not a few cases of intermittent limp have been seen in subjects with flat foot—evidently the deforming degree of the latter, for the milder type is too common to have much significance in this connection. It is in such cases that the pains occasioned by the deformity serve to mask some of the symptoms of the angiosclerosis.

The limp itself may be referred to the flat foot. From the opposite viewpoint the angiosclerosis can aggravate the deformity. As a result of the former the muscles undergo atrophy, the extremity becomes cold and moist as a result of failing circulation. Flat foot is chiefly bilateral, while angiosclerosis is often unilateral. The significance of this association is at present obscure. It is of course not certain that it is primarily only a coincidence, but the association forms a definite clinical entity, in as far as it represents a vicious circle.

Münchener medizinische Wochenschrift.

October 22, 1912.

Extraperitoneal Cesarean Section.—O. Küstner up to September 12 of this year had operated by this route in seventy-two cases. He is averaging two or three operations monthly, and is doubtless the heaviest operator in this intervention. As in all such procedures, there is more or less confusion, for some appear to make no distinction between the strict extraperitoneal and the cervical transperitoneal routes. A new term, peritoneophobia, has been coined to denote the unfounded aversion on the part of some surgeons to opening the peritoneal cavity. The indications are simple—practically contracted pelvis with unfavorable outlook for the birth of the intact child. The indications are therefore determined largely by the state of the fetus—poor heart sounds, escape of meconium, early escape of waters, etc. In the seventy-two operations the author lost but four children. Three were in deep asphyxia and the fourth had meningeal hemorrhage. But one mother was lost, the death being attributed to the anesthetic.

Simple Mechanical Resource for Epistaxis.—Ritschl employs the socalled Naegeli's maneuver for nose bleed. As is known, the last named author wrote in 1894 a monograph on mechanical interventions in various portions of the body for neuralgias and neuroses, which recalls the management of these and other conditions of "osteopaths" in the United States. Two maneuvers termed by Naegeli the "head support" and the "head extension" are said to exert an energetic anemization of the head and adjacent structures. Such a degree of anemia may be induced as will provoke first vertigo and then syncope. Naegeli's explanation of these results may not, however, be the correct one. He ascribes the anemia of the brain to a sort of suction by the large veins, while the author invokes a stretching of the cervical sympathetic with stimulation of the vasoconstrictor fibers. He came to this conclusion when he found that the maneuvers caused constriction of the arterioles of the Schneiderian membrane and accidentally arrest of epistaxis. One hand is placed under the jaw while the second is applied to the occiput. A uniform upward traction is now made upon the head. To reinforce this action the maneuver may be made with the head extended strongly backward. Hemostasis must result in from one to two minutes.

Treatment of Pertussis.—Althoff has now gone through two epidemics of whooping cough in which he obtained distinguished success with a combination of sedatives in association with other measures such as mustard baths and menthol embrocations over the spine. The sedatives comprise chiefly antipyrin, heroin, and sodium bromide. This management, however, must begin during the initial catarrhal stage to be efficacious, and it then operates by curtailing the duration of the second or spasmodic stage. The child receives three mustard baths in daily succession at the outset. A quarter pound of mustard of medium strength is used in a general tub bath, naturally to antagonize the bronchitis. The dorsal inunctions of strong menthol ointment are given three times daily. In addition to the sedatives already enumerated the author also prescribes ipecac and aristolochia.

Deutsche medizinische Wochenschrift.

October 24, 1912.

Posttraumatic Pachymeningitis.—Kasemeyer cites an instance which illustrates how a trauma of the head may insidiously lead to death even in the absence of symptoms during a prolonged interval period. The patient, a young man, was admitted to the clinic with evidences of acute meningitis. Five years before while serving as a soldier he was kicked on the head by his horse. He went about his business as usual and never mentioned that he was even stunned. He finished his service, and the few and mild symptoms complained of during that period could not be referred definitely to the results of injury. He married and begot children. Habits good throughout. A day or so before admission he had been attacked suddenly with severe headache and chills, and on admission presented an undoubted picture of cerebrospinal meningitis. Cultures made from the throat and spinal fluid showed virulent pneumococci. He did not respond to treatment and died in coma. Section showed an old fibrinous adhesive pachymeningitis with an area of softening in the cortex. The latter having become infected set up a general diffuse purulent cerebrospinal meningitis. The author's deductions are as follows: At the time of the injury a small subdural hemorrhage resulted. This organized, but the newly formed blood-vessels degenerated and ruptured. Now for the first time pachymeningitis interna hemorrhagica developed, and led to adhesions between dura and pia. As a result of circulatory disturbance in the cortex a focus of softening developed and became infected through the nasopharynx.

Thyreoidin in Vomiting of Pregnancy.—Koreck, a Hungarian practitioner, discovered on purely empirical grounds that thyreoidin has some power over vomiting of pregnancy. Of importance was the fact that the usual physiological action of the drug was not in evidence, the cardiac frequency being even diminished. The improvement was pronounced and when the drug was discontinued vomiting reappeared. The morning vomiting was the most refractory. The author tested the drug on other patients with the same good results. One of the women on two previous occasions had her pregnancy terminated by induced abortion, but now went on to term. The possibility of suggestion as a therapeutic factor is not mentioned by the author.

Serotherapy of Diphtheria in Heubner's Clinic.—Eckert makes a very valuable report of seventeen years continuous use of antitoxin in Heubner's Berlin clinic. This on the whole is eminently favorable. The summary is in part as follows: There is a certain experimental foundation for the efficacy of serum in preventing paralysis, but the problem has not yet been worked out fully in mankind. The possibility of fatal serum disease thus far authorizes the routine use of the intravenous method. For the prevention of anaphylaxis there is an abundance of recommendations, some of which concern the preparation of the serum itself, while others involve the exhibition of counteracting remedies. The author does not give any routine procedure in use at the clinic. The high dosage used in the latter has not for many reasons been carried out in private practice; but efforts will be made to make this course practicable. Of collateral measures the author recommends the most roborant diet including wine and concentrated meat preparations. Of local measures the author finds pyrocyanase in no wise superior to ichthyol. Bolus alba is much used at the clinic. As heart tonics adrenalin, strychnin, and caffein are recommended. The general tendency of early well dosed serum therapy is to do away with the need of other remedies. A lethal element is seen in an early severe myocarditis which can neither be antidoted nor offset by substances which raise blood pressure.

Insurance Medicine.

Hazardous and Unhealthful Occupations and their Rating.—F. B. Mead states that while conditions in England differ radically from those prevailing in this country, a careful study of the returns of the Registrar General for England and Wales showing the mortality in different occupations and the causes of death in each, is very interesting and instructive. The following are the returns for 1890, 1891, and 1892, indicating average mortality per 1,000: Clergyman, 533; farmer, 563; schoolmaster, 604; farm laborer, 632; grocer, 664; carpenter or joiner, 783; lawyer, 821; blacksmith, 914; baker or confectioner, 920; druggist, 926; physician, 966; general shopkeeper, 973; butcher, 1,096; brewer, 1,427; innkeeper, spirit, wine or beer dealer, 1,642; inn or hotel servant, 1,725; file maker, 1,810. One of the purposes of introducing the foregoing comparative figures is to emphasize the important influence that occupation has upon mortality. In order to illustrate further how mortality varies among certain important occupations which are acceptable for standard policies, the following table is introduced showing the mortality experienced by the Gotha Life Insurance Company from 1829 to 1890, among physicians, Protestant clergy, and teachers in the primary schools. The rate according to the American Experience Table is added for purposes of comparison:

GRADUATED RATE OF MORTALITY AFTER ELIMINATING THE FIRST FIVE YEARS OF INSURANCE

Age	American Experience Table	Physicians	Protestant Clergy	Teachers
25	.0081	.0070	.0049	.0051
30	.0084	.0076	.0051	.0055
35	.0090	.0106	.0055	.0063
40	.0098	.0127	.0063	.0074
45	.0112	.0138	.0077	.0095
50	.0138	.0168	.0106	.0131
55	.0186	.0262	.0171	.0187
60	.0267	.0373	.0271	.0283
65	.0401	.0549	.0430	.0441
70	.0620	.0779	.0702	.0708
75	.0940	.1062	.1066	.1096
80	.1445	.1614	.1690	.1617
85	.2356	.2142	.2764	.2307
90	.4545	.3630	.4317	.3262

It will be especially noted in the second table that the mortality varies for the different occupations at the very earliest age tabulated and that the difference increases up to about age 60 or 63 and then rapidly diminishes until the mortality for the different occupations practically coincides at age 73.

The occupational risks included in the new specialized mortality investigation that is now being conducted embrace all risks insured in the occupations covered, whether they were accepted as standard risks or under special conditions. In this way will result a more accurate representation of the general average mortality of each special occupation than was the case in the specialized investigation published in 1903, for, as has been repeatedly pointed out the latter investigation embraced only such risks as were issued standard policies and they represent the very best grade of risks in their respective classes.

The following figures represent the experience of the New York Life Insurance Company as to the mortality of certain occupations:

Bartenders, expected deaths, 42, actual deaths, 75, ratio of actual to expected deaths, 178 per cent.; saloonkeepers, expected deaths, 222, actual deaths, 294, ratio of actual to expected deaths, 132 per cent.; proprietors, managers, and clerks of hotels and restaurants with bar, expected deaths, 66, actual deaths, 98, ratio of actual to expected deaths, 148 per cent. Hunter states that no absolute lines can be laid down for the treatment of proprietors, managers, and clerks of hotels and restaurants, that the best of them are acceptable on any form of policy without discrimination, while the average is not entitled to any better treatment than the average saloonkeeper. Working miners, expected deaths, 79, actual deaths, 195, ratio of actual to expected deaths, 247 per cent. There were no coal miners included in the above, nor placer, drift or hydraulic miners. Two tables are introduced which are based upon the experience of a certain British company upon a large number of risks engaged in the sale of intoxicating liquors. From these it will be gathered that the required number of years of rating up is 24, and at age 40 it is 14 years while at age 60 it is 6 years. On the other hand, the difference in premiums by the two tables increases with age, the extra premium required by the liquor sellers being $14.18 at age 20, $18.12 at age 40, and $21.00 at age 60. The liquor industry may be considered as a somewhat typical occupation in which the extra mortality is due for the most part to unhealthful conditions. Not only does a level extra premium for all ages at entry not conform to conditions but rating up likewise fails to meet the case.

Consider on the other hand another type of occupation in which the extra mortality is due to the increased hazard from accident. Hunter tells us that the experience of the New York Life shows that hazard from accident decreases somewhat with age and this characteristic is displayed by other experiences. The younger men are more reckless and caution is developed as a result of length of service, For practical purposes, however, the assumption of a uniform extra mortality for all ages meets the conditions in a satisfactory manner.

To meet the actual conditions best it seems that occupations should be divided into classes according to whether the accident hazard is the predominating cause of the extra mortality or whether the extra mortality is due in large part to unhealthful conditions.—*Proceedings of Second Mid-Year Meeting of the Medical Section American Life Convention.*

Can Modern Life Insurance Survive?—Dr. George W. Hopkins, of Cleveland, Ohio, says that life insurance is theoretically a philanthropic institution designed to protect the dependents of the insured from the pecuniary loss because of his death. The basis of insurance is the determination of the mortality rate at various ages of individuals in various occupations and under various economic conditions. The main purpose of the man of moderate means should be to secure the maximum protection for his family at the lowest annual premium rate. Thus every doctor should be vitally interested in insurance, its variations in policy forms, costs, and benefits. The paper by Dr. Hopkins is a criticism of cash surrender values. Hopkins asks whether modern life insurance can survive when we see how the solvency of the whole system is constantly threatened by what he calls the prevalent cash surrender evil. Cash surrenders, he says, are not, and never will be, in any sense life insurance. Life insurance is a substitute for a man's earnings after his death. Anything more than pure protection for one's dependents is not life insurance at all, but banking or investment.—*Medical Review of Reviews*, September, 1912.

The Significance of Some Urinary Constituents, by J. Bergen Ogden, M.D. (See page 893.)

Book Reviews.

X-Ray Diagnosis and Treatment. A Text-Book for General Practitioners and Students. By W. J. S. Bythell, B.A. (Cantab.), M.D. (Vict.); Hon. Physician to the Ancoats Hospital, Manchester (Electrotherapeutic Department); Medical Officer to the *X*-Ray Department of the Manchester Children's Hospital; Medical Officer to the *X*-Ray Department of the Salford Royal Hospital; and A. E. Barclay, M.D. (Cantab.), M.R.C.S., L.R.C.P., Medical Officer to the Electrical and *X*-Ray Departments, Manchester Royal Infirmary; Late Clinical Assistant to the Electrical Department of the London Hospital. Price $5.50. London: Henry Frowde, Oxford University Press; Hodder & Stoughton, 1912.

This volume is written for the general practitioner, and not for the *x*-ray specialist. The entire subject of *x*-ray diagnosis and treatment is presented in such manner that the general practitioner can gain an adequate working knowledge of this valuable resource. The authors emphasize the fact that "the rays are, as it were, a new sense added to the other five; they do not in any way relieve us from the necessity of training ourselves in the use of the old-established methods of observation that may be used equally well at the cottage bedside or in the wards. Although by themselves the rays may be of value in diagnosis, yet their range of utility and the accuracy of the information given becomes greater and greater the more we combine the information available from every source." The subject-matter of this book is subdivided under the following headings: the *x*-rays and their use in medicine; injuries of bones and joints; diseases of bones and joints; examination of the bones and joints in children; examination of the head; the detection of foreign bodies; examination of the thorax; examination of the abdomen; examination of the urinary system; *x*-ray therapeutics; and *x*-ray apparatus and technique. After each chapter there is a series of full-page plates showing *x*-ray photographs illustrating the important topics discussed in the chapter. These plates are consummate for their clearness and beauty of reproduction. There is a total of 118 illustrations. A mere examination of the latter, together with a perusal of the descriptions accompanying them, will give one a fair knowledge of *x*-ray diagnosis. Of particular interest are the plates illustrating pathological conditions in the thorax and abdomen. The authors are to be congratulated upon the excellent manner in which they have handled this difficult subject. The paper, binding, typography, and general artistic features of this work are in keeping with the excellence of its text.

Emergency, Medical and Surgical Aid. What to do and What Not to Do. A manual of first aid for laymen, with special reference to industrial accidents. By Ernest A. Wells, M.D., Associate Medical Director, Ætna Life Insurance Company; formerly House Surgeon, the New York Hospital; Assistant Attending Surgeon Hartford Hospital; Member American Medical Association, American Academy of Medicine, etc. Hartford: Ætna Life Insurance Company, 1912.

This is a convenient pamphlet, describing in simple language and with the aid of photogravures the principles of first aid, with special reference to industrial accidents. The subjects are arranged alphabetically with marginal headings. Such subjects are included as the treatment of electric shock, dog bites, internal hemorrhage, caisson disease, etc. This little book may be recommended as an excellent presentation of the subject.

Einführung in die Lehre von der Bekämpfung der Infektionskrankheiten. Von E. v. Behring. Mit Abbildungen in Text, Tabellen und farbiger Tafel. Price 15 marks. Berlin: Verlag von August Hirschwald, 1912.

The field covered by this volume is a large one. The author has played such an important part in the development of modern sanitary science that his description of the science of fighting the infectious diseases acquires an added importance and interest. The evolution of this subject is fully dealt with. Chapter I discusses the terminology and the historical aspects of the infectious diseases. In Chapter II the author describes the infectious poisons, forms of virus, portals of invasion, incubation, specific proteolysis, and toxic caryolysis. Chapter III includes a review of the historical aspects of therapeutics; the Hippocratic system, allopathy, homeopathy, and symptomatic therapy, Sydenham and the specific medicaments, empirical isopathy and isotherapy, etiological therapy, Jenner's vaccination, Pasteur, the bactericidal antibodies, the antitoxic theory, and the history of the anti-infectious action of the blood. In Chapter IV the history of antitoxic antibodies is set forth. This includes the history of the discovery of the diphtheria antitoxin. The serum treatment of this disease is dealt with more extensively in the following chapters. The succeeding chapters deal with the following subjects: Anaphylaxis, modes of combating poisons; antitoxic tetanus therapy; the knowledge of diastatic processes; phagocytosis; blood investigations; tuberculosis and its control, and disinfection. The volume contains a mine of information that cannot fail to be of value to all students and laboratory workers interested in the campaign against the infectious diseases.

Arteriosclerosis. Etiology, Pathology, Diagnosis, Prognosis, Prophylaxis, and Treatment. With a Special Chapter on Blood Pressure. By Louis M. Warfield, A.B., M.D.; Assistant Superintendent and Resident Physician to Milwaukee County Hospital; Assistant Professor of Medicine, Wisconsin College of Physicians and Surgeons, Milwaukee, Wis.; formerly Medical House Officer, Johns Hopkins Hospital, Baltimore, Md.; Member American Medical Association. With an Introduction by W. S. Thayer, M.D., Professor of Clinical Medicine, Johns Hopkins University. Illustrated with twenty-eight engravings. Price $2.50. St. Louis: C. V. Mosby Company, 1912.

This work in its present form represents a careful revision of the first edition that appeared four years ago, and contains two new chapters on "The physical examination of the heart and arteries" and on "Arteriosclerosis in its relation to life insurance." The growing importance of the clinical recognition of arteriosclerosis imparts considerable value to this volume. This is well written, and with its numerous illustrations serves as an admirable guide to the general practitioner seeking light on this subject.

The Sexual Life of the Child. By Dr. Albert Moll. Translated from the German by Dr. Eden Paul. With an Introduction by Edward L. Thorndike, Professor of Educational Psychology, Teachers' College, Columbia University. Price $1.75 net. New York: The Macmillan Company, 1912.

To quote the language of the introduction, the author "has undertaken to describe the origin and development, in childhood and youth, of the acts and feelings due to sex; to explain the forces by which sex responses are directed and misdirected; and to judge the wisdom of existing and proposed methods of preventing the degradation of a child's sexual life." The subject matter is dealt with under the following headings: introductory and historical; the reproductive organs—the sexual impulse; sexual differentiation in childhood; symptomatology; pathology; etiology and diagnosis; importance of the sexual life of the child; the child as an object of sexual practices; and sexual education. No one can deny the importance to the physician, to the educator, and even to the parent, of a knowledge of the subjects touched upon in this book. The authority of Dr. Moll, coupled with his delicate though fearless handling of this difficult topic, has succeeded in presenting a book of permanent value.

Fresh Air and How to Use It. By Thomas Spees Carrington, M.D., Assistant Secretary of the National Association for the Study and Prevention of Tuberculosis; Author of "Tuberculosis Hospital and Sanatorium Construction." Price $1.00. New York: The National Association for the Study and Prevention of Tuberculosis, 1912.

This volume is published under the auspices of the National Association for the Study and Prevention of Tuberculosis as a means of supplying the demand for information as to methods of obtaining fresh air. It is remarkable to what extent even the city dweller is able to secure the advantages of living in the open air. The following chapter headings indicate the wide scope and usefulness of this volume: ventilation, window tents, roof bungalows, wall houses and iron frame porches for city use, temporary fresh-air porches for country use, permanent sleeping porches and loggias for country homes, methods of protecting and screening porches, tents, and tent houses, open-air bungalows and cottages, suggestions for planning new houses with open-air apartments, roof playgrounds for children, and clothing, bedding, and furniture. The book contains a large number of illustrations which admirably supplement the text. There is no doubt that the author has a complete mastery of his subject and that he has supplied a distinct want in the preparation of this admirable volume.

Society Reports.

CLINICAL CONGRESS OF SURGEONS OF NORTH AMERICA.

Third Annual Session, Held in New York, November 11-15, 1912.

(Special Report to the MEDICAL RECORD.)

Monday, November 11—First Day.

THIS meeting was opened by Dr. GEORGE E. BREWER of New York City. He said that there were present the largest body of surgeons that had ever met in the history of the world. There was nothing spectacular to be shown and those who expected to see extraordinary operations, rare methods, and unusual cures would be disappointed. What was wanted was to demonstrate the methods employed in daily usage with a maximum of safety and the minimum of discomfort to the patient. To this end they hoped to demonstrate laboratory work, serum therapy, *x*-ray methods, and the methods of pathological examination. Dr. Brewer then introduced the president, Dr. Albert J. Ochsner, of Chicago.

Dr. OCHSNER said that the large attendance at the Congress was a great inspiration. New York had always been a surgical center, but never more so than at the present moment. There was a time when wealth, victory in combat, or personal aggrandizement was the measure of man's greatness, but now personal service was the prime element of achievement. About a half century ago teachers grasped this fact and impressed upon their pupils that education must include ethical development. A willingness to render service was more profitable to him who received than to him who gave. If they were here only to improve themselves personally, this Congress was a failure, but if it gave better service to the people, then it was a useful element in American progress. Many important facts would be carried by the men to their homes all over the country, which would be utilized for the welfare of the public. Among the younger men there were surgeons who were doing excellent work and this congress gave them an opportunity to demonstrate their methods. They thus learned to appreciate each other's work and were stimulated by mutual comparison to do away with provincialism. He felt confident that witnessing the clinical work would stimulate them to a greater amount of scientific reading. The great surgeons of this country had very generally acquired their knowledge and skill after leaving medical school. If one should select ten men who rank highest, not more than three or four would be found to have a university education. It was the men who had been inspired and who worked constantly who had risen to high rank. Better opportunities would be provided for the next generation. After expressing his appreciation for the honor conferred upon him in being president of the strongest body of men in the profession, he said it gave him great pleasure to present his successor, a man who had done much—in fact, no one had done quite so much as the president-elect—for the development and advancement of this Congress, Dr. Edward Martin of Philadelphia.

Dr. MARTIN then introduced some of the visiting delegates, among them Dr. Otfrid Foerster of Breslau, Germany, Prof. W. Arbuthnot Lane of London, Dr. J. B. Murphy of Chicago, ex-president of the American Medical Association, Dr. Robert F. Weir of New York, Dr. Abraham Jacobi, the present president of the American Medical Association, and Dr. John B. Witherspoon of Nashville, Tenn., the president-elect of the American Medical Association.

Dr. JOHN B. MURPHY, in responding to the introduction, said he had only been told a half hour before that he was to speak and this was not fair to the audience and most unjust to him. However, he could not let the opportunity pass without congratulating the Congress for the magnificent enthusiasm and earnestness of this body of men. He mentioned the name of Dr. Franklin Martin of Chicago, who, he said, should not be forgotten, as he was the founder and perfecter of the organization. He wished everyone to consider the cost of this meeting and its value to those who attended. Each one spent from two to six per cent. of a year's time, to say nothing of the expense. As to the return received, each surgeon was brought face to face with the best teachers and clinical opportunities that the present time offered. They each received an inspiration and each became in his own locality a standard of medical procedure and practice. This organization surpassed anything so far thought of for standardizing the principles and practice of surgery.

Dr. WEIR expressed his admiration for clinical work and believed that great possibilities for progress lay in this direction.

Dr. WITHERSPOON said he was glad to be welcomed at a meeting of men who had made surgical progress the marvel of the age. He said it was an inspiration to all and he was glad to be one of those to welcome visitors and to give his congratulations to the surgeons of America, who formed one of the grandest bodies of life-savers in this country. The American Medical Association was proud of her child, the Surgeons of North America.

Treatment of Hepatic Cirrhosis.—Dr. EDWARD MARTIN chose this as the topic of his presidential address. He said that in the surgical treatment of this condition the first element was the approach, which must be advantageous for sight, touch, and manipulation. The second point of importance, and one which had retarded the surgery of the liver so that it was far behind that of the kidney, was hemorrhage. In many pathological conditions of the liver, the tissue was brittle and yielded to local trauma, but it was resistant to wide pressure. This organ possessed no mechanism for stopping hemorrhage, but rather favored it, since the large vessels were held open by attachment to the parenchyma. The blood pressure could be quite easily controlled by pressure on the vessels with the finger. They had experimented on the cadaver by taking a liver and attaching it to a water supply and had found that manual pressure effectually controlled the flow. Another method of controlling hemorrhage was by stitching around the area to be controlled. He used a needle about the size of a knitting needle, with a blunt end, so that he could feel his way and avoid large vessels. The needle was provided with a socket into which could be screwed an attachment carrying the thread and could be bent to any angle. The thread acted as a pack in case of small hemorrhage from the needle puncture. He used triple and quadruple catgut and with the mattress suture they could stitch around practically every wound. If it was found that the tissue was brittle, a strip could be cut from the rectus and placed on the liver wound and stitched through. He had found these muscle flaps excellent homostats. They had found decapsulation an excellent procedure in kidney surgery and it seemed rational that it might be an advantageous procedure in hepatic cirrhosis. In performing a decapsulation on the liver, one got more superficial trauma than with the kidney. Dr. Martin believed that ascites was an advanced condition of hepatic cirrhosis and was not due to back pressure, but to the diseased condition of the endothelium of the peritoneum. As a remedy for this condition he had endeavored to modify the collateral circulation and for this purpose had selected the cava and iliac vein and had made an anastomosis between these vessels. This had not been done on the living subject, but had been successful on the cadaver. Dr. Martin gave a lantern slide exhibition showing methods of making the incision and the details of this operation. The incision which he recommended was a vertical one through the rectus muscle to within two fingers' breadth of the umbilicus, and then transversely a second incision at right angles to the first. This gave abundant exposure and plenty of room for manipulation.

The Relations of the Biochemical Functions of the Liver to Surgery of the Liver.—Dr. ALONZO TAYLOR of Philadelphia read this paper. He said that the functions of the liver might be divided into three groups: (1) Digestive. (2) Glandular or secretory. (3) Metabolic. He stated that the surgical possibilities of any organ depended upon the specificity of its functions and upon the degree of susceptibility of the function to compensation. The apparently indispensable function of the liver was the glandular; the other two functions were susceptible of modification and compensation. He then considered in detail the relation of the function of the liver to the outside circulation and to the portal circulation. The question arose, might not all the functions be performed through the arterial system? After showing that compensation seemed possible for all functions except the glycogenic, he said that if the liver failed to perform the glycogenic function levulose appeared in the urine. Some compensation for this might be made by regulating the diet and limiting the amount of cane sugar, fruit, and honey. He also showed that in the storage of glycogen the muscles exceeded the liver. He then went on to discuss the digestion of proteids in the liver and said that evidence failed to support the theory that the liver function was absolutely necessary for the disposition of the proteids. These were

largely cared for by the small intestine. Recently it had been shown that the blood of the portal vein contained amino acid and that this passed through the liver unchanged. He had shown by experiments on dogs that the formation of urea proceeded after complete removal of the liver. The weight of evidence, therefore, showed that the glandular function could be partially replaced, even though the portal circulation was cut off. In regard to the nutrition of the liver itself, it seemed logical that this should be dependent upon the arterial supply. A knowledge of the hormones produced by both the arterial and the portal circulation might help to throw light on this subject, but thus far they had no practical knowledge in regard to these.

Surgery of the Spleen.—Dr. WILLIAM J. MAYO of Rochester, Minn., read this paper. He said that we had acquired a fairly exact knowledge of the functions of all the organs contained in the abdomen with the exception of the liver and the spleen—two organs which were closely associated in their physiology and pathology. The liver was essential to life, one of its chief functions being to receive the products of gastrointestinal absorption and change them into tissue building material. The spleen was not essential to life. It performed for the general circulation a function somewhat analogous to the digestive organs, namely, removing from the circulation broken down blood corpuscles and other material of probable nutritive value which was sent as part of the portal circulation to the liver for further elaboration. It was also concerned in the metabolism of iron. In its ontogeny the spleen probably went back to a time before the development of the cerebrospinal nervous system had become a controlling factor. This was indicated by the fact that its only known nerve supply consisted of filaments derived from the splanchnic sympathetic system to the capsule, stimulation of which caused contraction. The spleen was an organ or internal secretion controlled by chemical stimulation through the blood stream. Evidently the internal secretion of the spleen was not important since splenectomy did not produce serious results, the associated organ taking up the function. The liver destroyed poisons both chemical and bacterial and stood as a gigantic defense of the general circulation. Processes in the liver which interfered with function were often accompanied by changes in the size and parenchyma of the spleen, while primary splenic enlargements were sometimes accompanied by secondary cirrhosis of the liver, as was seen in the late stages of splenic anemia. It was probable that cirrhosis of the liver was caused by poisons sifted from the general circulation by the spleen, or by poisons from the digestive tract, carried by means of the portal circulation to the liver. While the spleen appeared to have the function of destroyer of obsolete red blood corpuscles, it did not appear to have the power to destroy the microorganisms it captured, but delivered them to the liver for destruction and in the perversion of this dual function most of the diseases common to the spleen had their origin. With the present insufficient methods of diagnosis diseased spleen was not often mapped out until its size was made manifest on palpation beyond the free border of the ribs. In speaking of splenic enlargements Dr. Mayo said that these enlargements with an excess of white corpuscles were characteristic of myelogenous leucemia and the microscopical examination of the blood was essential to the diagnosis. Leucemia appeared to be a reversion to the embryonic type of blood in which all of the original blood-making organs had to do with the overproduction of the white cells. The blood picture in leucemia was well known. The leucemic spleen had been removed a number of times and in all of the cases in which the diagnosis had been established the patient promptly died as a result of the operation. Since the leucemic spleen was but part of the general condition, splenectomy would be unavailing. Splenic anemia was probably a definite entity. This condition was described as a progressive disease characterized by an enlarged spleen, by a reduction in the number and value of the red blood corpuscles and low hemoglobin, and often by a reduction in the number of white corpuscles. Clinically the disease might be accompanied by hemorrhages, especially from the stomach, by progressive weakness, and often by pigmentation of the skin and chronic jaundice. Splenic anemia was apparently due to hyperplasia of the spleen, and if the disease was uncomplicated, removal of the enlarged spleen cured the patient. Banti's disease was simply a late form of splenic anemia. As a rule, the red blood corpuscles dropped below 4,000,000, often to 3,000,000, and the hemoglobin to the vicinity of 40 per cent. The white corpuscles varied from 3,500 to normal. After removal of the spleen the blood picture became more nearly normal. At St. Mary's Hospital they had removed the spleen in eighteen cases of splenic anemia with most gratifying results. Perisplenitis or hepatic cirrhosis with perihepatitis might be present in these cases so that the spleen could not be removed without enormous risk to life. Following splenectomy, there was pain for a time in the long bones in about 25 per cent. of their cases, and in one or two cases a temporary enlargement of the lymphatics; this was evidently a compensatory hypertrophy of the bone marrow and glands. The speaker next considered conservative splenic enlargements referring to those due to malaria, syphilis, typhoid, and tuberculosis. Those enlargements due to animal parasites were treated by specific poisons, as quinine for the plasmodium of malaria. In a few cases of tuberculosis, when the infection was apparently primary and limited to the spleen, the spleen had been removed with cure of the patient. Franke had reported 29 cases of tuberculosis of the spleen, 10 of which were operated upon with seven cures. It had been necessary to remove the spleen in some cases of chronic malaria and Jonnesco and other surgeons had removed the spleen in such cases with gratifying results. A spleen which had developed a complete mesentery, permitting of a wide range of motion, was not common. Rotation of the spleen, completely cutting off the circulation, had occurred in a number of cases leading to death or splenectomy. Several operations had been devised for reducing or holding a movable spleen in a normal position, but, generally speaking, splenectomy was the wiser plan in this class of cases. Splenoplexy did not always relieve symptoms and splenectomy was exceptionally easy and safe. They had operated on three cases of movable spleen, one by fixation after which the patient suffered more or less pain. In the other two cases the organ was completely removed and a complete cure followed. Sarcoma was the type of primary malignant disease of the spleen and was rare. Pathologists were divided in their opinion as regarded these tumors; some held that they were sarcomas and others that they were a type of hyperplasia. One patient with lymphosarcoma of the spleen was operated on at St. Mary's Hospital, November 14, 1905, and was still in excellent health to-day. Three cases of the Weichselbaum and Gaucher type of splenic tumor which they had operated on, were clinically splenic anemia. Two had remained well since, one dying from the operation. As a rule, disease of the spleen was far advanced before a diagnosis was made and usually the entire organ was involved, making splenectomy the only rational procedure. An incision was made in the outer margin of the rectus muscle extending from the costal arch downward until there was a space sufficient for manipulation. On opening the abdomen the hand was passed over the spleen under the diaphragm and if adhesions were present they were, if not too firm, broken down by the hand. The spleen could then be brought entirely out of the abdominal incision. A large gauze pack was carried into the cavity from which the spleen had been removed. The spleen was then steadied and all the attachments tied and divided until it remained attached only by its vascular pedicle. A rubber-covered elastic clamp of the lower variety was placed on the pedicle about three inches from the spleen. The vessels could then be divided close to the spleen into three or four sections and ligated carefully with catgut before the holding clamps were removed. The clamps were loosened gradually, the large guaze pack removed and bleeding points in the deep cavity closed with catgut on a fine needle. Accessory spleens were frequently found in the pedicle, but if the primary disease was benign they might be conserved. The mortality following splenectomy had been estimated at from 18.5 to 27.5 per cent. Carstens reported 730 cases with 137 deaths; Johnson found a mortality of 27.4 per cent. in 708 cases. Under present conditions the mortality was much smaller than these statistics seemed to indicate. The mortality should not be above 10 per cent. and possibly not above 5 per cent. In their 27 cases there were two operative deaths.

Dr. CHARLES H. PECK of New York, in discussing Dr. Mayo's paper, said that he hesitated to say anything as the subject had been so well covered. Trauma of the spleen or ruptured spleen was most apt to occur from severe crushing injuries. The symptoms were obscure and were largely those due to shock and hemorrhage. The indications for treatment in these cases depended on the severity of the symptoms. There were some instances of spontaneous recovery. A most important point was the control of hemorrhage and this was usually done by the gauze pack. If the hemorrhage was severe, splenectomy was indicated. In a series of 150 cases which had been operated upon, there were 99 recoveries and 51 deaths. This high mortality was due to exsanguination and shock, as

removal of the spleen in itself produced but little injury to the organism. Splenectomy had given brilliant results in splenic anemia and Banti's disease. Dr. Peck then related the history of a case of congenital hemolytic jaundice in which cholecysostomy had been performed without giving relief, and later a second exploratory operation had been done and no abnormalities of the biliary passages found. Finally a diagnosis of disease of the spleen was made and an examination of the blood showed a remarkable fragility of the red blood corpuscles. The spleen was removed and the jaundice began to diminish three days later and ten days after the operation it had disappeared and had not since returned. While the cases demanding splenectomy were rare, the experience of the past ten years had placed them in possession of the indications for this operation.

Dr. Abraham Jacobi, in response to a request from the president, said he wished to say a word for cooperation. He believed in the fraternity of the medical sciences and of those who worked in them. Formerly surgeons worked only with the knife, but now surgeons had other tools—the expert brain and the heart. It was formerly said that operations were the reproach of surgery, but this was not true to-day because they now did better and more successful work. Fraternity among surgeons meant the equalization of all sciences and art, and if they wished to see this they should come to the American Medical Association; in fact, they should all belong to that organization.

Tuesday, November 12—Second Day.

Anesthesia and Anoci-Association.—Dr. George W. Crile of Cleveland delivered this address. He stated that by this term was meant a condition in which all harmful effects to both the sensory and sympathetic nerves were excluded. He said that in general anesthesia all the cells of the brain were not anesthetized or death would ensue. There were a large number of brain cells that responded to trauma of the nerves. Thus the stored energy of the brain cells that did not go to sleep during anesthesia was consumed during operation, and how to avoid this drain on the brain cells was one of the problems of surgery. Dr. Crile reviewed the action of the various anesthetics in general use and showed that while each had its special field none alone could produce anoci-association. Therefore it was by selection and combination that they aimed to obtain an anesthetic which would exclude all stimulation and not lower the threshold of anoci-association. The lecture was liberally illustrated by lantern slides by which Dr. Crile demonstrated the effect of the different anesthetics on the brain cells. Nitrous oxide anesthesia showed some deleterious effect, while ether showed an enormous loss of power. The reason of this was that when the patient was under nitrous oxide anesthesia the brain cells were unable to burn up oxygen and this was because the amount of oxygen was limited. Harmful effects of anesthetics were due to both the psychic factor and the traumatic. Dr. Crile then explained how he used novocaine in the operative field at each stage of the incision; this served to block the nerves so that they did not report what was going on in the field of operation. If operating in the abdomen, when he reached the peritoneum, he used quinine and urea hypochloride. When this was properly used the walls of the abdomen remained relaxed. The speaker then showed charts of a large series of operations, embracing hysterectomies, appendectomies, thyroidectomies and herniotomies, in which he had used these agents to produce anoci-association. Both the temperature and pulse were better with the blocked field and the effect of the quinine and urea hypochloride lasted two days after the operation. He had come to believe that postoperative fever was not due to absorption from the wound, but to psychological causes. In doing thyroidectomies the postoperative hyperthyroidism was often a great danger; he had found that under anoci-association anesthesia there was a small degree of change. An appendectomy could be done under this form of anesthesia by blocking the mesoappendix and the abdominal wall with quinine and urea hypochloride. This method did away with postoperative gas pain. This method of blocking the operative field could not be used in acute infection or in cancer. Dr. Crile concluded that a comparison of the effects of different anesthetics in his series of one thousand cases showed that this procedure reduced morbidity, and if it reduced morbidity it also reduced mortality. In the Lakeside Hospital the mortality rate for all operative procedures was six per cent. for all cases in 1898, 4 per cent. in 1908, and under anoci-association anesthesia they had reduced it to two and one-half per cent.

Dr. George D. Stewart of New York, in discussing Dr. Crile's paner, said he would have to disagree with Dr. Crile or else agree and then apologize for not using his method. Dr. Stewart recalled that some fifteen years ago Dr. Crile had read a paper in which he attributed surgical shock to vasomotor disturbances and lowered blood pressure. Up to that time everyone had his own theory. Dr. Crile had gone on from one brilliant theory to another until he gave us this one of brain cell modification. Dr. Crile told them they must block the operative field in order to take care of the wide-awake brain cells. Was there a physical basis for this theory? And, again, were there changes? He said he would accept these questions as answered in the affirmative, since he could not disprove them. He would also accept the proposition of fear as an element to be overcome, but was not the surgeon who inspired his patient with confidence at the time of an approaching operation practising anoci-association? They would all accept that point of view. With reference to the blocking, it was admitted that the effects of cocaine and novocaine were very transient indeed. He had used cocaine and found very little less pain after its use than without it. Dr. Crile had said that ether was sometimes bad and that nitrous oxide was better. They might assume that that was correct, but why, then, were they not all following Dr. Crile's method? First, because the time element was important and this method recommended by Dr. Crile added enormously to the time, and he preferred the general anesthetic which allowed him to hurry through the operation. Secondly, with nitrous oxide he had always, or nearly always, failed to secure complete relaxation. Some one had suggested nitrous oxide and oxygen and that when the patient began to come to he should be given more. He did not wish to have his patients coming out of the anesthetic during operation. He thought it must be admitted that ether was very satisfactory in most cases. In several series of cases with which he was acquainted a comparison of temperatures and pulses under different anesthetics had shown insignificant differences. Dr. Stewart expressed his admiration for Dr. Crile as a wonderful technician.

Indications and Results of Excision of the Posterior Spinal Roots in Man.—Professor Otfrid Foerster of Breslau, Germany, spoke on this subject. After thanking the audience for the welcome he had received and congratulating the surgeons of America on the perfection of surgical technique that had been reached he expressed the hope that Germany and America would continue as they always had done, to go ahead hand in hand. "They all belonged to the commonwealth of science." He stated that the indications for resection of the posterior spinal nerve roots were based on the physiology of sensibility. In reviewing the history of this operation he recalled that Dr. Dana of New York had been the first to employ it, in 1888, for ascending neuritis. Many of the failures occurred because not enough roots had been divided; it was formerly believed that it was sufficient to divide three or four roots, but such a resection did not affect sensibility. He advised the resection of from seven to ten nerves, according to the indications. The location of the pain should decide whether the operation should be extended in the upward or downward direction. He had done 44 posterior spinal nerve root resections for pain with six deaths. Of these, 22 were cervical cases and 11 thoracic. He had performed the operation for plexus neuralgia in 15 cases, for traumatic neuritis in 5, arteriosclerosis in 2, herpetic neuritis in 2, cancer or sarcoma in 7, and once arachnitis, athetosis, tuberculosis, and phlebitis. He had had 12 successes and 23 failures. He had done the resection for gastric crises in 64 cases with six deaths. Here he had had 56 successes and six failures. There had been no relapse in 29 cases, 13 were considered improved, and 9 unimproved. He had done root resection for spasticity in 150 cases, with 14 deaths. He had done 88 of these operations for congenital spastic paraplegia and the results were excellent; for hydrocephalus, 3 times; infantile spastic paraplegia, 3 times; for syphilitic spinal spastic paraplegia, 6 times, but in the latter condition the operation should only be undertaken after specific treatment, and if this was successful then the prognosis for the operation was good. He had also performed resection in disseminated arteriosclerosis 6 times and in spastic arm paralysis 23 times. The operation had been done quite often for the gastric crises of tabes and in some instances the results had been excellent, the patients being able to resume their usual employments; in other instances it had been a failure. Not all forms of gastric crisis were amenable to this operation, as the condition might be due to disease of the pneumogastric ganglion. Dr. Foerster illustrated his paper with numerous lantern slides and described his method of determining which

nerve roots should be resected by applying electric stimulation to the nerves in the field of operation. Resection was not suitable to cases of idiocy as the after treatment required a certain amount of intelligence and long training in order to acquire some degree of function. The arm paralyses were not very suitable for operation, especially the very severe spastic paraplegias.

Some Problems and Procedures in the Surgery of the Spinal Canal.—Dr. CHARLES H. FRAZIER of Philadelphia read this paper. He was of the opinion that surgery of the spinal column had not attracted the attention that it deserved. The accessibility of the cord on every aspect and the absence of vital organs served to make operations on the cord safer than on the cranial contents. Allen in his work with fractures where there was contusion of the cord showed that relief could be given by incision of the cord at the seat of the injury. His results had been brilliant and striking and while the speaker said he had not been so successful himself he nevertheless wished to report a case in which there was a fracture of the third dorsal vertebra. After incision there was a rush of bloody fluid, and while there had been a return of sensation, there had been no return of muscular power. Cases for operation must be carefully selected. He had found that tumors of the cord lent themselves readily to operative procedures. Relief from pain might be secured in operable tumor no matter what its origin. He described a case in which resection had been done for relief of pain in operable cancer of the breast which had involved the brachial plexus, the patient obtained relief of pain for a long period and the relief obtained made the operation seem well worth while. He said he would not consider spasticity and the gastric crises of tabes as these subjects had been so thoroughly covered by Professor Foerster. He thought, however, that in the gastric crises of tabes the operation should not be done until all other measures had failed and they should remember that there were cases which would not respond to mercury which would respond to salvarsan. The intradural method of operation was preferable to the epidural. The results of the operation were very variable; in some instances the pain persisted, in others it was partially relieved; in some cases there was anesthesia and in some hyperesthesia. The anterior nerve roots played some part in carrying afferent impulse and this might account for the persistence of pain. He described his method of making an end to end intradural anastomosis and the combinations that were feasible. This procedure might be made applicable to poliomyelitis. The free escape of spinal fluid was not necessarily a danger, but it was an annoyance which might be obviated by placing a pledget of cotton between the dura and the cord. The patient might also be placed in a position with the lower portion of the body elevated so that the force of gravity might exercise some control over the flow of spinal fluid. The position with the face down was also a disadvantage as the weight of the body disturbed respiration, especially under anesthesia. The patient might be changed to the lateral position. An investigation as to the amount of expired air in the dorsal and face down positions showed that the proportion was as ten to seven in favor of the dorsal position. In these cases Meltzer's intratracheal insufflation was indicated. The two stage operations could be used if necessary. The external line of incision should not be directly over that in the aponeurosis. Unilateral laminectomy had no particular advantages. Dr. Frazier gave a lantern slide demonstration of his method of operating and of suturing the wound in three tiers. He did not generally use drainage, but in one instance had left drainage for eighteen hours and in this case he had infection which he attributed to the drain. These operations required great delicacy of touch and the fact should be emphasized that there was no manipulation that did not produce harm, and that the manipulation of the cord was distinctly harmful, especially handling of the ventral roots. The differentiation and separation of the roots had a bad effect. He thought it would be an improvement if some effective block was introduced and suggested a 4 per cent. solution of stovaine.

Surgery of the Spinal Cord from the Neurological Standpoint.—Dr. D'ORSAY HECHT of Chicago discussed this topic. He stated that the subject assigned to him was too wide and that he would continue himself to a consideration of the surgery of the spinal cord in relation to the tumors. In the surgical treatment of the spinal cord their mistakes were due to inaccuracies of diagnosis, especially in the chronic diseases of the cord. They must have a better understanding of the newer clinical distinctions. In serous meningitis he took issue with the textbook view that treatment should be largely surgical. Their diagnoses were not clinically refined and they could not advance far until more of the psychical side was put before them. There was one sign that deserved mention in spinal cord cases, namely, the presence of a yellow fluid, which coagulated rapidly, and had an increased cell count. In reviewing the literature he had seen many cases much at variance with the textbook statement before referred to. A spinal osteoarthritis was a local process that could be relieved by laminectomy. One condition sometimes regarded as a tumor was multiple sclerosis. The most of the errors in diagnosis were made in the early stages of disease when the symptoms did not follow the usual classical picture. In some cases of tumor the pain became radiating fulgurant, continual, and intense and the physician might look on them as a vagrant form of neuralgia; even when he found the pain bilateral he might continue to think it neuralgic. Tumor of the cord might be present even if pain was absent, but the objective sensory disturbance was of value, especially if it was of segmentary type. As to anesthetic areas, their line of demarcation was never as definite in spinal tumors as in other conditions. One frequently found these tumors situated lower than was anticipated and a wide laminectomy should be done. Not infrequently the typical syringomyelitic sensory syndrome was present. Sensory disturbance alone was no contraindication to operation. Some of the queer complications of spinal cord tumors that had come to his attention were optic neuritis and symptoms of hydrocephalus. Edema of one or both legs was not an uncommon symptom of spinal cord tumor. In circumscribed spinal meningitis many improvements had been made in the classification and the future was promising from a clinical standpoint. He compared circumscribed idiopathic intraspinal cyst with tumor and said that their differences were not yet solved. These cysts very closely resembled tumors. The clinical attributes of circumscribed spinal meningitis were symptoms of greater diffuseness and greater variability. The plea from the neurologists was for early surgical interference in cord tumors and symptoms suspicious of tumor. They urged this because the operative field offered fewer barriers than that of brain surgery and the prognosis was better than it ever could be in brain tumors.

Dr. ALFRED S. TAYLOR of New York City discussed Dr. Foerster's paper. He thought this paper would arouse more interest in this subject in this country and his own experience led him to make no objection to the statements made in that paper. He strongly advocated hemilaminectomy in exposing the cord and said that this enabled the operator to see the dorsal side of the cord without difficulty and to perform his operation with but little manipulation. If the tumor was too large to be removed by hemilaminectomy then they could open the other side. When a hemilaminectomy had healed nothing but the *x*-ray would disclose any abnormality. When, during operation, there was blood in the arachnoid coming from crushed nerve roots this could be controlled by clamps. A local anesthesia possessed advantages in these cases. In some cases of paralysis they had found it an advantage to divide a portion of each root and then to skip the third one. If a wide laminectomy was done it should be compensated for by relief of pain and he had known a number of cases where the laminectomy was very wide and yet there was no relief of pain. He knew of a case where anterior section also failed. Neurologists said that the pain was a psychic memory in these cases. One should approach a resection of the pneumogastric ganglion with much caution. These cases that suffered from so much pain should be sent to the surgeon before they became drug fiends if they were again to become useful members of society. While the spastic cases of the upper extremity did not give very good results, they did yield some results, the operation relieved the spasticity and usually the pain. He had had two mortalities in a series of twenty cases. He never used drainage. The operation relieved the spasticity, but this merely prepared the way for long after treatment which was necessary for any restoration of function. The improvement in the mental condition and disposition of these cases was remarkable after operation and was attributed to relief from the continued muscular strain and nerve irritation.

Dr. CHARLES A. ELSBERG of New York said that the surgery of the spine was now coming into its own and that it was true that the results were far above those obtained in brain surgery. There were a large number of diseases of the spine besides brain tumor which were amenable to surgical treatment. He believed, contrary to Dr. Taylor, that in very few instances was hemilaminectomy the operation of choice. Every time they touched the cord they did harm and therefore they should have as wide an exposure as possible. There was often a low grade meningitis which extended into the roots above the

incision, and if they did not get all of the roots thus affected the pain might persist. Dr. Elsberg believed that a two-stage operation was often necessary. First, when the operation was high up under the occipital bone, for when one opened the canal he caused a difference in pressure conditions. Secondly, when operating on intermedullary tumors, one should allow the tumor to be outside of the cord and close up the wound as though the operation was completed. The excluded tumor could be removed later and sometimes one got a cure. In case of fracture of the spine, Dr. Elsberg thought it best to be conservative. If one had a serious injury to the cord nothing could help it in the way of surgery. If there was only a partial lesion one could safely wait unless there was need of decompression because of bone pressure on the cord. Where the injury was not too serious some of these cases improved in the course of a year or two. In deciding whether it was worth while to resect posterior roots for pain in any case, the speaker had followed the practice of injecting stovaine up into the canal, and if this gave no relief operation was useless. He was in sympathy with those who said that a long laminectomy should be done. In closing he called attention to the importance of a recognition of the anatomical relation of the ligamentum denticulatum.

Dr. Albert Bauer of Breslau, Germany, closed the discussion. He cited several series of cases in which the average mortality in these operations was 7½ per cent. He also reported a number of cases where a two-stage operation would have given better results than were obtained by a single operation. He did not think the danger of infection in a two-stage operation was as great as had been claimed.

Wednesday, November 13—Third Day.

The President introduced Surgeon-General Stokes of the U. S. Navy as a guest who in his response informed them that the bill providing for a reserve corps of surgeons had been passed and that in the event of war he would expect to call on this body.

Dr. Richard R. Smith of Grand Rapids, Mich., then gave a "Description of the Enteroptopic Woman." He said that visceral prolapse was always accompanied by other abnormal structural changes and these needed the same attention as the prolapse itself. He then described the two types of enteroptosis congenital and acquired. The congenital type consisted in those who were lacking in vitality from infancy and showed defective development, frequently of the framework of the body as well as of the visceral organs. The causes of this condition were frequently hereditary and due to insufficient nourishment. The acquired type consisted in those who developed this condition through malnutrition, faulty posture, childbirth and overwork. The size and shape of the thorax would often give information as to the origin of the condition. The shallow-chested, stoop-shouldered individual, who sometimes had a slight spinal curvature, usually belonged to the first type. Dr. Smith gave a lantern slide exhibit of radiographs showing typical enteroptic stomachs, sinking hepatic and splenic flexures and displacement of the colon. Many of the displacements were due to the great laxness of the supports of the abdominal viscera. In children the ptoses were slight but there was sometimes a sagging of the lower pole of the stomach; there was never found movable kidney in young children. A stable nervous system was the greatest asset in the treatment of these cases, and this being given a great deal could be done by the institution of proper hygiene. Where the nervous system was unstable therapeutic measures seemed hopeless. Dr. Smith then discussed the psychic disturbances, the accompanying pains in back, head, feet, and limbs. He also considered the disturbance of the function of menstruation, digestion, etc. Intestinal stasis was usual in these cases and its degree could be determined by the bismuth meal. He showed by radiographs the progress of the bismuth meal in some of these cases. The local defects were not of the same degree in each case and were often dependent on factors outside the abdomen. In the study of this condition they should be careful not to lose sight of the general picture in the study of any particular organ.

Dr. W. Arbuthnot Lane of London, England, then read a paper on "Chronic Intestinal Stasis." He said that when he had first begun to study this subject it was not exciting much interest, but that the profession was now occupying itself with the problems connected with this condition more and more every year. Those who formerly scoffed now saw that this condition played a common but very important part in the production of many pathological states. The poisons absorbed from the intestinal tract damaged tissues, and reduced the resistance of the various organs. Intestinal stasis facilitated the multiplication of bacteria so that these extended beyond the bounds of their normal habitat, and thus produced infection of organs directly connected with the intestines. Furthermore, the toxins being absorbed by the blood stream were carried to distant tissues and produced progressive degenerative changes. Diseases of the liver, heart, kidney, and other eliminative organs were the evidence of overwork due to the intestinal stasis, and were not necessarily distinct diseases. Pigmentation of the skin was often the result of intestinal stasis, and he had seen persons who had been copper-colored for years resume a natural color after the removal of the colon. Low temperature of the extremities was usually due to intestinal stasis. The improvement in this symptom was even more striking than in that of pigmentation after the removal of the colon. Dr. Lane then recited a case of serious derangement of the nervous system which had been corrected by a short-circuiting operation. All these things showed that it was better to attack primary causes than end results. Chronic mastitis and cystic degeneration of the breast might be caused by intestinal stasis and he did not believe that cancer would develop anywhere unless intestinal stasis existed. He had seen a marked condition of exophthalmic goiter cured by colecystotomy. The stasis was most likely to occur at the points of attachment. Obstruction was liable to occur at the junction of the duodenum with the jejunum, or it might be due to rotation caused by a prolonged mesentery. For this condition he sutured the jejunum to the under surface of the transverse mesocolon. The jejunum was so fixed that it could not exert traction on the jejunal junction. Duodenal ulceration was usually secondary to obstruction at the ileum. Duodenal tenderness was evidence of ulceration of the duodenum or gall-bladder disease and some surgeons had made the unjustifiable mistake of removing the appendix in such cases. One should not operate until he had exhausted every means of diagnosis; the exploratory operation was not considered as creditable a procedure as formerly. He had known a case in which bismuth had been delayed eighty-five hours in the ileum and yet there was no intestinal obstruction; such a case might be said to belong to the simple static variety. He thought that the site of obstrucion could be gauged by bismuth and the *x*-ray. It had been assumed that the absorption of toxins occurred only in the large bowel, but this was not the truth; the chief site was in the small intestine and this had been left unconsidered and was not understood. Stasis in the small intestine was secondary to that in the colon. If the cecum became overloaded, the small intestine was likewise overloaded and stasis occurred all along the line, even affecting the stomach and the biliary ducts. In these cases there was some absorption of toxins from the stomach. In the treatment of these cases germicidal drugs, such as arsenic, mercury, and iron, autogenous vaccines, purgatives, foods not easily decomposed, large quantities of water, and colonic flushing had been among the measures employed. Sometimes these gave temporary relief. Dr. Lane believed, however, that the effects produced by these remedies were by no means to be compared to the results obtained by the use of liquid paraffin. The effect of this agent when administered at appropriate intervals during the day was to produce evacuations which ceased to be firm, to hasten the passage of the intestinal contents. Accumulations of feces were obviated. Pressure on the splenic artery was relieved and this allowed of a better blood supply to the brain. When obstruction was due to a kink at the end of the ileum, from the appendix or by an acquired mesenteric ligament an operation was indicated. Sometimes after operation the symptoms returned. In appropriate cases he did not hesitate to remove the colon, but if this removal entailed great risk to the patient he short-circuited. Dr. Lane illustrated his address very profusely with lantern slides.

Dr. John F. Clark of Philadelphia said that a great many of these cases were due to embryonic abnormalities and there was little or nothing that surgery could do for them. No case which did not present distinct evidence of obstruction was suitable for sugery. These cases were so largely dominated by neurasthenia that surgery was of little avail. It was only in those cases in which the physi-

cian had failed that the surgeon was justified in interfering. The speaker said he made no claim to having invented a new operation, but he had tried various ones in use by other surgeons. In the beginning he had been dominated by the idea that anatomy and the *x*-ray would furnish the indications for operation and he had probably operated on cases where he would not do so today. He had learned that there might be wide anatomical variations. A colon might be markedly prolapsed and yet functionate very well. There were cases in which they could not rely on the *x*-ray; the individual history of the patient furnished the best basis upon which to make a decision. He had removed the colon in seven cases, and in one of these patients the bowels went fourteen days without moving. He had done the hammock suspension of the transverse colon and secured functional relief in 50 per cent. of the cases; of the remaining 50 per cent. some were improved and some were worse than before the operation. Neurasthenics who were not made better were apt to be made worse. Where the colon had dropped so that it could be fixed to the anterior abdominal wall, this had sometimes given relief. Where the transverse colon was redundant he had done a resection which gave satisfactory results. Some of his anastomosis cases had been failures. He had operated upon redundant sigmoid with good results. Of the seven cases in which he had removed the colon, two gave good results, two more were improved, in two there was no improvement and perhaps the patients were not so well. One died from the effects of an adhesion which was remote from the seat of anastomosis, but before death had gained twenty-four pounds. None of these patients suffered from excessive thirst and did not suffer from diarrhea after the operation, but two had developed diarrhea after the lapse of a year. This made it seem that they should consider the remote effects of this operation. He could not feel quite the enthusiasm for this operation which Dr. Lane had expressed.

Dr. Robert C. Coffey of Portland, Ore., read an exhaustive paper on "Replacing and Retaining Operations in the Treatment of Gastric and Intestinal Stasis," which he said had been published in the *Journal of Surgery, Gynecology and Obstetrics*. He stated that gastric stasis was usually secondary to and a direct result of downward displacement of certain poorly supported parts of the alimentary canal, while other more firmly fixed points remained stationary. Dr. Coffey reviewed the history of the various operations used in the endeavor to correct these defects and said he had spent as much of the past year as possible in visiting men in this country and in Europe who were interested in this work and found that each was enthusiastic concerning his own theories, and one-sided when compared with others. After reviewing the comparative anatomy of man and animals, the speaker expressed the belief that these prenatal fixations by adhesion or fusion which were found in man were without doubt for the purpose of holding the organs in place and preventing them from piling up in the lower portion of the abdomen. After reviewing the embryology of rotation and fixation and the anatomy of suspensory supports of the abdominal organs, Dr. Coffey turned his attention to the surgical procedures that seemed most desirable. In some instances the appendix and its mesentery had become adherent to the paricetal peritoneum and thus became a ligament. Many times in such cases the appendix had been removed at a previous operation and, as a result, the cecum had gone lower than before and the patient was not benefited. In the course of his investigations he had found in a considerable number of cases obliteration of the omental bursa had not taken place, in which case there was no gastrocolic omentum and therefore no support for the colon. In these cases the transverse colon was particularly prone to ptosis with sharp kinking at the splenic flexure. A floating left kidney was one of the positive symptoms which identified a case of general ptosis. In case of breast changes, the degree of the changes bore a direct relation to the degree of autointoxication and this slowly but surely disappeared after cholecystotomy. Observation of a considerable number of cases of Lane's kink had led him to the opinion that this was entirely separate from the various forms of ptosis; nearly all of these cases gave a history of subacute attacks of appendicitis. In such cases of right-sided pathology, when dietary and medical treatment had failed, the proper treatment was fixation of the cecum and ascending colon in its normal position to the parietal peritoneum by a series of pursestring sutures when the operation was done through a right rectus incision. With the cecum mobile, pericolic membrane, and kinked appendix, he, in some instances, removed the appendix and fixed the cecum and ascending colon well up into the flank through a right rectus incision. Where the right kidney was movable the operation was performed from behind. An incision was made along the line of the lumborum muscle, turning forward along the crest of the ileum, and should be ample. The deep incision should just pass the outer edge of the quadratus lumborum. The peritoneum was opened in front of the kidney. After the appendix was removed, the cecum and ascending colon were sutured to the peritoneum along the line of incision as the peritoneum was closed. Dr. Coffey then described the manner in which he fixed the kidney by opening the capsule and lifting a flap of the fibrous capsule on either side of the median line of the convex border. Three quilt sutures of chromic gut were passed through each flap. A strip of the quadratus lumborum sutures of the fibrous flap next to the spinal column was drawn through the slip in the muscle and tied to the corresponding sutures in the opposing flap. This brought the kidney substance in direct contact with the muscle and utilized the fibrous capsule as a hand swung around the muscle. The fatty capsule was then drawn around the muscle, made taut, and sutured. In dealing with pericolic membrane uniform fixation of the ascending colon through the parietal peritoneum, with or without removing the membrane, gave better results in a number of cases. Dr. Coffey demonstrated these methods by lantern slides and also his method of dealing with Lane's kink and midline ptosis. He described his modification of Beyea's method by which they first shortened the natural supports of the stomach and liver as Beyea did. They then sutured the great omentum to the abdominal wall below the transverse colon with sutures passing entirely through the omentum. The third step in the procedure consisted in expanding the upper abdomen in order to restore, as nearly as possible, the normal shape, giving room for wandering organs. The fourth step in the operation consisted in doing a plastic operation for the purpose of contracting the lower abdomen in cases where it was very pendulous. In summing up his results Dr. Coffey said he had done the operation in 41 cases; 26 were cured symptomatically, 9 were much improved, 4 were somewhat improved, and one was unimproved. In all cases the patient was kept on her back for four weeks after the operation.

Dr. Joel E. Goldthwait of Boston spoke on "Orthopedic Principles in the Treatment of Enteroptosis and Chronic Intestinal Stasis." He said that the justification of the orthopedist for being interested in the subject of enteroptosis lay in the fact that this condition exerted an influence on the bony frame of the body and on the joints. These effects were drooping of the shoulders, prominent scapulæ, spine inclined upward and backward from the lumbar region with very little curve, being almost straight until the upper dorsal spine was reached. Many chronic joint diseases were due to malposition of the viscera as well as to absorption from intestines which were usually in a condition of stasis. The treatment of this condition by medical or surgical means was incomplete unless the strain was removed. What Dr. Coffey had said about the upright posture in the human race was perfectly true. The human race paid a penalty for the erect posture which would be unfair were it not for an intelligence which might teach how this penalty was to be avoided. The congenital sausage-shaped stomach was an embryonic type. There were also embryonic types of intestine; he had seen one only ten feet long. In many instances the colon was free except for a very short attachment—only two or three inches. In the congenital type of enteroptosis the trouble began when the child assumed the erect posture and lost his fat. The ptoses of the acquired type were mostly due to bad posture and these could be corrected, but would have to observe a proper regime as regarded hygiene and might have to continue certain exercises. When there was pressure on the solar plexus this might be relieved by change of posture. In cases of the congenital type the thorax was so narrowed that one could not expect a cure, though the patient might be benefited. However, the task of the orthopedist was to correct the defects as far as possible. They should remember that in these cases the patients were tired. Their muscles were in the "gone state" and so the first thing to do was to put such patients to bed in the recumbent position. They should be put on a flat bed with a pillow under the junction of the dorsal and lumbar regions. If the stomach did not empty itself in the prone position, the hanging or knee-chest position might be assumed. Intestinal indigestion was usually worse at night when the abdomen was relaxed; to correct this the patient sometimes was put in a plaster jacket for two or three months. When he got up he wore

an apparatus adjusted to the new posture. The apparatus made slight pressure at the lumbar-dorsal junction. Sometimes a little support was given for the lower abdomen. The patient should be impressed with the necessity of continuing his exercises and attention to hygiene. It was a very simple matter to relieve a few cases, but when one considered that one child in every five had a free mesentery and might become enteroptic the problem assumed larger proportions. They should begin with the school children who had this condition and were slow and dull. By proper attention to these children their condition might be greatly improved and in many instances might be entirely overcome and thus the defect would not be accentuated and handed down. When a farmer found an undesirable strain in his stock he went to work to breed it out and this was what should be done by the human race.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Thirty-eighth Annual Meeting, held at Chicago, Illinois, October 22, 23, and 24, 1912.

THE PRESIDENT, DR. LOUIS FRANK, LOUISVILLE, KENTUCKY, IN THE CHAIR.

AFTER the usual addresses of welcome, the reading of papers was proceeded with. The scientific work of the Association was divided into two sections.

Pernicious Anemia.—Dr. J. H. STEALY of Freeport, Ill., reviewed sixteen cases of this disease. Prognosis and treatment depended wholly upon the physician's ability to determine the etiology. The arsenic treatment was the best adjunct in cases of known etiology, and the best single system for those cases whose cause could not be established. He uttered a warning as to the use of proper arsenic dosage. Dietetic measures were essential. Food should be selected with care and careful attention paid to the frequency of feeding.

Arteriosclerosis.—Dr. G. W. MCCASKEY of Ft. Wayne, Ind., said the most important factor in the production of this disease was overstraining. This was a relative matter, depending upon the strength of the arterial wall on the one hand and the blood pressure on the other. The various intoxications derived either from within or without played an important rôle. They might act either directly by producing anatomical changes in the structure of the blood vessel wall by causing an asthenic condition of the muscular structure of the media, or through the nervous and muscular mechanism of the vascular apparatus, raising blood pressure and causing overstraining. Fibrosis and spasm were the two changes found in the arterial wall. The former was impossible of removal; the latter more or less completely amenable to treatment. The proper objects of treatment, therefore, were not to attempt the impossible task of removing fibrous tissue, but to overcome vascular spasm, conserve the failing myocardium in the later stages, and so far as possible to overcome autointoxication by rational measures. The best means for accomplishing these results must depend upon the individual case, especially the character of the dominant arterial change, whether fibrous or spastic, the stage in which the case came under observation, the degree of involvement of the heart, associated autointoxications, habits of life, etc. If blood pressure was high, degenerative changes advanced and the general aspects of the case threatening, rest in bed was the most important initial measure of treatment. The diet should be as near the minimum requirements of the body as possible. This was less important with regard to the starches and fats than the proteids. The storage capacity for the former was very elastic, and a slight excess could do no harm, providing primary digestion was normal. With the proteids, however, the question was quite different, as the kidneys were involved and should be saved all necessary work, and for the further reason that the very toxins were nitrogen containing bodies, the formation of which was favored by an excess of proteids. Vasodilators, iodides, and in advanced cases with failing hearts, digitalis, and in certain cases, a special bath devised by the author at 100° F., the duration of which was gradually increased for one hour, were the general measures of treatment advocated. A special measure of treatment advocated in a group of cases in which the habit of cardiac hyperactivity was in excess of circulatory requirements and tended to keep up high blood pressure, was the use of aconite in increasingly hourly doses to the limit of tolerance or accomplishment of therapeutic results. With a strict hospital régime, the prognosis of even the very serious type of cases was not nearly as bad as we had been led to believe. He recalled a case in which serious attacks of angina pectoris, due to coronary disease, in a patient sixty years of age, were completely relieved, and in which the patient had remained relatively well for ten years.

Phylacogens.—Dr. B. F. ZIMMERMAN of Louisville said a patient receiving a sufficient number of doses of phylacogen to afford him symptomatic relief could not be assured of a complete recovery. After he had received a sufficient quantity to overcome certain acute or painful symptoms he would frequently express a desire to discontinue the treatment, in which event, in all probability, he would suffer a return of the condition, all of which could probably have been avoided by a few more additional doses following the disappearance of acute symptoms. In some cases he had found the subcutaneous injections ineffective. In such patients the intravenous administration would usually be followed by a prompt abatement of symptoms. In his experience this had been particularly true of chronic infections and in such cases he employed daily increasing doses intravenously until the infections were no longer followed by systemic symptoms. At no time, however, had he given more than 10 c.c. intravenously at one dose. These remedies, as indeed all sera and vaccines were intended to combat infection and not to effect changes in joints which had become altered or deformed by long deposits, except such changes in these deformities as would naturally ensue from the eradication of the infection. It was too early to state definitely what the ultimate results of this method of treatment would be. He thought much depended upon the accurate diagnosis of cases and the administration of the phylacogen until the systemic reaction no longer appeared. In cases where the subcutaneous administration failed to give results the intravenous method should be employed.

Unmistakable Clinical Proof of the Therapeutic Value of Tuberculin.—Dr. FRANCIS MARION POTTENGER of Monrovia, Cal., said our motive, as clinicians, was so to use tuberculin that we might keep the body fluids well supplied with specific antibodies, and at the same time produce thoroughly controlled focal reaction which would produce the maximum stimulation of healing without producing an extensive congestion and doing harm. If one was conversant with dosage, this could be done quite readily because the limitations of danger were somewhat wide. First, if tuberculin would stimulate the machinery of immunization and increase the amount of protective antibodies in the blood, we must expect this to manifest itself in the treatment of tuberculosis by a lessened tendency for the disease to spread. Resulting from this we expected fewer complications. Second, we expected tuberculin by its focal stimulation to favor healing of the focus and as a result of this we expected a more rapid healing of the disease, and the improvement of whatever complications might be present, providing they were remediable; as a result of both the increase in the immune bodies and the focal stimulation we expected to produce good results in more patients, to produce them more quickly and to make the results more permanent.

The Resistance of Luetic Red Cells to Cobra Venom Hemolysis and the Value of the Reaction.—Dr. WILLARD J. STONE of Toledo stated that with normal red cells (4 per cent. suspension) plus dilutions of cobra venom varying from 1 in 70,000 to 1 in 80,000 hemolysis took place in twenty-four hours. With luetic cells hemolysis was retarded or absent in dilutions varying between 1-15,000 and 1-40,000. The lecithin of luetic red cells was apparently not so freely available to unite with cobra venom to form the hemolysin as was the case in normal red cells. The resistance of luetic red cells to hemolysis with cobra venom was first described by R. Weil in 1909. It was a well-known fact that syphilis attacked the lipoid constituents of the body cells since less lecithin could be extracted from syphilitic tissues than from normal tissues. Apparently the luetic toxin after seven to eight weeks so affected the lecithin of the red cells as to render it less available to unite with cobra venom and the cells appeared more resistant. Possibly the cholesterin content of luetic red cells was increased, which might account for the resistance to hemolysis with cobra venom. It was well known that cholesterin might inhibit hemolysis. The reaction had been made the basis of a test for lues by him in 112 cases of syphilis. It was found that in "secondary" cases after seven to eight weeks the reaction was positive in 87.8 per cent., while in tertiary syphilis the reaction was positive in 83.4 per cent. In eighty normals and controls, including typhoid, purpura, diabetes, cancer, tertian malaria, pseudoleucemia, biliary cirrhosis with jaundice, and many exanthemata, the reaction was negative in

all but one, a patient with transient morbilliform erythema. This was the first test made and may have been due to faulty technique, or the patient may have had latent lues. He had never been able to check up by further examination of this patient. The reaction appeared to have a distinct sphere of usefulness in latent syphilis, since the positive readings were considerably higher than with the complement fixation method of Wassermann. It was also of value in determining the extent of treatment, since the cobra venom reaction, in a large percentage of cases, remained positive after the Wassermann reaction had become negative. The cobra reaction after disappearance under treatment might again become positive if the treatment had been insufficient. The test was open to fewer technical difficulties than the Wassermann. Further experience in the hands of more workers might demonstrate the value of the test. In any case the resistance of luetic red cells to cobra venom hemolysis was an extremely interesting biochemical phenomenon and might be of value where the Wassermann failed.

The Management of Pregnancy and Labor in the Presence of Pelvic Contraction.—Dr. HENRY SCHWARZ of St. Louis said that cases of moderate pelvic contraction in primiparous women, in which the head had failed to enter the pelvis a week before term, should enter a hospital and be given the test of labor. If this test failed they should be delivered by pubiotomy. Cases of moderate pelvic contraction in multiparous women, with a record of craniotomy, high forceps or pubiotomy, should enter the hospital six weeks before term and be delivered by artificial premature labor. Cases of highly contracted pelvis should enter the hospital near term and be delivered by cesarean section.

A Third Cesarean Section on the Same Woman.—Dr. J. H. CARSTENS of Detroit, drew the following conclusions: 1. In cases of cesarean section for bony deformities, with normal pelvic organs, and ordinary health, we were not justified to sterilize the woman. 2. In cases of cesarean section for eclampsia or placenta previa, we were not justified to sterilize the woman. 3. In cases of tumors of various kinds, they should be removed at the time of operation, if possible, and the woman not sterilized. 4. In cases of multiple fibroid tumors, where they cannot be enucleated, hysterectomy was indicated. 5. In rare cases, where constitutional conditions existed, such as tuberculosis, etc., sterilization might not only be justifiable, but actually indicated.

Cesarean Section.—Dr. ASA B. DAVIS, New York City, stated that obstetric surgery shared the progress of general surgery, making it possible to perform abdominal cesarean section now with a maternal mortality of not more than two per cent. in clean, uncomplicated cases and no fetal mortality. This method of delivery was easier than normal labor for the child as it was not compressed. Better results than these may be looked for. Already some operators reported considerable series without mortality. Improvement in morbidity was well marked. The reduced danger made the operation applicable to a greater variety of difficult labors. Now it was an operation of election, coming into competition with other forms of operative delivery. Some forms of contracted pelvis formed the greater number of indications for the operation, as eclampsia, placenta previa, malignant disease of the cervix, old cicatrices of the cervix preventing dilatation, atresia or deformities of the vagina after ventral suspension of fixation without progress of labor, marked disproportion between the fetal head and capacity of pelvis, accidental hemorrhage, moribund mothers to save the child, tonic contraction of the uterus, obstructing tumors, rupture of the uterus with living child, impacted face, chin posterior. In cases where the mother had been repeatedly delivered instrumentally, resulting in a stillbirth each time, prolapse of the cord in undilated cervix might be suitable indications for the operation in well considered cases. He reported 149 consecutive cesarean sections in twelve years, with the loss of seventeen mothers, maternal mortality in all cases, 11.4 per cent.; 152 children delivered, twins three times, twenty-five children stillborn or failed to live, a fetal mortality of 23 per cent. He reported seventy-one consecutive cesarean sections in the past two years, with a loss of four mothers, maternal mortality of 5.6 per cent. There were seventy-two children delivered, eight died or were stillborn, a fetal mortality of 11 per cent. He reported fourteen cases of eclampsia so delivered, ten lived, 71.5 per cent.; four died, a mortality of 28.5 per cent. Sixteen children were delivered, eleven lived, 68.8 per cent. Five children died or were stillborn, a mortality of 31.2 per cent.: twelve mothers were para I, one para II, one para III, none were in labor. Sterilization of the patient was not practised. Repeated cesarean section had been performed twenty-seven times, eighteen the second time, seven the third time, one the fourth time, and one the fifth time. The best time to operate was at once after labor started, thus insuring a mature child. If one was sure of the duration of pregnancy, the operation might be done at one's convenience at any time near term. It was not necessary to wait for dilatation of the cervix. After operation it relaxed enough to allow ample drainage. This was noted in the primiparous eclamptics who were not at term nor in labor. Unless there were urgent reasons, he advocated performing only the cesarean section, allowing involution to take place and then, if necessary on account of tumors, malignant diseases, etc., do such operation as was required. He prepared the patient as for any laparotomy, injecting ½ dram of ergotol half an hour before operation, so as to secure a tonic uterus. The operation was done by a short median incision wholly above the umbilicus, in the midline. The uterus was held up to this opening by an assistant pressing against the flanks. The uterus was opened in front midline from just below the fundus downward. It was closed by an interrupted layer of chromic sutures down to the mucosa, and this layer was buried by a continuous suture, so that no raw surfaces were left upon which adhesions could form. The uterus dropped into the lower abdomen as after normal delivery. Adhesions could not take place between it and the abdominal wound, which was high above it. He had not seen hernia in any of his high operative cases.

The President's Address.—Dr. LOUIS FRANK of Louisville said he often wondered if four years of study in a medical school really qualified one to undertake all the responsibilities of practice—the graver ones of medicine and of surgery, and those which came often in the still hours of the night—when not only one but two lives were dependent upon the skill of the attendant. In a long experience with recent medical graduates, in twenty years' observation of young hospital internes, he regretted to say that his belief was it does not. In this department of work the American schools were far behind and this in what was one of the most important branches of our art. Obstetrics must be better taught and must be viewed from a broad standpoint. Williams had recently drawn attention to imperfect obstetric education and to the inability of many of our obstetric teachers. It would seem we had retrogressed, certainly there had been no advance. The branch was poorly taught and the practice as generally carried on was worse. Most obstetricians, both teacher and practitioner, had been deprived of, or surrendered, such surgery as rightly and properly they should do. The surgeon of to-day should no more be called upon to do a primary perineorrhaphy or other operative procedure in the lying-in room, than to put on forceps, do a version or an accouchement forcé; yet our obstetricians, for the greater part, assigned such work to the surgeons, not only in practice but in teaching the subject. Our students must have better training, a larger actual experience, hospital training, and more rigid requirements before entering this field of practice. Let us insist that the men who were to introduce our progeny into this world should be something more than "grannies"; that they should be not only obstetricians but obstetric surgeons. Here was a great field for our post-graduate schools, one which if properly carried out with demonstrations and practical teaching of the requisite kind could, with the abundance of material at hand in our large cities, fill a place far more useful to the profession and public alike than they at present occupied. It must be confessed that our post-graduate schools, and even our surgical clinics, had been in many instances an inspiration not always for good. The mercenary spirit was still dominant in post-graduate schools of medicine, and these institutions, rich in endowment though the large ones might be, and with ample hospital facilities and excellent men in their faculties, required investigation as to the duration of courses, the manner of their teaching, and the conferring of certificates; if necessary, they must be regulated. Specialists could not be made in six or eight weeks, yet certificates of proficiency were granted following courses of such duration, during which time the sole opportunity for qualifications had been to observe some seventy-five or one hundred operations, and, for a fee, to do two or four operations with the assistance (?) of the tutor. He urged special examinations for those members of the profession who desired to wield the scalpel, with additional requirements in an increased hospital experience for all specialists, surgical, obstetrical, and medical. Then recognizing as such those who were able to qualify as specialists, compelling them to adhere to such practice and not surreptitiously engaged in work other than that for which they declared themselves particularly qualified.

Biological Interpretation of Abdominal Pain and Its

Surgical Relation.—Dr. GEORGE W. CRILE of Cleveland, Ohio, took this as the title of his address in surgery. He said that the only types of infections that were associated with pain were those in which the infection might be spread by muscular action or those in which the fixation of parts by continued muscular rigidity was an advantage. The type of infection that might cause muscular action when it attacked one region of the body might cause no such action when it attacked another region. But turning to the significance of abdominal pain, he considered a new viewpoint and a practical as well as fascinating one. He could best illustrate this point by referring to two cases. In the medical ward of the Lakeside Hospital several years ago there was admitted a man seventy-eight years old, whose chief complaint was obstinate constipation. The abdomen was only slightly distended; there was no fever; no increased leucocytosis; no muscular rigidity, and but slight general tenderness. He claimed to have lost in weight and in strength during the previous several months. A tentative diagnosis of malignant tumor of the large intestine was made, but free movements were secured rather easily and he abandoned the idea of an exploratory operation. The patient gradually failed and died without a definite diagnosis having been made by either the medical or the surgical service. At autopsy there was found a widespread peritonitis, arising from a perforated appendix. An infant several years old was taken ill with some indefinite disease. A number of the ablest medical and surgical consultants of a leading medical center thoroughly and repeatedly investigated the infant. Although at last they could make no definite diagnosis they all agreed that it surely was not appendicitis, because there was no muscular rigidity and no tenderness. The autopsy showed a gangrenous appendix and general peritonitis. How could the absence of pain in these apparently anomalous cases be explained? Among 8,684 abdominal sections performed by his associates, Drs. Bunts and Lower, and himself in the Lakeside Surgical Service, 923 were on the stomach and intestines, 725 on the urinary tract, 744 on the gall-bladder, 2,130 on the female genital organs, and 3,988 on the appendix. In a recent conference, after tabulating all their cases, they felt that certain conclusions could be drawn; that certain lesions of the viscera mentioned caused pain and indigestion; whereas lesions of the solid viscera caused usually no primary pain; that lesions of the hollow viscera causing no pain were rarely benefited by operation; that most cases of painful indigestion, if not duodenal or gastric ulcers, were extragastric; that the cause of the pain was the stimulus to muscular action; that pain was a damaging agency to health; that acute abdominal pain was usually surgical; that these phenomena obeyed a general biological law of adaptation; that the adequate stimulus of many of the phenomena acted through the brain; that when the brain was disconnected these phenomena disappeared and thus might the mortality and the morbidity be placed measurably further under the surgeon's control.

The Stomach from the Standpoint of the General Practitioner, the Specialist, and the Surgeon.—Dr. CHARLES G. STOCKTON, Buffalo, in this address in medicine, said he had frequent opportunity of observing the working of good and evil in the professional management of stomach diseases. This field was rich in illustrations because derangements of the stomach formed so commonly a part of pathology starting in almost any part of the economy; because disease arising in the stomach often concerned directly the physician, the specialist, and the surgeon. Few regions more generously rewarded the correlated study of the physiology and chemistry, of psychology and general medicine, of special technique and wise surgery. Nowhere, now that the craze for oophorectomy and for fixation of the kidney had subsided, might one so often see the unhappy results of unthoughtful surgical interference; the failure from timid negligence of needed operative intervention; especially the evil consequence of arly misunderstanding, misinterpretation, and subsequent mismanagement of cases. He reviewed a few conspicuously familiar cases illustrating various pathological conditions and arranged these in three groups.

First Group.—A case of unrecognized tuberculosis, with gastric irritability. A specialist, after analysis of stomach contents, recognized a gastric neurosis and treated it by lavage and restricted diet. Improvement was not forthcoming, so a surgeon was invited. He saw a reflex, secondary to chronic appendicitis, and removed the innocent organ. Following a brief period of improvement, the result of psychic impression and suggestion, the case marched on; there was now fever, cough, expectoration, heralding infiltration, softening, and vomiting.

Comment.—It was a case for general medicine, not one for specialist or surgeon; yet it might have been, and both these might better have studied the case jointly with the family physician until the diagnosis was established.

Illustrations showing the need of the specialist and in which the general practitioner and the surgeon were inadequate were present in the following group:

Second Group.—A case of gastric atony, with anemia, emaciation, and mental depression; with constipation, slight hepatic derangement, tenderness, and recurring bilious attacks. The general practitioner perceived the denutrition, yet harmed the patient with superalimentation and chalybeates. A surgeon, noting the gastric distress, the moderate motor insufficiency, the colonic stasis, and the disturbed liver, felt that the primary fault was an infected and irritable gall-bladder, and drained the useful organ with no worse effect than making it small, limiting its movements, and binding it by adhesions to the surrounding parts. In fact, the case was one for the skillful specialist, who, by local treatment, carefully suited diet, and general development of the patient, in the end relieved the symptoms; then, by educating the patient as to his dietetic limitations and necessities by teaching forbearance, willingness, and waiting, had the satisfaction of seeing him restored to reasonable health. Our defeats might often have been converted into victories had we adopted the sensible and uplifting course of united, closely knit effort in the diagnosis and management of cases. Yet more, the spirit of modern democracy, which well might flaunt the old French legend, "Liberty, Fraternity, and Equality," had invaded our profession. With its spread there would come, at least temporarily, an enormous advance in mediocrity and self-sufficiency. Higher medical education could not stop it; at best it could only hinder; at worst, it would accelerate it; legislation could not control it. The remedy lay in the united stand for higher ideals, for a better sentiment; in an actual, not nominal, getting together in our work. The management of an important medical case was a responsibility suited to a carefully selected committee, not to an individual who represented but one side of the truth. Not to the staff of one of those clinics whose subalterns were subsidized for the magnification of a single phase of medicine.

Cleft Palate Operation: Results as Demonstrated upon Dog's Palate.—Dr. GEORGE V. I. BROWN of Milwaukee said there would seem to be no question of the correctness of the following conclusions, based upon the results of the demonstrations of the experiments thus far accomplished:

1. The application of compressive force sufficient to cause traumatic injury or disarrangement of the developing teeth or surrounding jaw structures, or the application of clamps of any kind which might inhibit growth across the palate in infant harelip and cleft palate cases was unnecessary even in the most difficult types of these affections and could not fail to do permanent harm to the future development of the nose, palate, teeth, jaws, face, and pharnyx, and thus militate against the acquirement of correct speech.

2. Expedients, such as the carrying in of external tissue from the lip or skin, or the turning up-side-down of the muco-periosteum for the purpose of bridging the palate fissure were not acquired because the same purpose could be accomplished otherwise in practically all cases and because the resulting scar tissue formation with loss of bone development rendered the best speech result impossible.

3. Notwithstanding such unavoidable disadvantages and difficulties as might be encountered, the effort from first to last in the treatment of all cases of harelip and cleft palate should be to restore the parts in such manner that in every possible way the normal growth and development might be favored.

Experiences in Spinal Surgery: Observations upon Sixty Laminectomies for Spinal Disease.—Dr. CHARLES A. ELSBERG of New York City presented observations based upon sixty primary laminectomies, twenty-two for tumor, nine for section of posterior spinal roots, four for inflammatory bone disease, five for old fracture of the spine, two for syringomyelia, one for intramedullary cyst, one for aneurysm of spinal vessels, three for a peculiar disease of the cauda equina, and thirteen exploratory. He showed that the dangers of a laminectomy should be very small, but that spinal surgery was a special field demanding special training and experience. After considering the technical aspects of the operation it was his belief that the value of the Wassermann reaction in making the indications for operation in spinal disease had been overestimated. In several instances a glioma was found at operation in patients with a positive serореaction. It was almost as great an error to allow a pa-

tient with a possible spinal tumor to become totally paraplegic while antisyphilitic remedies were being tried, as to allow a patient with a possible specific brain tumor to become blind while mercury was being given. The correct diagnosis of the level of the lesion should usually be made, but one must not forget that a stasis of fluid above the lesion might give level signs above the true level. Secondary degenerations might rarely cause a shifting upwards of the level signs. The supposed danger from the sudden escape of cerebrospinal fluid during an operation was not great; the author had never seen any symptoms in his patients. Retention of urine might occur ofter a spinal operation, but the frequency of its occurrence was in direct proportion to the injury done to the cord. A very marked abdominal distention often occurred after laminectomy in the lower dorsal region. After complete laminectomy, the function of the spine was fully recovered because the main support depended upon the vertebral bodies. As many as seven spines and laminæ could be removed and perfect function of the spine recovered. Some stiffness and rigidity might remain for a few months, especially after operations, in the lower dorsal and lumbar regions. Free mobility was most quickly recovered after laminectomy in the cervical region.

He considered the surgical aspects of old fractures of the spine, and showed by a report of cases that the results of operations for old fracture of the spine with evidences of compression of the cord were little short of brilliant. Ultraconservatism was indicated in fresh fracture of the spine and only few patients should be subjected to an operation. But in the patients in whom symptoms only appeared after weeks or months after the injury and in the patients in whom there was improvement at first and stationary symptoms persisted, decompressive laminectomy should be done. Marked angulation of the cord could be straightened out, intramedullary cysts drained, etc. Laminectomy for decompressive purposes was often indicated; the opening of the spinal canal might and often did have a profound effect upon the spinal cord, which might act beneficially upon some spinal diseases whose nature was as yet not understood and whose pathology was unknown. The removal of an extramedullary tumor of the spinal cord was one of the most satisfactory operations in surgery. The operation could usually be done in less than one-half hour and the danger was small. Two stage operations were indicated in intramedullary growths and in the giant tumors of the roots of the cauda equina. The treatment of localized intramedullary tumors by the method of extrusion had opened up a new field. It was both feasible and safe to incise the cord in order to allow of the extrusion of intramedullary tumors, to empty cysts of the cord, for decompressive purposes in infiltrating growths and in spinal gliosis.

Pancreatic Lymphangitis and Chronic Pancreatitis.—Dr. John B. Deaver of Philadelphia said that pancreatitis must still be studied with an open mind in regard to its etiology and particularly in respect to its relation to chronic inflammatory disease of the alimentary tract that resulted in retroperitoneal lymphangitis; that treatment was promising in the early stages and practically hopeless when the stage of interstitial deposit of fibrous tissue was reached; that the most promising field for treatment consisted in the means already devised for the treatment of chronic inflammation in the organs with which pancreatitis was commonly associated and upon which it appeared to be dependent; finally, that pancreatitis was common and not rare, that its presence should be suspected in all cases of obscure upper abdominal indigestion, and that like other chronic inflammatory lesions of the abdomen when it was uninfluenced in a reasonable length of time by medical measures it should receive surgical attention along surgical lines.

Pre- and Post-Operative Treatment of Prostatectomy.—Dr. William N. Wishard of Indianapolis said that the more discriminating use of urinary antiseptics had been suggested by gastric and renal irritation, following the prolonged use of large doses of urotropin. If renal elimination was good, as shown by urinary analysis, prolonged use of urinary antiseptics was not imperative. Where the urine was alkaline and offensive in odor, and pus present in considerable amount, it had seemed desirable to use urotropin for several days before operation, and to continue its use guardedly for a few days afterwards. The average period of preparatory treatment required in the writer's cases, had occupied from one to two weeks, and while some cases had been operated upon earlier, others had been maintained upon preparatory treatment for a much longer period. Whether a suprapubic or perineal operation was performed, liability to postoperative hemorrhage was much influenced by the carefulness with which enucleation was done. In median perineal operations, the writer had found much advantage from the use of a solid metal inflow and outflow tube devised by his assistant, Dr. H. G. Hamer. If a two-way rubber tube was used, its walls should be as firm as possible, as pressure from packing within the wound and around the tube might occlude the outflow. On changing the dressing and removing the gauze packing the morning following operation, the metal tube above referred to was also removed and subsequently a single soft rubber drainage tube used. While incontinence might not follow suprapubic operations, a fistula might occur either after suprapubic or perineal prostatectomy. Careful and thorough excision of the cicatricial tissue and thorough curettment of the deeper portion of the fistulous tract followed by suturing, and the maintenance of drainage by an anchored catheter in the urethra, had been followed by prompt closure in all the few cases of persistent fistula which the writer had observed after suprapublic or median perineal prostatectomy. Two cases of fistula had been referred to him where an inverted V-shaped incision and extraurethral enucleation had been done, and in one of these closure was secured, but in the other the fistula persisted and in both there was associated incontinence. Occasional occurrence of fistula, however, was not necessarily an argument against any form of enucleation. Permanent incontinence had not followed in any of the writer's cases operated by median perineal incision, although it had persisted for a great or less length of time in some of them. Systematic and persistent use of dilatation of the prostatic urethra and vesical orifice with Kollmann's dilator had usually given prompt relief.

Symptomatology and Pathology of Prostatic Hypertrophy.—Dr. E. O. Smith of Cincinnati said the symptoms of prostatic hypertrophy were due either directly or indirectly to a mechanical obstruction to the outflow of urine from the bladder. The prostate gland, located as it was around the proximal portion of the urethra and in very close relation to the bladder could but interfere with the normal urine channel when it underwent changes that disturbed these normal relations. Increase in size and shape of the prostate would necessarily produce a mechanical change in the shape, length, or entrance into the urethra. Among the earliest changes noticed by the patient was the decrease of the force with which the urine was ejected. There was no projectile force that carried the urine away in a good stream. It was possible for a patient to have both a cord lesion and prostatic hypertrophy. This applied more particularly to cases that came during the early period of expected enlargement of the prostate.

As a result of the nature of the mechanical obstruction to the outflow of urine and the effect on the bladder, there was sooner or later a failure on the part of the bladder to completely empty itself, which was the beginning of residual urine. Acute, complete retention might come on suddenly without warning, following indiscretions on the part of the patient. From a prognostic viewpoint, probably the most important symptoms were those referable to the kidneys. The kidneys were affected either from back pressure, from infection, or both. Dilatation of the ureters and pelvis might follow long-continued obstruction to urinary outflow, thus making a pressure on the renal parenchyma. Resulting from this was a functional insufficiency of the kidneys. The quantity of urine might not be diminished but the urea and other products of elimination were below the normal. It had been his observation that a great many, in fact, a majority of patients troubled with prostatic hypertrophy suffered from marked mental depression. There were two general varieties of changes in the structure of the gland. One in which there was an increase in the so-called glandular part of this structure and the other when there was but little tumor mass with greatly increased amount of dense, tough, fibrous tissue. In the open dissection of the perineum, the first part of the gland met was the posterior lobe which must be cut through before the real hypertrophy was reached. This bit of anatomical relation might explain some of the difficulties encountered by those attempting the open dissection method for the first time. Unless one got the enucleating finger into the capsule, the line of cleavage would be missed and a very difficult task was made out of a comparatively simple one. The easiest place to find the line of cleavage was in the roof of the prostatic urethra.

(*To be continued.*)

Miscellany.

Religion and Sanitation.—The religious customs of the non-Christian portion of the British Empire are generally brought into public notice by the problems of hygiene, health, or sanitation which these customs raise. The latest example of this is the comprehensive survey which the Government of India is instituting into the best methods of improving the sanitary arrangements at the various centers where Mohammedan and Hindu pilgrims meet for starting on their journeys to Mecca or for other religious purposes. The number of such pilgrims has increased so enormously with modern traveling facilities that there is always a serious risk of the importation as well as the outbreak of disease at these centers. The inquiry is expected to co-ordinate the arrangements which have already been enforced at some of the more important centers. Each province will have the benefit of the Imperial Sanitary Commissioner's presence, who will draw up a report on the result of the local inquiries. On each local committee will be a representative of each railway which is engaged in the pilgrim traffic. These facts have peculiar interest as showing how Western science complicates at first Eastern religious customs by making their observance possible to even larger numbers of the devout, and then, by regulations necessary for the public health, may end in modifying them to a degree not foreseen or contemplated.—*The Hospital*, October 19, 1912.

Some Attributes of Success.—R. A. Walker enumerates some of the qualifications which are more essential to the physician than to any other professional man. The doctor should have good health and tact to use the knowledge he possesses. He should exercise promptness in responding to calls. He should cultivate the virtue of sympathy, for the physician who does not display sympathy for suffering humanity can never endear himself to his patients. If to this be added cheerfulness and charity then, if carefully handled, church, lodge, and political affiliation can be used as a lever to advantage. Of some of the hindrances to success at the beginning of a young man's life, wealth is the greatest, for in many individuals it begets laziness, carelessness, and a tendency to shirk work in unpleasant weather, because there is no sense of compulsion. Poverty, while an unfortunate handicap, may be frequently overcome by grit, energy, and good management. Another great hindrance to gaining and holding the confidence of one's patrons is excessive self-aggrandizement. The physician who is always on the go night and day when all other doctors in the community are comparatively idle, who passes through epidemics of malignant diphtheria and scarlet fever and cures every case, the doctor that treats hundreds of cases of pneumonia and typhoid fever and never loses a patient, is generally the doctor, if the truth is told, that is incapable, as a rule, of making a correct diagnosis. Such boasting is, to say the least, in bad taste, and the best people lose respect for the doctor who descends to this practice. The too frequent use of technical terms in conversations with laymen can be overdone and in some cases it creates disgust.—*Virginia Medical Semi-Monthly.*

"Shop Talk."—J. G. Mumford discourses on this subject as follows: "The solemn converse of young professional people always interests me. It is not babble; and sometimes it is informing, because it shows how the wind sets. Students of law and medicine and young practitioners seem to be most given to this sort of talk. The awful person who chatters of stocks develops his awfulness late in life; and the politician is nearly always acceptable, because the politician, whether wise or foolish, deals with subjects of widest interest. Moreover, his talk is rarely technical. Medical talk in public—"doctor rot" as one of my tired friends calls it—is sometimes heard even from venerable lips which should have been better trained. I have agonized memories of hanging on to trolley-car straps with certain merciless consultants, while they poured out upon me and upon our long-eared neighbors the details of the case we were about to visit. I've tried to escape from my misery by sitting down even while my companion remained standing, but that maneuver stimulates one's tormenter to worse aggressiveness and louder shoutings. The best plan is to murmur appreciation and to approach a listening ear as near to his lips as decency will permit. Even so, painful moments arise, as when he nips off his discourse suddenly and demands in truculent tones what you would do under the conditions he has described. I have learned to say that I can't tell until I have seen the patient."—"A Doctor's Table Talk."

The General Practitioner and His Mission.—In a recent book entitled "The Doctor and His Work," C. J. Whitby states that the successful physician is an artist, not a mere prescribing machine; he treats the individual, not a label. To do this he must know the personal peculiarities of the patient. Herein lies the justification of the general practitioner's existence. A man of sense who has brought human beings into the world; who has tended them through the disorders of infancy; who has seen them grow up, marry, and have offspring of their own whose early years, at any rate, he may well have the opportunity of observing; succeeds in knowing them as a consultant, even of the keenest clinical insight, cannot know them. He knows how they react to diseases and to remedies. He knows how heredity shows itself in matters pertaining to health. In a word, he knows the natural history of disease in a way beyond the teachings of the laboratory or instruments of precision. A man of this kind has a store of knowledge, acquired during long years of observation, and developed by practice till it becomes intuition. This experience cannot be transmitted and for the most part dies with the possessor, but while he lives it is invaluable, and it will be an evil day if ever the charge of sick people is handed over to medical officials who have not the same opportunity of studying their peculiarities, and whose treatment, therefore, must be largely a matter of cut and dried formulæ. There is, moreover, the psychological factor to be taken into account. The general practitioner necessarily learns much of the mental as well as of the bodily structure of his patients, and the faith in him that makes them stick to him as their family doctor for many years is a professional asset beyond price. If there is to be no choice of doctor, as would result from the nationalization of the practice of medicine, this potent element of cure must tend to fade away. —*British Medical Journal*, October 12, 1912.

Eugenics in Constantinople.—The Armenian Patriarch in Turkey recently issued a decree forbidding the clergy to celebrate any marriage unless the parties thereto furnish a medical certificate showing that they are in physical and mental health.

CALORIMETRIC OBSERVATIONS.

By GRAHAM LUSK.

NEW YORK.

(From the physiological laboratory, Cornell University Medical College, New York City.)

ONE of the important considerations for the welfare of the people is that of their food. In the recent Congress of Hygiene held at Washington, consideration was given to the action of foods, in the special section of the congress entitled Dietetic Hygiene. This section was presided over by Dr. R. H. Chittenden and the most notable guest present was the distinguished international president of the congress, Professor Max Rubner of Berlin.

Carl von Voit, the master of Rubner, working in association with Pettenkofer, was the first to measure accurately the end-products of oxidation in man, using the celebrated Pettenkofer respiration apparatus which was built in 1862 through the financial aid of King Maximilian of Bavaria.

To Rubner the world owes the construction of the first calorimeter which correctly measured the heat given off from an animal. This calorimeter Rubner constructed with very modest means in the University of Marburg to which, as a young man, he had been called to be professor of hygiene. With this apparatus he was able to show that the heat eliminated from a dog in 24 hours was exactly the amount of heat which would have been produced by the dog from the oxidation of those materials which he destroyed in his body during the period in which he was in the calorimeter. This quantity of fat, carbohydrates, and protein which was oxidized was measured by Rubner through determinations of the products excreted from the animal during the time.

Here, then, for the first time, the law of the conservation of energy was proved to apply to the living organism. The heat produced was simply the heat which would have been produced from the materials oxidized during the period of 24 hours when the dog was in the calorimeter. The effect of various foods was noted. Also, the effect of various temperatures was observed. Rubner has called attention to the fact that men, through the use of clothes, seek to surround their skins at all times with a tropical temperature so that thermal influence need not usually be considered as modifying the heat production in human beings.

Atwater worked in Voit's laboratory with Rubner and derived his ideas from this source. Returning to America, Atwater, with the aid of the physicist Rosa and supported by United States Government funds constructed in 1890 a calorimeter sufficently large for a man and showed that the same principles held true for a human being that Rubner had shown for the dog. Benedict, succeeding Atwater, has carried on work with enthusiasm and success in the new Nutrition Laboratory of the Carnegie Institution of Washington, the laboratory being located in Boston.

Through the generosity of Col. Oliver Hazard Payne, sufficient funds were given to allow of the construction in this laboratory of a calorimeter modeled on the lines of those in the Boston laboratory, but smaller in size, so that the heat production of dogs, babies, and dwarfs might be accurately determined. The construction of this apparatus was under the charge of Dr. H. B. Williams, who, besides being a physician, is also a physicist and mechanic of the highest attainments, and through his skill sensitive regulatory apparatus was installed in connection with the new calorimeter so that Dr. John Howland was able to determine in hourly periods the heat production of a baby weighing less than seven pounds, and to compare this with the quantity of heat which should have been produced from the materials destroyed in the baby's organism during the time. The quantity of fat, carbohydrate, and protein oxidized were calculated by determining the amount of oxygen absorption, carbonic acid elimination, and nitrogen outgo of the body.

Metabolism experiments upon a dog were, for the first time, possible in hourly periods. It was possible, for example, to follow the heat production after giving meat and to see how it varied from hour to hour and also the action of other foods.

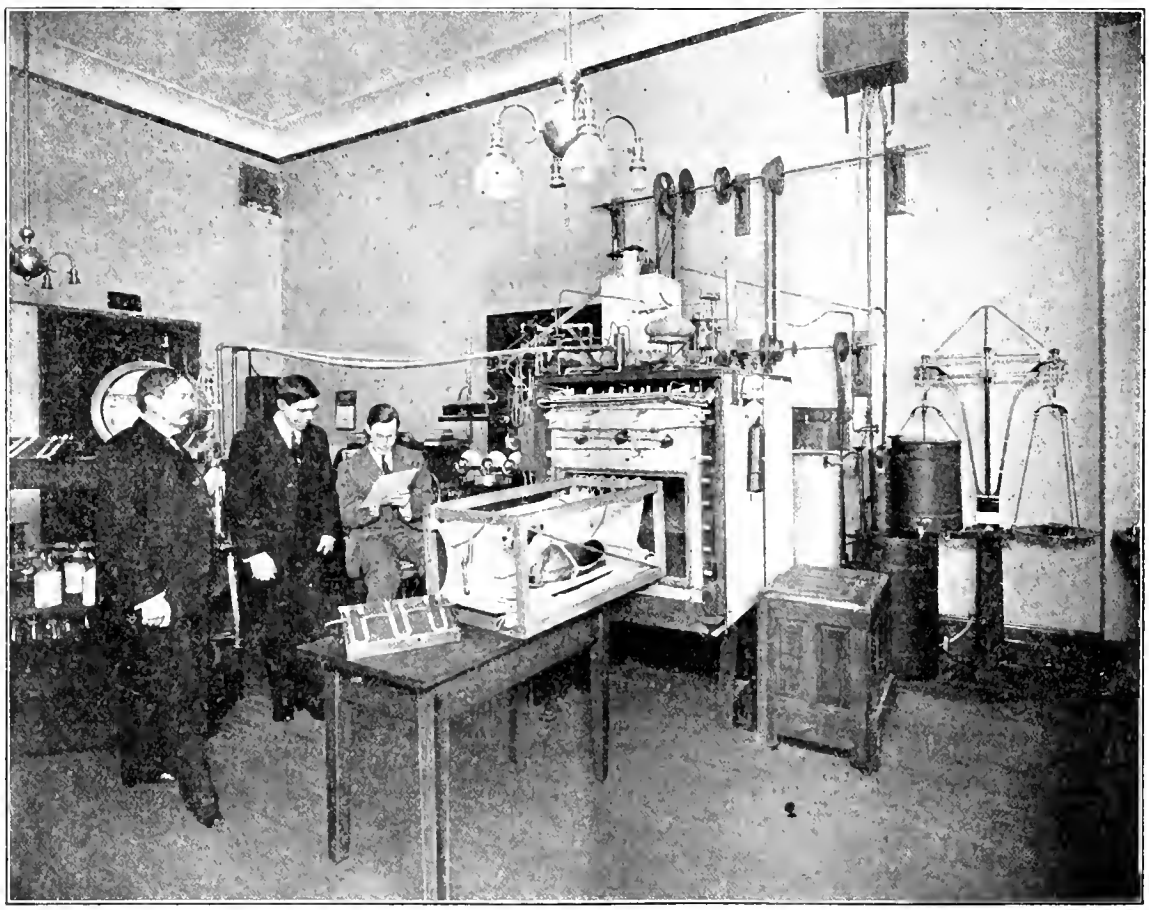
When meat was given in quantities as high as 1,200 grams at once, it was found that the heat production in one dog rose from 22.3 calories per hour before the food was given to a level of 36 calories during the second hour after food and to 42 calories during the third hour after food, near which level it remained until the eleventh hour, when it gradually declined to 25 calories 21 hours after the ingestion of the meat. It is apparent, therefore, that meat given in this quantity can nearly double the heat production in the animal.

The question now arose, what was the cause of this great heat production? Rubner explains the rise in heat production after giving meat by stating that protein is of such a chemical structure that much of it cannot be used as a source of energy for the cells of the body, but is destroyed with the production of free heat. Such heat is simply that fraction of fuel value which is wasted because it is not furnished to the cells in the form of sugar or fat, which substances are the essential fuel supply of the cells. In order to understand the action of protein it is necessary to recall that it is made up of a great many chemical units called amino-acids which, strung together in various quantities, build up the varying proteins of the different cells. When

protein is eaten it is digested through the digestive juices, and it is broken down into the individual fragments or individual amino-acids of which the large molecular complex consists. These amino-acids are soluble in water, soluble in the juices of the gastro-intestinal tract. They are absorbed directly into the blood, carried by the blood to the tissues and deposited in the tissues, as has been recently demonstrated by the work of Folin and Denis, work which has been confirmed by Van Slyke. Folin and Denis have shown that amino-acids increase in quantity in the blood and increase in quantity in the tissues one hour after they are introduced into the intestinal tract, although, during this first hour, there is no increase in the quantity of urea in either the blood or the muscle, which indicates that the process of destruction of the amino-acids is not immediately effected.

The simplest of all the amino-acids founds in the organism is glycocoll, which is amino-acetic acid. This substance introduced into the gut of a cat by Folin gave the results indicated above. Glycocoll is also a substance which, if fed to a diabetic dog, can be converted completely into glucose, as work in the writer's laboratory has demonstrated. If Rubner's idea were correct that the great heat production which followed the ingestion of protein was due to the fact that the materials in the protein were not completely convertible into sugar or fat which could be utilized by the cells, then the ingestion of glycocoll, which is completely convertible into sugar, should have no more effect upon heat production than would a quantity of sugar which could be produced from the glycocoll administered.

Since 25 grams of glycocoll result in the production of 20 grams of dextrose, the effect of these two substances was compared in these quantities. It was found that when 20 grams of dextrose were given to the animal in a certain nutritive condition, the heat production was increased to the extent of 2.5 calories, whereas when 25 grams of glycocoll were given, the heat production was increased 31.3 calories. It was apparent, therefore, that glycocoll had an enormously greater power to increase metabolism than its equivalent quantity of sugar possessed. It might be thought that the increased heat production here observed was due to the elimination of an increased quantity of urea, but experiments showed that after giving urea to the dog there was no increase in the heat production. Again, it might be thought that the process which involved the removal of the nitrogenous portion, that is, the NH_2 group, from the non-nitrogenous remainder of the amino-acid might evolve heat. However, it was shown that when another amino-acid called glutamic acid was given, there was no increased heat production whatever. The nitrogen of this amino-acid was recovered as urea, hence it must have been deaminized. The process of deamination, as it is called, that is, the removal of the NH_2 group, has therefore no effect on the heat production. These experiments proved that the great



This figure shows a respiration calorimeter built at a cost of about $5,000. The dog, wearing a bandage which holds a rectal thermometer in place, is shown lying on a cot suspended from a frame which may at any time be slid into the open chamber of the calorimeter. This accomplished the front is then sealed. The animal respires within the chamber, the water and carbonic acid which he eliminates are removed by circulating the air through absorbing chemicals, and fresh oxygen is admitted automatically to replace the oxygen absorbed by the animal. Four people are constantly employed during the experiment. The heat produced by the dog is removed and measured by a current of water flowing through a system of pipes within the calorimeter.

heat production after giving glycocoll was not due to the elimination of urea, a substance formed in the course of its metabolism, and was not due to the process of deamination. It is therefore necessary to conclude that the action of glycocoll upon metabolism is in virtue of its chemical structure and that it has a stimulating effect upon the cells, causing an increased heat production.

Other experiments showed that a high heat production was caused by alanine, a substance which is completely convertible into dextrose in the organism, and that leucine and tyrosine also had some effect in this regard.

Zuntz believed that the increase in heat production was due to the work of the intestines or "Darmarbeit," but Benedict has shown conclusively that the introduction of cathartics into the intestinal tract or the introduction of indigestible agar agar do not in the slightest way affect the metabolism of man. Alanine and glycocoll act as irritants to the mucous membrane of the stomach, frequently causing vomiting, and it might be considered possible that the results were due to this stimulation. However, the dog employed remained perfectly quiet throughout the hours of experimentation and showed no signs of nausea. Furthermore, a solution of urea, which causes nausea, has no effect whatever upon the metabolism. From these facts the conclusion must be drawn that amino-acids absorbed into the blood, carried and deposited in the tissues, as they are, act directly as stimuli upon the tissues, increasing their heat production.

As regards the influence of carbohydrate, new points have been brought out in these recent experiments. If a dog be given 50 grams of dextrose in water, the heat production rises from 16.2 calories per hour to 20 calories per hour and remains at that height during the second, third, and fourth hours after administering the substance. It is found from the respiratory quotient during this period that, aside from the small protein metabolism, the whole of the heat production is derived from the dextrose which has been ingested. At the end of the first hour the dextrose has risen in percentage in the blood and then on account of the osmotic conditions the blood becomes more dilute as is indicated by a decrease in the percentage of hemoglobin present in it. During the fourth hour, the last hour of the high metabolism, a large volume of urine is eliminated and the blood tends to regain its former composition. During the process of dextrose absorption, dextrose is carried through the liver into the general circulation, affording opportunity for its ready oxidation on account of its free diffusion into the cells. The writer has called this increased heat production a metabolism due to plethora. Urea and salt solutions which must produce osmotic changes between the blood and the tissues have no effect upon metabolism when they are given to the dog *per os*. If fat be introduced, the metabolism will also be increased, an increase which is evident during the second and subsequent hours after its ingestion. Experiments show that emulsified fat introduced into the stomach quickly induces a considerable flow of milky chyle from the thoracic duct, which is due to absorbed fat coming from the intestine. Here again one can speak of an increase in metabolism as due to plethora.

It appears almost certain that mechanical work can be done more easily if this condition of plethora exists. That is to say, if carbohydrate and fat are continually entering the blood stream so that they can be carried to the cells in increased quantity.

Rubner in recent brilliant experiments has shown that when the yeast cell acts upon a sugar solution, the energy of the fermenting yeast is derived from the conversion of sugar into alcohol and carbonic acid. A small portion of energy is also liberated exo-cellularly, the yeast enzymes acting directly upon dextrose present in the solution itself. One might conceive that a similar effect is produced in the organism after giving sugar. One might imagine that the greater portion of the suar poured into the circulation is used directly for the motions of cell life, whereas a small fraction is destroyed on account of the presence of enzymes in the circulating fluids. In the latter case, the reaction would produce only free heat.

This hypothesis, fascinating though it be, is not borne out by the results obtained when a mixed diet is given to the dog. A diet was given consisting of 50 grams of cracker meal, 33 grams of meat, and 10 grams of lard. The heat production rose from 16.2 calories to 20.2 calories. When alanine was added to this mixture, alanine which of itself alone would raise the metabolism from 16.2 calories to 19.2 calories, no effect whatever was observed. When 20 grams of glycocoll were given, the metabolism rose just about as high as the glycocoll itself would have caused it to rise if it had been given alone. It has been set forth that glycocoll acts in virtue of its being a stimulus to cellular protoplasm. When it is given, however, in a mixed diet which has already established a rhythm of cellular motion equal to that which the amino-acid would have caused if given alone, there is no increase in the heat production. It would seem, therefore, that the increased heat production after giving carbohydrate was not due to an increase in the liberation of free heat, but that it was due to a mechanism akin to the mechanism set in activity by the amino-acids. In other words, amino-acids entering alone would cause a certain extra amount of oxidation. Carbohydrates entering in quantity would establish, perhaps, a similar level of oxidation, but the amino-acids entering with the carbohydrates would encounter a height of metabolism already established which they themselves alone could produce, but to which they can not further contribute.

These results lead to the general conclusion that there exist the following forms of metabolism in the quiet or sleeping dog excluded from thermal influences.

1. *A basal metabolism* when the cells are nourished by a blood stream which does not receive food from the intestinal tract and the composition of which is regulated by the organs of the body.

2. *A metabolism due to plethora* induced by an increased quantity in the blood of carbohydrate or fat metabolites which are being absorbed from the intestine.

3. *A metabolism due to the stimulus of incoming amino-acids* acting upon the cells.

The metabolism of plethora and the metabolism of amino-acid stimulation cannot be added to each other; there is no summation of effect when both influences are brought into action together. In other words, cellular activity induced by the presence of carbohydrate is not further intensified by the stimulus of amino-acids unless the latter alone would accomplish the result.

The height found for the basal metabolism of the perfectly quiet resting organism, excluded from

thermal influences and determined eighteen hours after the ingestion of food, confirms Rubner's law of skin area, but places the heat elimination at a lower level. Thus the basal metabolisms of two dogs of different weights and that of a dwarf seventeen years old and weighing 21.3 kilograms showed the following values for calories produced per square meter of surface, calculated as for a period of 24 hours.

	Weight in kg.	Surface area in sq. meters	Calories per square meter of surface
Dog I	13.8	0.696	759
Dog II.	9.3	0.496	784
Dwarf, J. P.....	21.3	0.946	775

The values in the last column agree within 3 per cent. In sleeping infants, however, the basal metabolism reached 1,100 calories per square meter of surface and here the metabolism was also shown to be especially sensitive to protein ingestion (amino-acid stimulation), indicating that a high metabolism is characteristic of youthful protoplasm.

As a practical conclusion of these experiments it appears that in a quiet and resting animal the heat production is increased by about 20 per cent. after the ingestion of a mixed diet, and this increase continues during the period of intestinal absorption; also addition of moderate amounts of protein to the diet has little effect upon the production of heat, even though this protein given alone would of itself cause a considerable rise in the heat production. Hence, a mixed dietary is physiologically economical.

Experiments are soon to be undertaken to establish the validity of the conclusions set forth in this paper as regards man both in health and disease.

ETAT VERMOULU—A FORM OF SENILE CORTICAL DEGENERATION.*

By EDWARD MERCUR WILLIAMS, M.D.,

PHILADELPHIA.

INSTRUCTOR IN NEUROLOGY AND NEUROPATHOLOGY IN THE UNIVERSITY OF PENNSYLVANIA AND ASSISTANT NEUROLOGIST TO THE UNIVERSITY HOSPITAL.

THIS form of degeneration of the brain cortex to which Marie ascribed the name Etat Vermoulu, or worm-eaten state, has been reported by several of his pupils (Dougherty, Léri, Ficai, Rossbach), but up to the present time has not been described in any of the English or American journals.

*Presented at the meeting of the Philadelphia Pathological Society, April 25, 1912.

For my material I am indebted to Dr. William G. Spiller and Professor Pierre Marie, in whose laboratory I started the work on this subject. I wish also to thank Dr. Allen J. Smith for his kindness in photographing the specimens.

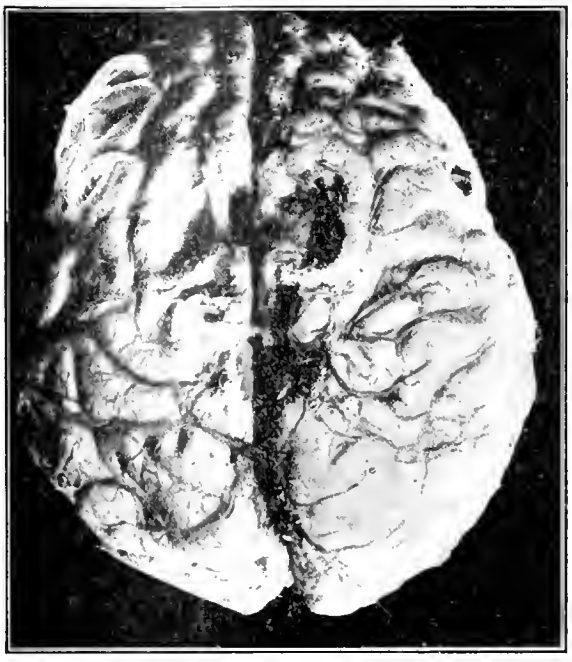

FIG. 1.—View of top of brain showing ulcerated appearance of the frontal and paracentral areas. (Case of Dr. Spiller.)

Etat Vermoulu is found in senile brains, particularly in those having a more than usual degree of arteriosclerosis. According to Léri it was present in two per cent. of all the brains examined at the Bicêtre.

It occurs as somewhat irregularly shaped and sized ulcerations on the surface of the brain with the formation in the more advanced cases of small cysts or cavities in the deeper subcortical tissue.

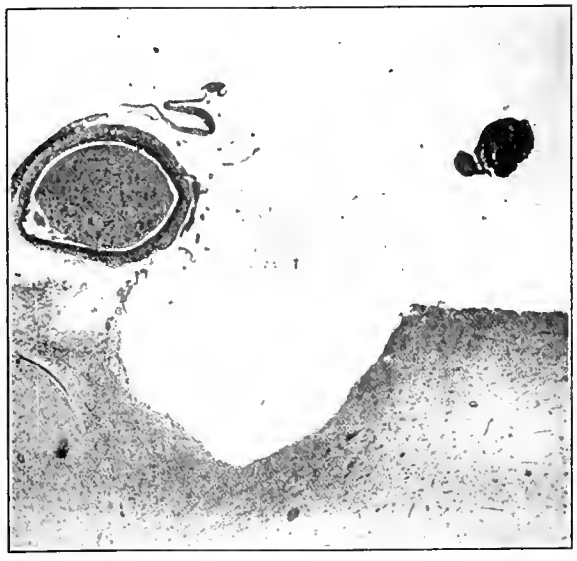

FIG. 2.—Section of the frontal cortex, stained by Van Gieson's method, showing the cone shaped ulceration of the cortex and the glial thickening of the cavity wall. (Case of Prof. Marie.)

The clinical picture as a rule is not other than that of a senile dementia of greater or lesser intensity. Perhaps this is in part due to the frequent occurrence of the disease in the frontal lobes,

though the place of predilection seems to be the temporal region. The involvement of other cortical areas, according to the location, may give different symptoms. Often there are some motor disturb-

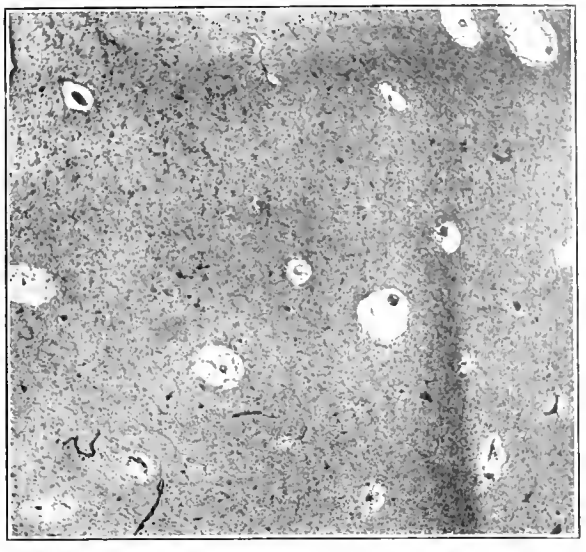

Fig. 3.—Specimen of temporal cortex, stained by Van Gieson's method, showing the intense degeneration around the walls of the blood vessels, forming the large perivascular spaces. (Case of Prof. Marie.)

ances from the presence of additional subcortical lesions, such as small areas of softening (lacunæ) in the internal capsules.

The gross appearance of such a specimen is that of numerous small ulcerated areas on the surface of the brain. In a fresh specimen they appear yellow, gray, or brownish in color, the walls usually becoming stained by the yellowish fluid or semi-gelatinous substance contained in the cavities. These ulcerations are irregular in shape and outline. They have sloping walls and extend only to the border of the white and gray substances. Several adjacent convolutions may be involved or there may be several unaffected convolutions intervening between those more seriously affected. The seemingly unaffected convolutions, however, by micro-

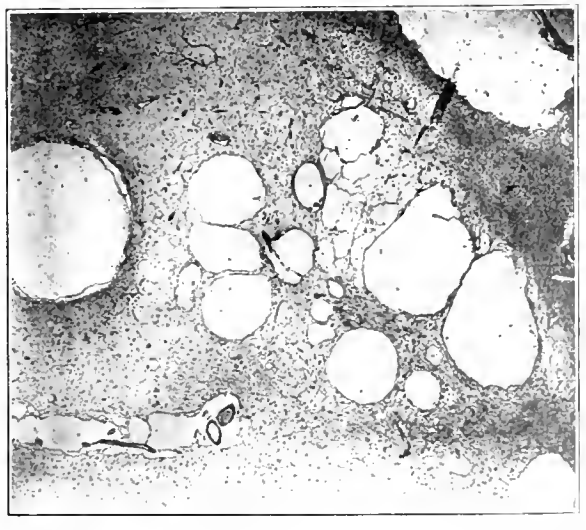

Fig. 4.—Section of temporal cortex stained with hemotoxylin-eosin, demonstrating the great degree of disintegration and vacuolization of the cortex and the absence of any ganglion cells. (Case of Prof. Marie.)

scopical examination show intense changes, probably the beginning of what would later have the characteristic lesion of the etat vermoulu.

The pia, due to its atrophied condition over these areas, usually tears very easily, falling inward and leaving irregularly sized funnel-shaped cavities with the bases outward.

Microscopically, the pia in close proximity to the ulcerated areas is infiltrated and thickened, the blood vessels are sclerosed, hyaline, and many of them almost completely occluded. Calcareous degeneration, so frequent, according to Ficai, was only present in one or two arteries. Directly over the ulcer the pia is usually thinned, atrophied, and fallen in, forming irregular folds near the edges.

The cortical substance shows a proliferation of the glia, this often taking the place of the tangential fibers as well as of the cellular elements. The glial overgrowth is mainly confined to the fibrillary substance as there appears to be no excessive increase in the glial nuclei. Such overgrowth is probably secondary to the earlier process of softening from the imperfect nutrition following the gradual obliteration of the lumens of the cortical vessels.

In a number of the sections there appeared to be an unusually yellow tinge in the walls of the ulcerated areas, suggesting the presence of blood pigment. This was probably caused by the ab-

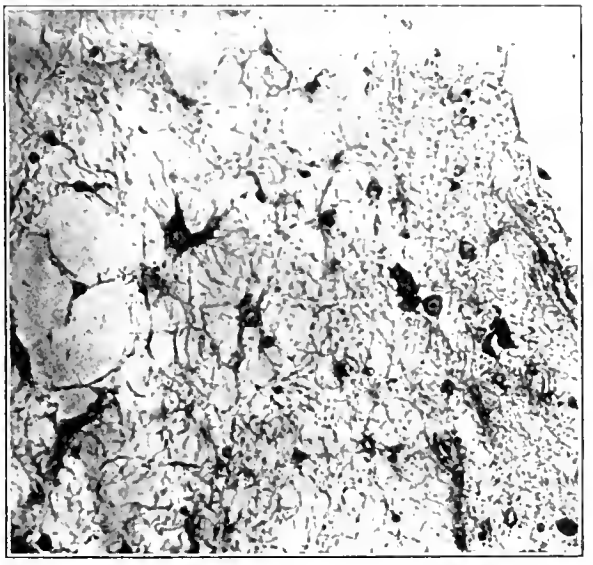

Fig. 5.—Area from Fig. 4 with greater magnification illustrating the absence of nervous tissue and the prominence of the neuroglial reticulum.

sorption of blood coloring matter before its chemical change into hemosiderin. No reaction was obtainable to the tests for hemosiderin, though several vessel walls stained a greenish blue by the ferrocyanide method showing the presence of albuminate of iron in the vessel coats. The possibility of blood coloring matter being carried in solution and not giving the iron reaction before a certain definite chemical change has taken place is shown in a recent article by Claude and Loyez.

Amyloid bodies are very numerous, much more so than in ordinary conditions of senility, and in some of the sections they form almost a solid layer in the region of the tangential fibers. Other bodies having a hyaline appearance are scattered throughout the sections, staining a deep pinkish red by both the hematoxylin-eosin and Van Gieson methods. These are blood vessels occluded by hyaline material so as to form solid hyaline masses, in which there are in many cases no distinct vessel walls visible. Where the longitudinal axes of the vessels have been cut there are long, irregularly shaped hyaline cords.

Throughout the gray cortex and to a much lesser

degree in the subcortex, the vessels are surrounded by broken-down, rarefied tissue, leaving in its place only a slight perivascular reticulum of glial fibers, containing a few nuclei, some cellular débris, and fluid. These perivascular cavities may be seen also in the substance of the cord in one of the specimens examined. Such small areas are doubtless points of origin for the cysts occurring in the advanced stage.

The areas or plates of miliary sclerosis described by Redlich and referred to by Léri and others as being frequent in this condition could not be found in any of the specimens examined.

With the extension and confluence of these cavities and the overgrowth of the glial and even, to some extent, of the connective tissue, the cellular portion undergoes destruction in varying degrees. Even in those cases where the cystic formation is absent and only a light grade of superficial ulceration is present, the brain cells show considerable disintegration and destruction, due no doubt to the faulty nutrition so common in the sclerotic cortical changes of senility. In some instances the cortical destruction and overgrowth of glia is so great that there remains practically nothing but a loose meshed network of neuroglia.

The disease most frequently affects the temporal lobes, often the frontal and parietal, and Léri reported even involvement of the cerebellum.

In its early stage this condition probably could not be distinguished from cases of senile arteriosclerosis, of which I believe it to be only a more severe and advanced form. These more severe changes are probably (Léri) due to the imperfect nutrition from the gradually occluded arteries, causing a slow breaking down and disintegration of the tissue around the vessels, with its absorption and an overgrowth of glia, to a certain extent compensatory in nature. In the ordinary senile sclerotic changes described by Alzheimer, however, unlike the etat vermoulu, the nerve cells are disturbed and often destroyed, but there is never a true destruction of tissue with disintegration and absorption and cavity formation.

A CASE OF CHRONIC PANCREATITIS WITH POLYCYTHEMIA (CLINICAL DIAGNOSIS: PANCREATIC LITHIASIS).

By G. A. FRIEDMAN, M.D.,
NEW YORK.

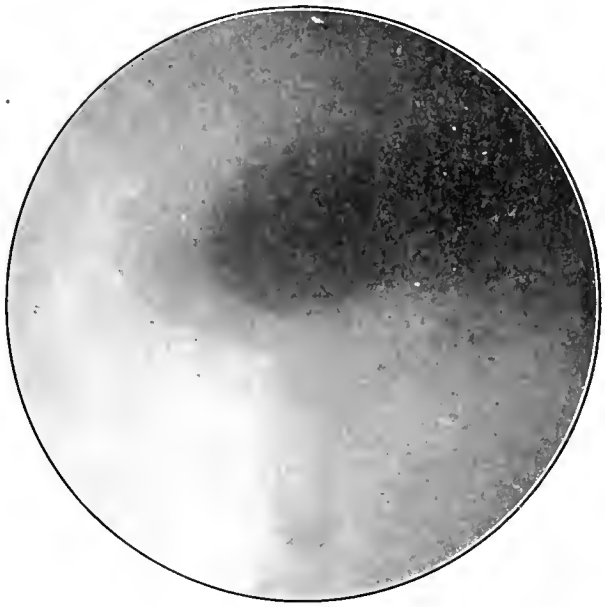
HIEF IN INTERNAL MEDICINE, MOUNT SINAI DISPENSARY; ATTENDING PHYSICIAN IN DIGESTIVE DISEASES, VANDERBILT CLINIC.

THE following case which was under my observation for a little over 4 months, presents many interesting points, and I therefore believe it worthy of publication.

Patient, D—d I——s, 32 years old, lieutenant in the Russian army, 7 months in this country, was seen at the Vanderbilt Clinic on January 12, 1912.

History.—Has had four attacks of severe pain in the epigastric region during the last 18 months. The pain, though chiefly localized in this area, radiates to the right and left of the back and upper chest. It is rather of a dull and gnawing character and lasts four to five weeks; in the intervals between the paroxysms patient is in perfectly good health. The attacks of pain are not so severe as in typical severe gallstone colic, and therefore never necessitated the injection of morphine.

No matter how annoying the pain may be, it ceases when the patient lies down for 30 to 60 minutes. After having been in the recumbent position for that time, he is relieved for a few hours. The pain occurs several times during the day and always ceases in the decubitus. At night patient is free from pain. When, during one of the paroxysmal attacks, he happens to be in the street, the patient is frequently compelled to partake of some food. This somewhat relieves, but does not stop the pain, as is the case in the recumbent position without a previous meal. These data were obtained from patient after cross-examining him many times. When, after four or five weeks, the paroxysmal pains subside, he finds he has lost five



Showing a Shadow, Probably of a Pancreatic Calculus, Below the Tip of the Third Lumbar Vertebra.

pounds in weight, which he recovers in the intervals.

He claims that the fourth attack was more intense and lasted longer than any of the three previous ones. During the attacks there was constant nausea, but actual vomiting occurred only on one occasion. He is also suffering from obstinate constipation.

Past History.—Twenty years ago patient suffered from dysentery; fifteen years ago from malaria (in the Caucasus); five years ago from smallpox in a mild form during an epidemic in Russia. When, eight months later, he became convalescent from smallpox, bulimia occurred, from which he suffered for one month. This condition passed away without any treatment. Has been in perfectly good health since then until 18 months ago, when he had to flee from his native country as a political convict, and it is to this time that he dates back his first attack. Patient has been married for six years, and is father of three healthy children. Syphilis was denied. Never takes alcohol in excess, but drinks occasionally: tea and coffee moderately. Smokes 10 cigarettes daily.

Family History.—Father died from blood poison-

ing after a trauma, mother from phthisis. One brother and one sister are living and well.

Physical Examination.—Patient does not give the impression of a sick man, but looks rather robust. Skeleton and muscles are excellently developed. Teeth in very good condition. Lungs: Left upper lobe in region of fossa infraspinata reveals somewhat rough vesicular breathing, no râles. Percussion note over both lungs shows normal resonance. Heart: Apex beat can be palpated in fifth left intercostal space, somewhat inside of the mammillary line. Heart sounds clear. Superficial and deep heart dullness normal. Systolic blood pressure 160. There are no signs of arteriosclerosis on inspection, and on palpation of the accessible arteries: temporals, brachials, radials, and dorsalis pedis. Abdomen is not distended. Border of liver not palpable; spleen not enlarged. There are no tender spots characteristic of gallstone colic or gastric ulcer, there is marked tenderness midway between epigastrium and umbilicus. Palpation in this region gives the impression of an inflammatory mass like a small adherent tumor. On many subsequent occasions this resistance could not be felt any more. Kneejerks somewhat exaggerated. Pupils react to light; accommodation normal.

The first examination of the urine did not reveal any albumin, nor an excess of indican, but sugar was demonstrated with Fehling's test. The sediment did not contain any casts; it was amorphous, and not a single crystal of calcium oxalate could be detected.

Considering that there were paroxysms of pain in the epigastric region with radiation to the back; that the pain did not become aggravated after meals; that there were no tender spots to the right or left, and that the attacks did not resemble renal colic at all, the provisional mental diagnosis could have been duodenal ulcer (pain and bulimia); but the presence of sugar made one rather suspicious of pancreatic lithiasis. This possibility was communicated to the patient at the first examination.

January 14.—Urine: Amount for 24 hours, 1,230 c.c. Albumin, none. Bile, none. Sugar, positive. Polariscopic examination: 0.7 per cent. = 8.4 gm. pro die. Indican, not in excess. Sediment, amorphous, no oxalates.

January 15.—Analysis of stomach contents on fasting after a preliminary test supper. Amount obtained 20 c.c., well digested: no stagnation, a few yeast cells, no sarcinæ. Urine: no sugar (Fehling, Nylander, and polariscopic examination). Sediment, enormous amount of large and small oxalates.

January.—Ewald's testmeal. Obtained 50 c.c. contents, well digested. Free HCl 98, total acidity 116, starch—blue. Urine: no sugar, but slight reduction with Fehling, negative with Nylander's test. Sediment, small oxalates.

Feces: Offensive smell, not clay-colored, but rather brownish. After weighing out 5 gm. of feces and adding 20 c.c. of physiologic salt solution, it took very much time to rub up the mass in a mortar. After centrifuging the filtration proceeded at an unusually slow rate. This filtrate showed the presence of trypsin, but diminished against normal (50 units).*

Amylopsin was about normal. Bile was clearly present. Test for occult blood negative.

*Friedman, G. A.: "The quantitative estimation oftrypsin and amylase in the feces and in duodenal contents." Preliminary report MEDICAL RECORD, February 24, 1912.

Microscopic: Many meat fibers and crystals of neutral fat.

Having obtained more evidence for pancreatic insufficiency (chronic pancreatitis) the possibility of calculus as a probable cause for the condition was strengthened. Having in mind the fact that pancreatic calculi, derived from cholesterin may be seen on a skiagram, patient was referred to Dr. L. G. Cole, whose report with one plate follows:

January 17.—There is a clear-cut, well-defined shadow just below the tip of the transverse process of the third lumbar vertebra, much further out than the normal course of the ureter, and this lies in the position of the head of the pancreas.

From a study of these plates the diagnosis of a calculus in the abdominal cavity outside of the kidney and outside of the normal course of the ureter, is justified. There is a very strong probability of its being a pancreatic calculus.

Second report, January 20.—Stomach filled with bismuth. The same findings, except that the relation of the shadow to the head of the pancreas was not discernible.

The following two tables show the quantitative analysis of the feces. The first analysis was made on January 18 when patient had his paroxysmal pains, the second one on April 17 when absolutely free from pain.

FECES ANALYSIS I. (DR. V. OEFELE.)

Amount received, 55.5 gm. Coherence, lumps of hazelnut size. Color, in different pieces from dark brown to yellow brown. Odor, slightly of putrid cheese.

Naked eye examination: Very few dark pieces, the largest about 3 mm. long.

Litmus reaction: Clearly alkaline. Stercobilin: Between slightly and clearly present.

Blood (Lyle) test: Inside of the fecal masses, absent; few particles of mucus on outside show a faint trace of blood.

Specific gravity: 0.910.

The feces dissolved in 9 times the weight of water.

Total sediment: 340 per cent. vol. (*a*) Poorly divided, none. (*b*) Finely divided, 30 per cent. vol. dark brown and tan-colored particles mixed. (*c*) Slime: 310 per cent. vol. medium brown.

The upper liquid not translucent medium brown. Cream 0.8 per cent. light tan-colored.

Total solids by weight, 30.9 per cent. Ash by weight, 13.92 per cent. slightly red.

Sol. minerals, 4.01 per cent. by weight. Insol. minerals, 9.91 per cent. by weight.

Coefficient of non-utilized food, 40.5:100.

Mucus by volume 370 per cent., by weight 21.62 per cent. solid to solids.

Bacteria by vol. 63 per cent., by weight 9.03 per cent. solid to solids.

The coefficient of intestinal autointoxication: 365 per cent. of normal.

Albumin sol. in H_2O vol., trace only; by weight, trace only.

First ether extract: 29.65 per cent. Color of first ether extract: Light olive. The first ether extract of 100 gm. solid matter needs 41.4 c.c. N/10 NaOH to neutralize.

Second ether extract, 8.27 per cent. Total ether extract, 37.92 per cent. Stearinic acid (Fried. Mueller), 1.18 per cent.

Unsplit fat (Mueller), 28.47 per cent. Split fat (Mueller), 9.45 per cent. Total nitrogen of fresh

feces, 6.02 per cent. Total albumin, 37.63 per cent. Carbohydrates, 17.80 per cent.

Microscopically seen: In sediment *b*—Some tissues of vegetables and fruit slightly masticated, many vegetable hairs; some triple phosphate, many muscle fibers. In sediment *c*—Mostly detritus and mucus of slight transparency, few muscle fibers.

Interpretation of Feces Analysis—By Dr. v. Oefele.—The time of voiding in the morning is normal. The voiding interval of 24 hours is also normal. But the total amount of 55.5 gm. in 24 hours (normal 90 gm.) is too low. The total solids of 31 per cent. (normal 25 per cent.) is too high. It is evident, therefore, that the organism intends to make a compensation by a higher resorption in the colon. The patient has a difficulty in moving his bowels. This causes very slight bleeding of the anus. There are no evidences of any bleeding through the intestines. The reaction to litmus is normal. The amount of bile is also normal; but the decomposition of the bile pigment goes to a higher degree than normal. There are very many muscle fibers of different sizes seen in the microscope. Most of these muscle fibers have sharp-pointed corners and are strongly pigmented. This is an evidence that the meat is well masticated and mixed with the saliva of the mouth, but the pancreatic juice does not perform its duty. The color of the feces is slightly plaid. This shows a slight degree of liver trouble. The amount of ash, 13.92 per cent. (normal 13.95 per cent.) is about normal; but the relation between soluble ash to insoluble ash 4.01 : 9.91 per cent. (normal 1.87 per cent : 12.08 per cent.) is increased in this way that the residue of food (soluble ash) is increased and the excretion of the organism (insoluble ash) is decreased.

The ether-soluble matter in these feces (commonly called fat) is twice increased (29.65 per cent. instead of 14.2 per cent.). The specific gravity is 0.970 (normal 1.062). The low specific gravity in this case comes from the high ether-soluble matter. If we make the examination according to Prof. Friedrich Mueller the total ether extract would be 37.92 per cent. (normal 17 per cent.), the stearinic acid or free fatty acids, 1.18 per cent. (normal 6.16 per cent.); soaps of Prof. Mueller, 8.27 per cent. (normal 2.80 per cent.); unsplit fat, 28.47 per cent. (normal 8.04 per cent.), and the split fat, 0.45 per cent (normal 8.96 per cent.). Therefore the fat splitting, according to Prof. Mueller, would be 22.3:100 (below 40:100 evidence), very strong for insufficiency of pancreas. The degree of resorption of split fat is about normal or maybe more than normal.

In a more chemical way the ether extract has 41.4 degrees of rancidity and 531 degrees of esterification (in 100 gm. total solids). It can be seen that the molecular weight of the present fat in average is normal; but the amount of true free fatty acids and soaps is too low and the amount of true neutral fat is too high. There are only 1.31 per cent. (normal 9.7 per cent.) true fatty acids (saponifiables), 17.66 per cent. of dyslysines and 10.68 per cent. (normal 4.50 per cent.) cholesterin and coprostearin. To the fat metabolism also belongs the steapsin, which in these feces is absolutely absent.

The ternary substances, mostly called carbohydrates, are in this case 17.80 per cent. (normal 18.10 per cent.); it is about normal. The carbohydrate-splitting ferment amylopsin is very strongly present (more than normal). It was isolated by glycerol. The calculated carbohydrates in this case seem to be normal, but they are decreased and this difference is only covered by increased amount of mucus.

The total nitrogen is 6.02 per cent. (normal 8.60 per cent.). True albumins soluble in water are only present in pathological cases, but in this case absent. Total albumins 37.63 per cent. (normal 53.75 per cent.) In regard to the high amount of ether-soluble matter the diminution is about normal; but especially the mucus and muscle fibers are increased and other nitrogenous matter decreased. The mucus of the feces treated by nine times its weight of water, that is 370 per cent. volume, should normally slightly exceed 150 per cent. The increased amount of mucus and the increased amount of cholesterin and coprostearin is a prevention against too high intestinal autointoxication, according to Prof. Oscar Liebreich. In this case the amount of bacteria is 9.03 per cent. of total solids (normal 33 per cent.). The intestinal autointoxication is 305 per cent. of normal according to the decreased amount of bacteria. The trypsin is clearly present, but in a smaller amount than normal and the splitting of casein gives more abinuret and less albumoses and peptones than normal. The oxidases are very strongly present and would be equal to the oxidizing power of a solution of 16 per cent. sodium nitrite.

Feces Analysis II.

Amount received: 85 gm. Coherence: Dry-formed coherent matter. Color: Inside and outside chocolate brown. Odor: Sweet putrid.

Visible with naked eye: Some dark pieces 4 to 5 mm. long.

Litmus reaction: Starting slightly alkaline, turns slightly.

Stercobilin: Clearly present.

Blood (Lyle test): Clearly present.

Specific gravity: 1.033.

The feces dissolved in 9 times its weight in water.

Total sediment: 155 per cent. vol. (*a*) Poorly divided; 22 per cent. grayish brown. (*b*) Finely divided; very dark brown. (*c*) Slime, 1.33 per cent. vol.; grayish chocolate brown.

The upper liquid not translucent reddish chocolate brown, marked trace of cream.

Total solids: 29.84 per cent. by weight. Ash: 12.97 per cent. by weight, strong reddish brown.

Soluble minerals, 1.41 per cent. Insoluble minerals, 11.56 per cent.

Coefficient of non-utilized food, 12:100.

Mucus by vol., 182 per cent.; by weight, 18.10 per cent. solid to solids.

Bacteria by vol., 12.5 per cent.; by weight, 2.72 per cent. solid to solids.

The coefficient of intestinal autointoxication, 1200:100.

Albumin sol. in H_2O vol. trace; by weight trace.

First ether extract, 23.22 per cent.

Color of first ether extract, dark coffee brown. The first ether extract of 100 gm. solid matter needs 122 c.c. N/10 NaOH to neutralize and 243 c.c. more to saponify.

Second ether extract, 4.64 per cent. Total ether extract, 27.86 per cent.

Stearinic acid (Fried. Mueller), 3.45 per cent.

Unsplit fat (Mueller), 19.77 per cent. Split fat (Mueller), 8.09 per cent.

The coefficient of fat splitting, 29:100. Nitrogen, 1.894 per cent.; Total albumin, 11.84 per cent. Carbohydrates, 51.97 per cent.

Microscopically seen: Rare starch granules, many large muscle fibers, some vegetable hair, many mucous threads.

Steapsin, absent. Amylopsin, clearly present. Oxydases, faint trace. Trypsin, marked trace. Sugar producing, marked trace.

January 23.—Examination of blood (Dr. Snyder): Hemoglobin, 100 per cent. Red blood corpuscles, 6,500,000. Leucocytes, 9,000. Differential: Polymorphonuclear, 67. Small lymphocytes, 28. Eosinophiles, 5 per cent.

On three more occasions polycythemia was found. Blood pressure on two occasions: when patient had pain, 160; when there was no pain, 120 to 130.

January 30.—Analysis of Urine. (Dr. v. Oefele.) Amount in 24 hours: 1,980 c.c.

Physical.—Amount received, 445 c.c. Appearance, clear. Odor, not abnormal. Color, in passing light, yellow; in reflected light, light orange.

Qualitative.—Reaction to litmus paper, clearly acid; indican, about normal; blood, absent; bile pigments, absent.

Carbohydrates.—Sugar, less than 0.05 per cent. (less than 1.00 gm.); other reducing matter, very strongly increased.

Fats.—Fat, acetone, absent; diacetic acid, absent.

Dissolved Proteins.—Mucin dissolved, absent; nucleoalbumin, marked trace; seralbumin, absent; albumin by ferrocyanide, absent; albumin by picric acid, absent; albumin by nitric acid, absent; albumoses, marked trace; peptones, absent; amino-acids, strongly present.

Centrifuge Sediment.—After 12 hours icebox: Total sediment, less than 0.1 per cent. This sediment consists mostly of very many small oxalates, very rare occasionally pus cells, very rare epithelia, occasionally one mucous cast (cylindroid) seen.

Microscopical and Microchemical Examination.—Cast, mucous casts; crystals, very many very small oxalates; amorphous deposits, absent; red blood cells, absent; leucocytes, very rare; epithelium, very rare.

Quantitative.—Specific gravity, 1.020; total acidity, 36 (713 c.c. N/10 NaOH).; normal should be 40; total solids by weight, 5.30 per cent. (104.94 gm.); by Haeser, 4.660 per cent.; organic substances, 3.72 per cent.; normal should be 3.634 per cent. or 78 per cent. of total solids. Ash, 1.58 per cent. (31.28 gm.); normal should be 1.026 per cent. or 22 per cent. of total solids. Urea, 2.20 per cent. (43.56 gm.); normal should be 2.096 per cent. or 45 per cent. of total solids. Uric acid total, 0.108 per cent. (2.14 gm.); normal should be 0.047 per cent. or 1 per cent. of total solids. Uric acid dissolved by 4° C., 0.108 per cent.; normal should be 0.047 per cent. or 1 per cent. of total solids. Ammonia, 0.068 per cent. (1.35 gm.); normal should be 0.47 per cent. or 1 per cent. of total solids. Chlorine, 0.610 per cent. (12.08 gm.); normal should be 0.699 per cent. or 15 per cent. of total solids. Phosphoric acid (P_2O_5), 0.200 per cent. (3.96 gm.); normal should be 0.233 per cent. or 5 per cent. of total solids. (9.27 gm.) sulphuric acid (H_2SO_4), preformed 0.468 per cent.; normal should be 0.233 per cent. or 5 per cent. of total solids. Etherified sulfuric acid, 0.017 per cent. (0.33 gm.); normal should be 0.020 per cent. or 0.43 per cent. of total solids. Lime (CaO), 0.050 per cent. (0.99 gm.); normal should be 0.023 per cent. or 0.5 per cent. of total solids. Magnesia (MgO), 0.009 per cent. (0.18 gm.); normal should be 0.012 per cent. or 0.25 per cent. of total solids. Sodium and potassium, 0.698 per cent. (13.82 gm.).

Special Remarks.—Trypsin, absent; amylopsin, strongly present; steapsin with cottonseed oil, marked trace; with ethyl butyric, absent; by calorimeter, color corresponds to an average urine with specific gravity, 1.012.

During the month of February urine was examined four times. On one occasion sugar was absent, oxalates present; on three others sugar present, 1.2 per cent, 1.4 per cent., 1.6 per cent., oxalates absent.

March 2.—Analysis (by Dr. Bookman). Amount of urine, 1,400, strongly acid; sugar, 1.68, 23.62 gm.; acet. diac., negative; preformed sulphates, 5.5356 gm.; etherified sulphates, 0.213; no oxalates.

March 14.—Sugar, 1.2 per cent., no oxalates.

March 20.—Sugar, 1.5 per cent.; no oxalates.

April 14.—Amount 1,650; sugar, 1.8 per cent.

An *x*-ray picture taken April 17 by Dr. Cole showed the same shadow as in the two original plates.

Patient was free from pain from the beginning of February until the beginning of May, when the attacks were even more intense and frequent than in the fourth attack.

On May 14 patient came to the clinic asking to be admitted to the hospital. While in the clinic he had such severe pain of the same character that he asked permission to lie down. After lying down for an hour, he was relieved, but the pain did not cease as in previous attacks. He was admitted to the Roosevelt Hospital on May 16 and on the next morning operation for pancreatic lithiasis was performed by Dr. Peck.

Report of Operation.—Duodenotomy, choledochotomy, pancreatotomy. Dorsal position. Gas and ether anesthesia.

Incision to inner edge of right rectus one-half inch from median line, abdomen opened, head of pancreas explored by separating the gastrocolic omentum at its right border, drawing the transverse colon downward and duodenum to the right. Head of pancreas was lumpy and thickened. No mass suggestive of a calculus could be felt. Several lumpy thickenings were explored with a fine long hypodermic needle, while the fingers held the head of the pancreas firmly from behind and in front without any calculus being detected by the needle. Incision through the retroperitoneum to the right of the duodenum with rotation of duodenum forward and to the left to expose the posterior part of head of pancreas and bring duodenum forward. Careful palpation with head of pancreas between the fingers and thumb failed to detect any calculus. Duodenotomy was then performed and a search for the papilla made. A small papilla, evidently an accessory pancreatic duct, was found, *but the main papilla of Vater could not be identified.* After a prolonged search duodenum further rotated forward, exposing the retroduodenal portion of common bile duct. This was incised and a probe passed downwaard through incision and duct into duodenum, curving this forward and using it as a retractor, the duodenum and head of pancreas were lifted forward and a second probe was passed from papilla up into pancreatic duct well out into the body. This could be felt within the pancreas by the palpating fingers. An incision was then

made through the pancreatic substance anteriorly down to the probe opening the main duct. Through this incision another probe was passed outward into the body and backward toward the duodenal opening without detecting any dilated portion of the duct or any calculus. Severe bleeding occurred from numerous veins during the procedure. Hemorrhage was checked with catgut ligatures passed on needles into pancreatic substance. After a careful search and further needling of all suspicious hardened nodules in pancreas, the pancreatic wound was closed with a mattress suture of catgut and the probe into the pancreatic duct was withdrawn. Opening into duodenum was carefully sutured with two tiers of continuous suture. The duodenum was then held forward, the opening in common duct explored and closed by continuous suture of No. 00 chromic gut. The exposure of structures and manipulation was difficult throughout and very prolonged. A rubber tube drain wrapped with gauze and rubber tissues of good size was then carried down to the region of the wound in the common duct alongside of duodenum. The wound was closed by layers with catgut, chromic gut for rectus sheath, silkworm gut and silk to exit of drain. Total time of operation, three and one-half hours. Condition fairly good, although the patient showed considerable evidence of shock. Pulse about 120 at end of operation, and small.

Patient died May 19, 1912.

Partial Autopsy performed by Dr. Mann. Abstract of Report.—Complete clinical diagnosis, pancreatic calculus.

Summary of History.—Exploratory laparotomy for supposed pancreatic calculus. Negative findings except for chronic pancreatitis.

Anatomical Diagnosis.—Chronic interstitial pancreatitis. Postoperative acute hemorrhagic pancreatitis with fat necrosis of surrounding parts, and local peritonitis beneath wound. Edema of the lungs. Renal congestion with parenchymatous degeneration.

Microscopical Diagnosis by Dr. Warren.—Fat necrosis with inflammatory reaction (tissue near pancreas). Chronic interlobular hepatitis with recent central degeneration. Intestinal chronic myocarditis with acute exacerbation. Diffuse mild parenchymatous nephritis. Necrosis of mesenteric fat. Chronic interstitial splenitis. Interlobular pancreatitis with autolytic necrosis and postmortem degeneration.

Discussion.—Although at the operation and autopsy only chronic interstitial pancreatitis was found, it is probable that a small concrement from Wirsung's duct could have escaped during manipulation, as the papilla of Vater could not be identified at the operation. The attacks of pain pointed rather to a calculus. As no adhesions were found it is hard to understand why the pain was promptly relieved (with the exception of the last attack) in the recumbent position: a condition occasionally met with in urethral calculus. It is a well known fact that in biliary obstruction a suspected calculus may not be found at operation, and yet symptoms due to the obstruction will disappear. The same holds good for renal calculi. I well remember a patient who had had several attacks from renal calculus, with bloody urine, and in whom a ureteral calculus was distinctly shown on the *x*-ray plates. At operation, however, performed by Dr. A. A. Berg in Mount Sinai Hospital, no calculus was found. The operation was performed about six years ago, and patient never had any attacks of pain during this period.

I wish to quote briefly a case of Atkinson and Hirsch, which very much resembles my case. "Patient, a coachman, had a number of malarial attacks six years previously, from which he made a perfect recovery. He had also had measles and grippe. Dyspepsia and abdominal pain, for which the patient applied for relief, had come on insidiously about eighteen months ago, the last attack being rather more severe than the preceding one. It occurred about two weeks ago and was characterized by abdominal pain in the upper quadrant, associated with a feeling of oppression about one hour after eating. These symptoms were never considered alarming by the patient, nor did they give him any marked discomfort and were generally relieved by some simple remedy. There was no evidence of loss of flesh. Possibly there were gallstones in the gallbladder or cystic duct. The man fell dead in the ward. At autopsy, chronic interstitial pancreatitis was found; about 2 cm. from the termination of the duct there was a calculus about the size of an orange seed, very irregular in outline." It is possible, therefore, that a concrement of such size or a little larger could have been present in the case reported without marked dilatation of the duct, which became lost during the long time of search for the papilla of Vater. Escape with the feces before operation is also possible, as at the Roosevelt Hospital one day before operation a shadow in the region of the pancreas could not be demonstrated.

The occurrence of glycosuria, at first transitory and later more permanent, is uncommon in chronic interstitial pancreatitis, but in the presence of calculi sugar has been observed, according to Albu, in 45 per cent. of cases.

And last, but not least, the most frequent cause of chronic pancreatitis is, according to Opie, obstruction of the duct of Wirsung due to pancreatic calculi, if biliary calculi in the terminal part of the common bile duct, or carcinoma invading the head or body of the gland are excluded. These conditions are ruled out in our case. There was neither syphilis, nor alcoholism. Supposing there was no calculus, then the etiology of our case remains obscure. Dysentery and malaria could not have been seriously taken to explain the etiology, as patient was well after these ailments. How much the smallpox played a rôle as an etiological factor for the occurrence of chronic pancreatitis, remains an open question. Yet, Robson pointed out the occurrence of chronic pancreatitis after infectious diseases.

In connection with the etiology of pancreatitis in the latter condition, I remember having saved a colleague several years ago from an exploratory laparotomy for gallstones or pancreatic cancer. Patient, who was over 50, suddenly became jaundiced, the icterus being a deep one. Treatment for several weeks was of no avail. It was known to me that he had grippe some time before icterus appeared, and, therefore, I considered his present condition to be a catarrhal icterus due to swelling of the head of the pancreas and pressure on the common duct. In about eight weeks the icterus disappeared and the patient has been well since.

Case I.—In a man with catarrhal icterus, speaks very much for the fact that a catarrhal icterus may be of pancreatic origin. In this case, low values were found for trypsin and amylopsin in the feces

while patient was jaundiced, the values becoming gradually higher as the icterus disappeared.

Though explanation to Table I of feces analysis was given, it is interesting to note that the analysis of feces showed slight liver trouble (chronic hepatitis confirmed at autopsy), but for chronic interstitial myocarditis and nephritis there were no signs during life, nor perhaps for chronic *splenitis* (malaria). The blood pressure of 160 on many occasions could be explained by pains, as in the intervals the blood pressure was 120-130. The polycythemia is interesting. Robson calls attention to the high color index in pancreatic disease, and he compares the findings in this condition with pernicious anemia, yet I could not find such a high red blood cell count in the literature on the subject of diseased pancreatic gland. In this respect, therefore, our case is unique.

Mention should also be made of the "vicarious oxaluria" when sugar was absent. Mayo Robson called attention to such findings in diseases of the pancreas.

A LARGE ABSCESS OF THE TEMPORO-SPHENOIDAL LOBE, COMPLICATING A CHRONIC PURULENT OTITIS MEDIA, WITHOUT ANY SYMPTOMS EXCEPT AN OCCASIONAL MARKED RISE OF TEMPERATURE.*

By ROBERT LEWIS, M.D.,

NEW YORK.

Mary McNeely, æt. 8, was admitted to my service in the New York Eye and Ear Infirmary, December 25, 1909. The history of her aural disorder, as ascertained from the mother, was as follows: Two years previously she had experienced an acute purulent inflammation of the right middle ear, complicating an attack of scarlet fever. In March, 1909, a polypus had been removed from the middle ear, and then for a few months she had been free from any visible discharge from the ear. In September or October the same year, however, the discharge had reappeared, and had continued up to within ten days of the time of her admission to the infirmary, when it suddenly ceased. Then, three or four days later, she began to complain of a severe pain in the ear, accompanied by general headache, which latter symptom had continued up to the date of her entrance into the hospital.

An examination made at the time of her admission to the infirmary showed her heart, lungs, and kidneys to be normal. The body temperature was 102° F., the pulse was 108, and the respirations were 26. The external auditory canal was stenosed to such a degree as to prevent a view of the drum membrane. Pressure upon the mastoid process showed a very marked tenderness of this bone, and evidences of a subperiosteal abscess were present.

Operation.—The subperiosteal abscess was first evacuated, and then it was seen that a small perforation existed in the cortex of the mastoid process. The removal of the overlying bone showed that the antrum was filled with a cholesteatomatous mass. This was thoroughly removed and the radical mastoid operation was performed. During the eight days immediately following the operation the temperature remained below 101.2° F.; on the tenth day it rose to 102.4° F., and on the twelfth day it reached 105.2° F.

During the next nine days, *i.e.* from the twelfth to the twenty-first day following the operation it rose, on four occasions, to heights varying between 104° and 105.2° F. On the morning of the twenty-second day after the operation, the temperature fell to normal and remained below 99° F. until 8 P.M. of the twenty-fourth day, when, following a chill, it began to rise and ultimately reached 105.2° F. at 4 A.M. of the twenty-fifth day.

Dr. Walter B. James and Dr. Walter Lester Carr, the consulting physicians of the infirmary, examined the patient at this period of her illness, and declared that they were unable to discover any lesion (apart from the disturbance in the region of the ear) which might account for the changes in her temperature.

The patient had no headache, no drowsiness, no stupor; on the contrary she was very bright, even when awakened from a sound sleep. The eye grounds were normal and the reflexes were normal.

The Widal test gave negative results. No tubercle bacilli were found in the stools. Smears from the aural discharge showed a mixed infection. On January 15 the blood culture furnished a negative result.

BLOOD COUNT.

	Jan. 5	Jan. 8	Jan. 12	Jan. 17
Red B. C.	4,800,000	4,800, 00	4,000,000	4,020,000
White B. C.	25,200	7,400	16,000	8,200

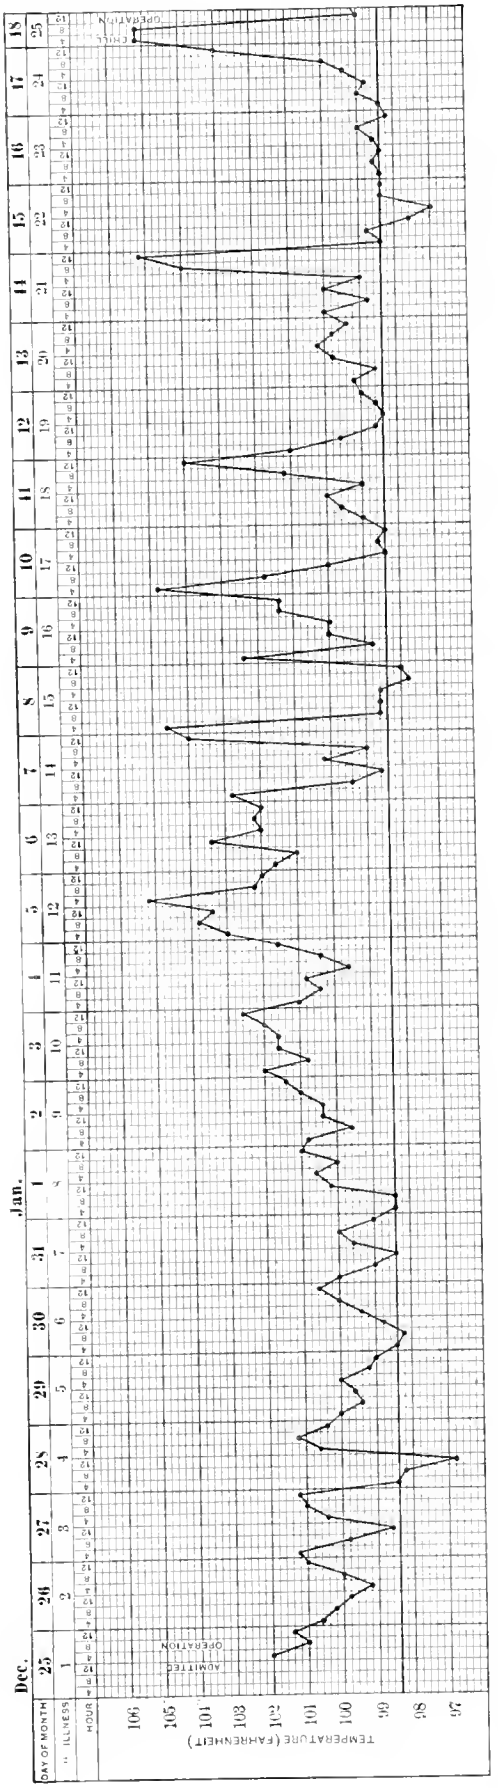
On only two occasions was the pulse slower than seemed compatible with the temperature curve.

On January 18 (the twenty-fourth day after her admission to the infirmary) she complained of a slight headache. She was weak and emaciated. There was no symptom of a definite lesion in any organ nor of a general dyscrasia. Had it not been for her temperature the girl would probably have been sent home.

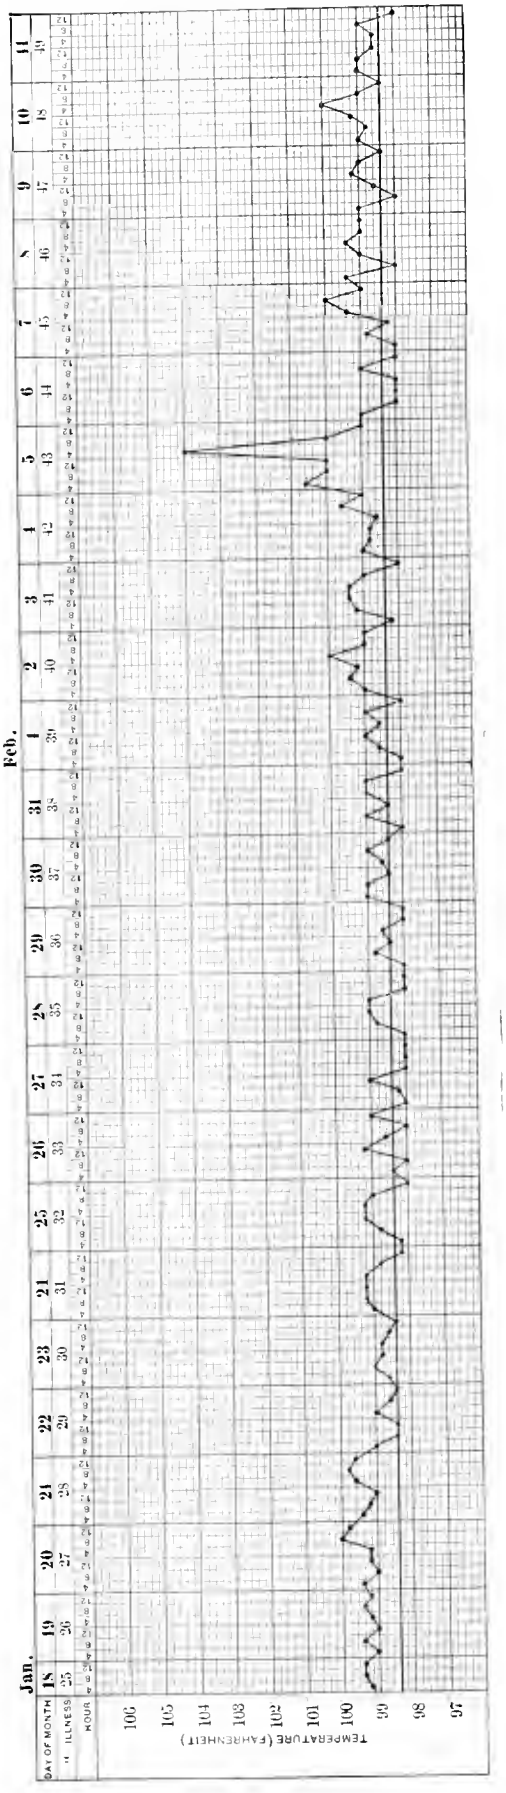
The wound had done well except over a small area in the extreme upper posterior portion of the region where the mastoid cells had been excavated. This area, the diameter of which was about that of an ordinary lead pencil, presented a dark coloration and manifested no tendency to develop granulation tissue. I determined to investigate this area more closely, and accordingly, on January 18, I reopened the wound and excavated the discolored region by means of a curette. I found that the area of discoloration increased as I made my way through the cellular structure of the bone towards the middle fossa, and as I removed a portion of the inner plate

*Read before the Otological Section of the New York Academy of Medicine.

of the bone forming the floor of this fossa there was a sudden gush of foul-smelling pus. The opening in the bone was enlarged and about three ounces of foul pus was evacuated.



The abscess cavity, measured from the dura at the point of ulceration in an upward, inward, and backward direction, extended fully two inches into the brain substance. It possessed well-defined



walls. It had ruptured through the dura mater immediately above the necrotic area of the bone, and was prevented from extending over the meninges by an exudate of plastic lymph.

Subsequently to the operation the temperature never exceeded 100° F., except on February 6, when it rose to 103° F. for a short time.

I believe that in the present case the abscess had been present for some time, and that the radical mastoid operation had kindled into action a latent inflammatory process. The fact that the abscess had well-defined walls undoubtedly increased very greatly the patient's chances of recovery.

During the first day or two after the abscess had been evacuated I used a rubber drain, but after that I depended entirely upon gauze for drainage purposes.

The patient made a rapid recovery.

LITERARY GENIUS AND MANIC-DEPRESSIVE INSANITY.

WITH SPECIAL REFERENCE TO THE ALLEGED CASE OF DEAN SWIFT.

By ARTHUR C. JACOBSON, M.D.,

BROOKLYN.

There is a strong disposition among many writers to postulate the essential "insanity of genius." In the Medical Record, June 15, 1912, there occurs the statement that "apparently no writer can dare to aspire to literary distinction without running the risk of submitting to psychological dissection by the alienists. In many instances it is no longer a question as to whether a certain genius was insane or not. The modern query is 'From what form of insanity did he suffer?' " These remarks were prompted by an article which recently appeared in the *American Journal of Insanity*, under the title, "Manifestations of Manic-Depressive Insanity in Literary Genius," the author of which, Dr. Eva Charlotte Reid, one of the physicians at the Government Hospital for the Insane, at Washington, D. C., sets forth that the study of the life and works of the literary genius would indicate that the literature was incidental to the psychosis and simply formed an outlet for the abnormal feelings and passions of the writer. This mental disease, it will be remembered, is marked by alternations of elation and depression, of frenzy and despair, of mania and melancholia, and Dr. Reid discerns in the writings of many of our greatest authors much evidence that they experienced such emotional turmoil. She draws the conclusion that they were victims of manic-depressive insanity and that their infirmity was the motive force that drove them on to more or less glorious expression. "With an emotional instability which raises him (the literary genius) to the pinnacle of exaltation one day and plunges him into the depth of despair the next, his industry must be spasmodic." Unable to adapt himself to his surroundings, "in his literature he finds an outlet for all his abnormal feelings and passions. Here he pours forth, under various guises, his rapturous joys and fears, his dreams of bliss, and his dread of impending calamity. The manifestations of his abnormal mental condition, which are denied him in actual life, find an outlet in poetry and fiction, under the guise of literary and poetical inspiration."

The present writer finds it difficult to lend his intellectual sympathy to such a thesis, which practically amounts to claiming that geniuses are geniuses *because* they are insane. There is a vast amount of evidence showing a family history of insanity or degeneracy of some sort in the case of many, if not most, of the greatest geniuses, and such geniuses are unquestionably more likely to become insane than are less highly organized people—and do so become very frequently indeed—but the writer contends that these facts in no way justify such assumptions as those of Dr. Reid, and the great majority of writers who have occasion to touch upon the subject of genius. A watch is not built to withstand lawn mower usage. And it must not be forgotten that literary geniuses differ from most subjects of psychological or psychiatric study in that they have written themselves down, so to say. Their hopes and fears, in some cases—like Rousseau—all their inner lives, are recorded. Who shall say that the emotional reactions portrayed are so vastly different in kind or in degree from those of other noble but less expressive minds under special stress? Then we ought to consider the adequacy of the factors entering into elation, depression, etc. If Swift was downhearted after his virtual banishment from England, if he was depressed after the death of his dearest friends, if he became choleric under the grievously hard political knocks he received from bitter enemies, if he was a sufferer from arteriosclerosis after the age of twenty-three, why must we read into such facts manic-depressive insanity, any more than the response to adequate factors that might be expected to occur in such a mighty mind, or even in any first-rate mind? Why is failure to react strongly to adequate intellectual stimuli made the criterion of sanity?

It seems an odd thing to the writer that a great literature is not emanating from the asylums of the land, if it be true that the relation of genius and insanity is so close. The answer is that the great genius must be eminently sane. He must possess in the highest possible degree the critical faculty directed toward his own literary productions. No great literary work can possibly be produced if this endowment be lacking. Such a lack is one of the most marked characteristics of the insane. The mind that produced Hamlet was super-sane. To the critic who insists upon intellectual mediocrity and slow emotional reaction as the criteria of sanity, such a mind seems essentially insane. The "normal" man, says Dr. Reid, rises above the common ills of life—poverty, sickness and death—that is, is not greatly or for very long affected by them. It was the presence of such things around him in Ireland, in superlative degree, that inspired the best efforts of the greatest of English satirists. The writer would say that Swift was the most "normal" man in the Ireland of his day because he did react so strongly to the terribly adequate factors that surrounded him, which reaction gave us the "Drapier Letters" and awoke his compatriots from their moribund state. It is the abnormality of the social masses of to-day, and not their normality, that precludes an effective reduction of infant mortality. Those who realize the appalling conditions and are fighting them are not victims of manic-depressive insanity, either. No critic with only a partial sense of humor ought to examine the writings of literary geniuses with a view to their conviction on the score of manic-depressive insanity. To one in whom this sense is somewhat atrophied or absent De Quincey's "Murder as One of the Fine Arts"

would certainly seem brimful of manic-depressive evidences. De Quincey, it is true, is cited by Dr. Reid as one of the group of insane geniuses. Probably a study of this masterpiece on murder helped to the fatal conclusion. To our mind, the writing of such a piece of literature is conclusive proof of what we have called super-sanity.

Dr. Reid confesses that Swift's brilliant satire, "A Modest Proposal for Preventing the Children of Poor People in Ireland from Being a Burden to Their Parents or Country," convinced her of his insanity. How utterly lame such a conclusion really is the writer will endeavor to show in detail. The effort is worth while, for a strong light will be thrown on the hasty and superficial character of the conclusions drawn by those critics who are determined to make unconformable facts conform to their theories. Dr. Reid not only betrays a total lack of the ironic humor sense, but she is either unfair or grossly uninformed as to the circumstances in which the "Modest Proposal" was written. The piece in question was written in 1729, after Swift's final break with Walpole. It is a wonderful piece of sustained irony, suggesting with a ghastly vividness the horrible state of the Irish people, whose champion Swift was. In studying it we must take into consideration the frightful conditions that inspired it, the motive of the writer, and its political effect. When this is done it will be seen very clearly to have been justified. Read in ignorance of such considerations, the piece might seem a diabolical fantasy. As a plain matter of fact it proved one of the most effective efforts of the great satirist. And it was only one of a long series of powerful attacks upon the indefensible English policy in Ireland against which Swift contended with all his tremendous intellectual power. The Irish "were a people to be crushed, ruined, persecuted, tormented, extirpated." (Sir William Wilde.) England had done everything destructive to Ireland's interests that could well be conceived of by the ordinary mind, and it was merely left to Swift, the Irish patriot and man of unique political genius, to suggest ironically the suitability of Irish children for English food, "examining the conception in every aspect, following it out in all its consequences, and deriving from it, systematically and consistently, a train of the most grotesque incidents." (Lecky.) Seeing that England had done almost every conceivable harm to the Irish, that she should eat them was at least metaphorically in order. Swift burned with a hatred of tyranny, injustice, and oppression, and while he had no special love for Ireland, if we may believe his own declarations, "his humanity and charity were equal to his wit, and required as good and true a taste to be equally valued." (Pope.) In what better cause could he have employed his great powers of sarcasm and irony, trenchant, original wit, and tremendous invective, than in that of Ireland of the eighteenth century? The intellectual qualities of this terrible partisan made him the natural leader of the exploited Irish, who fully recognized his patriotic services, despite his Protestant creed, his profession, and his personal intolerance of Roman Catholicism. Lecky credits him with being the first man to teach the Irish to rely upon themselves and to lead them to victory at a time when they were deprived of every hope. "He gave a voice to their mute sufferings and traced the line of their future progress. . . . An intense and terrible sincerity was one of the chief elements of his power." The poverty and desolation prevailing in Ireland at this time, due to English exploitation, could hardly be exaggerated, and resistance on constitutional grounds was out of the question. Only the peculiar literary genius of Swift met the indications adequately. His was the voice of the people, and it spoke with success. Its echoes "marked the transition from an age of semi-barbarism to an age of civilization—from the government of force to the government of opinion." (Lecky.) England had systematically crushed Ireland by draining her of sound money and substituting a debased currency (Wood's copper coinage, the patent for which was awarded to the King's mistress, the Duchess of Kendal, who jobbed it out to Wood for £10,000); by forbidding, in 1666, the importation of cattle from Ireland into England, cattle being the principal article of Ireland's commerce, three-fourths of which commerce was with England; by enacting, in 1696, that no goods of any sort could be imported directly from the colonies into Ireland; by penal laws of atrocious severity; by preventing as far as possible the holding of public office by Irishmen, lucrative and influential posts being given to Englishmen; by passing in 1699 an act "of crushing and unprecedented severity," which forbade the export of the Irish woolen manufactures not only to England, but to all other countries, this industry having threatened England's supremacy in the same field; by shipping her supernumerary beggars to Ireland, augmenting the alarmingly large number already in that unhappy country; and by smothering the legislative powers of the Irish Parliament and the utterances of Irish champions like Molyneux, whose "Case of Ireland" was formally condemned by the English House of Commons. Thus a premium was put upon destitution, chronic famine, beggary, crime, and servility. We are, of course, not unmindful of those apologists who tell us about political exigencies and the expedients sometimes forced upon even humane conquerors where the conquered present special problems, but their dialectics are not especially convincing.

Lecky appraised the celebrated piece of humor the inspiration of which we have discussed at its proper value, and Sir Walter Scott saw in it nothing worse than "inimitable gravity of irony," relating with keen amusement how a foreign author had seriously accepted Swift's proposal that the rich English feed upon the poor Irish. Scott represents Swift as concerned with the emancipation of the country of his birth and as wholly indifferent to personal aggrandizement. The "Modest Proposal" is assuredly shocking. It was intended to shock the England of Walpole's day, and that country certainly needed all the shocking that could be administered by the masterful Irish satirist or anybody else possessed, not by insanity, but by superb intellectual and literary power, for of constitutional remedies there were none. But Dr. Reid is quite blind to its political and sociological significance and can only say: "Many of his (Swift's) writings could only be the productions of an insane mind. For instance, in a pamphlet entitled 'A Modest Proposal for Preventing the Children of Poor People in Ireland from Being a Burden to Their Parents or Country,' he suggests that these children be fattened, sold to the wealthy, killed, their bodies used for food, and their skins for gloves and shoes. He dilates in the most horrible manner on the age at which they would be most palatable, the best man-

ner of cooking, and the relative weights and values at different ages."

Sir William Wilde, after a study of the available data, declared that there was no proof that Swift had ever been insane, and that his peculiarities in later life were due to the ordinary decay of nature. The opinion of this eminent Irish physician is practically conclusive.

A recent writer on true neurasthenia recites as leading emotional symptoms ill-humor, unreasonableness, peevishness, irritability, impetuousness and a tendency to fault-finding, trifling occasions leading to outbursts of temper; a prevailing mood of depression and despondency is characteristic of these sufferers; frigidity or sexual impotence is frequently observed. Swift had all of these traits and the diagnosis may well stop short in his case at neurasthenia. Dr. Reid's citation of such traits amounts practically to an attempt to show that Swift ought to have been insane, even if he were not, but nothing beyond the implication of neurasthenia can be tortured out of them. That he should have been a neurasthenic is quite understandable, when one considers the man's stormy political life, ill health, and inability to marry because of a sexual defect, as well as his misfortunes in general, and what might be called his involuntary failure as an ecclesiastic. He was not the first man, and will not be the last, to be suspected of insanity because he ferociously and effectively assailed political corruption. For a considerable period, before his exile to Ireland, land of his birth and education, he controlled English public opinion more than any other man, and was influential to that degree that he became the most powerful defender and counsellor of the Tory party, leading the way to the dismissal of Marlborough and the Peace of Utrecht. In the case of Swift we are not dealing with a second rate character, nor with a lunatic of any kind or degree, but with one of the greatest men of all time, possessed of marked defects easily lending themselves to the grossest exaggeration, and of traits that made him feared or hated by the pygmies and knaves of his own day and the "tin horn" critics of posterity. He was "the most tragic figure in the literature of the eighteenth century—the only man of his age who could be conceived as affording a groundwork for the creations of Shakespeare." One smiles in his case when he reads Dr. Reid's dictum that the industry of the victim of manic-depressive insanity must be spasmodic. There was nothing spasmodic about the indefatigable and continuous labors of the author of "Gulliver's Travels." One laughs in his case when he learns from Dr. Reid that the manic-depressive genius is unable to adapt himself to his surroundings and that it is this which leads to the selection of literature as an outlet for the thoughts that he has spun in his own unreal world. Swift had "an eminently practical mind, seizing with a happy tact the common-sense view of every question he treated, and almost absolutely free from the usual defects of mere literary men." (Lecky.)

The writer has spoken of Swift's arteriosclerosis. At the age of twenty-three he began to suffer from dizziness and ringing in the ears. As he grew older his querulousness, irritability, and other symptoms increased. We are well aware to-day of the relationship sustained between arteriosclerosis and neurasthenia. The autopsy that was made after Swift's death disclosed cerebral shrinkage and arteriosclerosis. Dr. Reid claims that the aural symptoms marked the beginning of the psychosis from which she alleges he suffered. The terminal breakdown at the age of seventy-three (death came five years later) Dr. Reid calls an "engrafted arteriosclerotic dementia." To the writer's mind, Swift's case typified arteriosclerosis as Osler and other observers have noted this condition in the very young, the symptoms of cerebral neurasthenia therefore resting upon an organic basis, a relationship which has been dwelt upon particularly by Stengel. Being a simple and sensible view, based upon known facts interpreted in a non-sensational way by one who is not a professional alienist obsessed by the bizarre doctrine that postulates the essential insanity of genius, it may not appeal to the lovers of the *outré*. Let us discourage all such doctrines of the crowd, lacking as they do any sound or even defensible psychiatric basis. They belong in the class of Lombroso's arguments touching upon the alleged insanity of Christ, whom he considered and tried to prove a paranoiac. The simple truths of science and of life are fascinating enough.

That the true genius is necessarily crazy is essentially a vulgar view, fostered, apparently, by every intellectual plebeian. It is high time that it be shattered. There is a failure to distinguish between the insane temperament and actual insanity. Too fine a distinction for the bourgeoisie of science, it nevertheless is a vital point. Still finer for them is the fact that the insane temperament itself, only less than actual insanity, is a handicap to the genius and not his "motor force." It is easier to conclude the essential insanity of genius and save a deal of sound, hard thinking. Why, say these short-cut philosophers to the writer, you yourself admit insane family history, insane temperament, and the frequent occurrence of insanity. What are you driving at?

Genius makes for insanity, but neither insanity nor the insane temperament makes for genius. The genius is usually, if not always, of insane temperament, but his best creative work reflects the man at his best, that is to say, sanest. To the degree that clinical insanity enters in, to that degree is his work vitiated. Insanity is the Nemesis of the delicately balanced genius, never his good angel. He does his work not because of, but in spite of, the Damoclean sword. The genius differs from other men in that he presents a curious capacity for superlative sanity alongside a similar capacity for insanity. In all respects clinical insanity is antithetic to the faculties that actuate the creative mind, but nature implants the insane diathesis in accordance with her law of compensation. Psychopathological states, the result of the insane temperament or of the toxins of tuberculosis or colon bacteriemia undoubtedly at times excite and color the creative labors of true geniuses, but they are not geniuses because of the psychopathology. The fundamental quality of mind is *sui generis* and the thesis of Dr. Reid utterly fallacious. Genius is not a disease.

115 JOHNSON STREET.

BACTERIN TREATMENT IN PULMONARY TUBERCULOSIS.

BY GEORGE SANDERS, M.D.,

NEW YORK.

THE following is a continuation of a report of Case II, published by me in the MEDICAL RECORD of February 24, 1912. In this case Mrs. M. commenced bacterin treatment on October 25, 1911, and received up to March 25, 1912, injections of the combined

bacterins twice a week, the dose being gradually increased until 0.9 cubic centimeters was reached. The bacterins used are a combination of streptococcus, multivalent, 50,000,000; staphylococcus, multivalent, 500,000,000; coli communis, multivalent, 100,000,000; and pneumococcus, 100,000,000 in each cubic centimeter, the initial dose used being one-half cubic centimeter or less.

During the time of treatment the patient stated that she felt better and better, that her appetite was improving, and that she noticed that her health in general was better. The patient did not return after March 25, 1912, and I have not seen her since.

On March 11, 1912, a microscopic examination of this patient's sputum was made in a private laboratory. The report showed the presence of tubercle bacilli, one or two in a field, and also a few staphylococci. A monthly examination of the sputum hereafter was contemplated in regard to all pathogenic germs in order to obtain a better record of progress, but no opportunity was given.

The subsequent larger doses of bacterins were well borne. The patient's chart of her fever and pulse, taken four times daily, showed that the temperature rarely reached 100° F. However, on February 24, in the evening, it reached 101 1/5° F., and March 1, at noon, 101° F. At no time was it subnormal. The pulse averaged 90. There was no gain in weight.

Tuberculin treatment was to be given this patient at an early date. Perhaps her condition of well-being made her discontinue treatment.

Case III.—Mr. C., aged twenty-two years, a steamfitter's helper, came to me on November 3, 1911, with the following history: Patient had had a cough for the past two years, but had been in fair health until July, 1911. At that time he had pleurisy and was ill for one week. Owing to a suspicion of pulmonary trouble he was sent to Sullivan County, N. Y., where he remained for seven weeks. His sputum was found to contain tubercle bacilli. Since that time he has been getting worse. He had an hemoptysis a week ago. He has experienced no feverish sensations, and has had no night sweats. He often feels chilly and has dyspnea on slight exertion. His appetite is good, his bowels are regular. He has no headaches. His former weight was 123 pounds, but he now weighs 108 pounds. A brother died of consumption.

On examination the patient's lungs showed the usual signs: dullness, subcrepitant and crepitant râles over the right upper and middle lobes, etc. Sputum positive.

On November 1, 1911, I injected 0.5 c.c. of combined bacterins, the initial dose. The patient came twice weekly for these injections until December 27, 1911, after which he failed to return. There was a slight reaction after the fourth injection, and rarely after the following ones. From the initial dose of 0.5 c.c., a gradual increase up to 0.8 c.c. was made. His weight increased to 112 pounds, a gain of 4 pounds. The pulse and temperature, taken only in the office, showed an average of, pulse, 120; temperature varying from slightly above to slightly below normal. The patient stated that he felt no change, except an improvement in the dyspnea on exertion.

Case IV.—Mr. C., aged forty-seven years, born in Italy, came to me on November 8, 1911, with the following history: He has had pulmonary tuberculosis for about three years. His cough, which began three years ago, has been steadily growing worse. His appetite is very poor. Bowels regular. He vomits a thin, clear fluid nearly every morning. His cough is excessive on rising in the mornings. His weight, which had been 155 pounds, is now 130 pounds. His sputum is thick and often greenish. At first he had night sweats, but he has none now. He has had no hemoptyses or feverish sensations. He has dyspnea on exertion and walking; he feels very tired and weak all the time. His surroundings are of the poorest kind and not clean. The patient looks very emaciated and unclean. He was advised to return to Italy at once as he could not live very much longer. There was no history of consumption in his family. On examination he showed signs of severe lung involvement. Sputum contained tubercle bacilli.

From November 8, 1911, to March 27, 1912, the patient received injections of the combined bacterins in doses varying from the initial dose of 0.2 c.c. to 0.8 c.c. twice weekly, after which he failed to return. He had some headache and malaise after only a few of the injections. His appetite began to improve almost immediately, and his general feeling of well-being became stronger and stronger. His cough became decidedly better. His temperature, taken at regular intervals, by himself, showed a variation between 99° and 100° F. in the afternoon and evening, and was always subnormal in the mornings. There was a decided improvement in the dyspnea. His weight averaged 141 pounds, at one time reaching 143 pounds, a gain of 13 pounds.

Case V.—Miss O'D., aged forty-six years, unmarried, came to me on November 9, 1911, with the following history: At the age of seventeen years she had pleurisy; thereafter whenever she took cold she had pains in her chest. Twelve years ago she had pneumonia, and about eight years ago she developed a bronchitis, and ever since she has complained of a severe cough, especially on rising in the mornings; expectoration is a thick, greenish mucopus. She does not remember having had night sweats. Her weight and strength have been steadily declining for the past two years, and she has had severe hemorrhages from the lungs. She has severe dyspnea on walking and on slight exertion. Her appetite is very poor, and for the past four weeks she has taken little nourishment. She has had fever for a long time. Her bowels are constipated. She sleeps fairly well except when severe coughing spells keep her awake and restless for long periods. Her weight when in fair health was about 116 pounds, and she now weighs 85½ pounds. Her father died of pulmonary tuberculosis. Her sputum contains tubercle bacilli.

This patient returned to me on December 10, 1911, for treatment. She was given 0.3 c.c. for the initial dose, which was followed by a severe reaction. This patient came twice weekly for these injections. She was kept on doses of 0.3 c.c. of combined bacterins for some time and the dose was gradually increased to 0.5 c.c., which dose later she stood very well. Her appetite improved at the beginning, but later varied exceedingly. She felt a slight improvement generally on some days. The temperature showed an average of 101° F., and often reached 102° F. and a little over. She had a constant normal temperature in the early morning. Her weight varied also, the last weighing showing 81¼ pounds. This patient stopped treatment after March 31, 1912.

The cases so far treated by me have all shown some good effects from the use of the combined bacterins. If in some cases no more was achieved than an increase of appetite or a better feeling gen-

erally, this in itself would be an indication to use this agent in order to cheer the patient, inspire hopes, and make his burdens easier.

It is an unfortunate circumstance that those who came for treatment to me did not have the patience to continue for at least eight months or a year, in order to reach a definite conclusion as to the ultimate effects of these injections.

210 West One Hundred and Seventh Street.

THE MILK SUPPLY.

By CHARLES CRISTADORO,

POINT LOMA, CAL.

When in connection with the prevention of infant mortality milk, as a food, was discussed at an international medical congress, and Dr. Abram Jacobi, who was present, was called upon for his views, he summed up the whole situation in two words, so it is reported, *"clean milk."*

New York City is being served with milk by 40,000 dairies, more or less, all within 600 miles of New York, the aggregate milk amounting to 4,000,000 pints daily. The dairies supplying such milk are all presumably subject to inspection by the New York Board of Health, 18 inspectors in all being employed by the Health Department for that purpose. An inspector may average one inspection of each one of the dairies in his district once a year, when in many, perhaps altogether too many, cases the inspector should make his rounds once a week or once a month at least, to insure sanitary conditions.

Before the days of the Chicago Drainage Canal, when Lake Michigan did double duty as receiver of Chicago's sewage and its source as a water supply, the Board of Health would when necessary notify the public to "boil all drinking water until further notice."

So, with inadequate inspection facilities at its command, the acknowledged presence of the tuberculous cow and the typhoid-tuberculosis stable bred fly, and the presumed lack of sanitary measures, in instances too numerous, there is nothing to do but, as Chicago did with her water, make the milk germ-free by pasteurization. It is the cutting of the Gordian, unsanitary knot, as far as New York City's milk was concerned.

Primarily the unscreened stable and the ungroomed cow opened up avenues of germ and physical contaminations in the milk—the typhoid fly and the manure-covered bag, udders, and flanks of the cow. The development of the tuberculous cow in conjunction with the now understood typhoid-tuberculosis fly, complicated matters in a germ sense.

The dangerous foremilk of even a healthy cow, streptococcus-laden slime, and tuberculosis carrying dust being harbored in the teats, added to the difficulties. The excreta also of the cow that contained virulent tuberculosis germs, when drying into dust, facilitated the scattering of these germs into the milk pail, upon the flanks, udders, and bag of the cow, and into the already more or less dusty hay in the manger of the cow.

The airing and sunning of the milk utensils in the open at and near the very homes and breeding places of the typhoid-tuberculosis fly (the cow stable and manure piles), instead of within outdoor enclosures, thoroughly fly-screened, added to the unsanitary list of infection possibilities.

The storing of open milk cans in the stable longer than necessary, instead of in the cleanly milk room where the pails of freshly drawn milk could be speedily carried added neither to the sanitation nor the flavor of the milk.

Inspection, frequent inspection, and, when necessary, the withdrawal of a license to ship one's milk to town, is the solution of and is the complete answer to this unsanitary proposition, fortified in each case by the process of clarification. As soon as the milk comes into the milk room, before it is cooled, warm from the cow, by machine clarification the foreign matter, manure, blood, germ-laden slimes (mostly from the udders), hairs, and dust are instantly mechanically precipitated from the milk, although the milk remains in its original, whole, unseparated condition, for this clarification of the milk is a measure of complete physical dirt and slime's expurgation, although in no manner disturbing the relations of cream and milk, the milk leaving the machine as it entered, whole and entire, but clarified as to dirt and slimes.

Milk separation, the dividing into separate and distinct bodies (the cream and the skimmed milk, freed from some of their impurities because of the centrifugal force) is a helpful process, but in no sense as thorough as clarification, whose office is to attend strictly to the precipitation of slimes and all germ-laden foreign matter.

The fact that cream, under the separating process, when dragged, as it were, through and away from the body of the milk, drags also with it more than its percentage of germ life, *making butter a greater carrier of tuberculosis than milk itself*, emphasizing strongly and pointedly the indisputable sanitary conclusion, that in the making of butter the warm milk should be at once clarified by the farmer as soon as the milk pail enters the milk room, and if the farmer does his own separation, the milk then separated, the cream cooled properly, and when delivered at the creamery the final pasteurization to take place. This would mean not only clean, well flavored, and well keeping butter, but absolutely innoxious germ-free butter.

Enlightenment on the milk sanitation question is speedily to lead up to the machine clarification of the milk, to rob it of all foreign matter (90 per cent. of which is manure), before machine cream separation, followed by pasteurization, takes place for butter making purposes.

Prof. Metchnikoff endorses the mechanical clarification of milk so pointedly, so strongly, that he insists that all milk be machine-clarified. It might seem that in the case of certified milk it would be gilding gold to clarify or pasteurize it. But we take a quantity of certified milk, unpasteurized, and by the plate process we find 12,000 bacteria per cubic centimeter present, 30,000 being the maximum allowed. We pass that same milk through the clarifying machine and, *in the slimes thrown down*, find 800,000 bacteria to the cubic centimeter. When Prof. Metchnikoff declares that all milk demands machine clarification it would seem that he had good and sufficient reasons for his contention.

Mr. Straus, realizing that milk, clarified first and then pasteurized, was a very sane and sanitary measure, now has the milk at all the pasteurized milk stations under his control clarified. A great step along the sanitary milky way. Clarification is adopted at various sanitary milk stations and is helping to solve the clean milk situation beyond compare. New York and a score of large cities are now partially using it.

But in the clarification of milk one thing should be well considered, namely, that if manure, slime,

blood, pus, seeds, dust (likely to harbor and give out, when dissolved, germs of tuberculosis), be present in the milk (and to a *greater* or *lesser* degree they are present in all milk, no matter what the precautions along sanitary lines), there can not be a single argument advanced, even restricted to the commonest ideas of decency and ordinary food cleanliness, against machine clarification. If such "foreign matter" can be effectually removed by mechanical clarification why should there be any delay; why should not removal be a matter of quick action, and this done in the milk when it comes fresh and warm from the cow and before solution of the foreign matter begins to set up fermentation and germ dissemination, a thing likely to take place during a 600-mile, more or less, railroad journey and a period of 24 hours between the dairy and the table of the consumer in New York? If during that time through refrigeration the milk is kept below the temperature that invites fermentation, the foreign matter, the physical "dirt" (90 per cent. of which is manure) gets little chance to ferment, but solubility has resulted in that time and just a little carelessness as to an allowing of higher temperatures because of refrigerator neglect, is sufficient to play germ havoc with the milk.

On November 17, 1906, an article of the writer's appeared in these columns pleading for Federal Milk Inspection and Compulsory Clarification. We have Federal Meat Inspection, and yet the nature of milk and its paramount food value, as compared with meat, as an absolutely necessary and essential food for infants and children, receives no official recognition at the hands of the sanitation officers of the Government. The helpless infant and the growing child, so far as milk is concerned, must take care of themselves.

The National Milk Commission of to-day is the first step towards solving the problem that New York City has failed in utterly—the inspection of 40,000 dairies within 600 miles of New York, supplying 4,000,000 pints of milk daily, and to make such milk safe for human consumption, 75 per cent. or 3,000,000 pints of it must be pasteurized to make the germs and physical dirt in it innocuous. Milk, like Shakespeare's man, must too have seven ages along its sanitary pathway of life and evolution. The neglected age, the watered age, the skimmed age; the preserved (salicylic acid, boracic acid, formaldehyde), the tuberculosis age; the pasteurized age, and finally the golden age, when we shall have Federal inspection; when the tuberculous cow will be quickly detected and removed from the herd; when, in addition to fly screening, every conceivable sanitary measure shall be employed around the stables and as to the cows; when no milking shall be done in the stable itself, but in an annex where no feeding is done, no manure, hay, and other flying dust is present; when all milk utensils shall be aired in the sun and air, in simple enclosures screened from the typhoid-tuberculosis carrying fly; when the milk, while fresh and warm, is instantly cleansed, mechanically clarified by hand-power machines; when the milk so clarified is cooled and aerated, then bottled under sanitary conditions, sealed and, to make assurance doubly sure, pasteurized in the sealed bottle and then cooled and kept cool until upon the breakfast table or in the nursery of the infant.

If the human salvage value, the worth to the nation of each infant's life prolonged into manhood and usefulness; if the saving of doctors' fees, nurses' cost, druggists' bills, and undertaking expenses, were made up into one great economic total, the results of Federal milk inspection and clarification would give a balance over and above the expenses of such inspection, large enough to save Congress the worry of deciding whether one, two, or three new battleships required appropriations.

Better milk means a higher price, of course it does, and it is because of the 2 to 3 cents per quart paid the farmer to-day that 75 per cent. of the unsanitary situation holds. It is cheaper to produce dirty, unsafe milk than it is to supply "certified" milk, in fact clean milk, and in the ratio to the willingness of the public to pay a good price for a good article, will the quality of the milk supply enhance.

Let us compare bread, milk, and meat on a food value basis, the actual food we get out of each that goes to nourish and energize our bodies and discard the moisture of the loaf, the water (natural) in the milk, and the moisture and bone in the meat.

A ten-cent loaf of bread weighing say 24 ounces yields 1 pound of "food value." A pound of steak, costing 25 cents, yields three and two-tenths ounces of "food value," and four quarts of milk, costing 32 cents, yield one pound of "food value."

So, on an actual food basis, we pay the baker 10 cents per pound; the butcher $1.25 per pound, and the milkman 32 cents per pound. Even if we pay the certified milk man 20 cents per quart for his milk we get a pound of "food value" at a cost of 80 cents and we are yet nearly 50 cents a pound to the good, compared with what we pay the butcher for our steak. So, ordinarily, we pay $1.25 per pound for the meat on our table but only 32 cents a pound for baby's meat that means to the little chap far more than our steak, because *we* can get reconstructive values and energy from a score of palatable and digestible foods, other than meat, whilst little Bobby in the nursery has to diet along on 32 cents, and it's a matter of Hobson's choice with him. He is up against it dietetically good and hard; if he gets dirty milk he dies, if he gets no milk at all he dies, and if he gets clarified and pasteurized milk he must pay 80 cents per pound for it instead of 32. If the public understood this, were willing to pay more for their milk, not necessarily a "certified" price, and some way could be devised to see that the advance went into the pocket of the farmer now getting from 2 to 3 cents per quart for his milk, instead of halting by the way to keep the middleman company, milk conditions would, as it were, automatically improve.

Duration of Immune Bodies in the Blood After Antityphoid Inoculation.—M. Wollstein notes that in a series of twenty-four persons inoculated with antityphoid vaccine, the immune bodies in the blood reached their height within two months after the first inoculation, or one month after the third, then fell rapidly within the next two months. Only nineteen of the cases could be followed longer, and eight of these were negative for bactericidins within ten months after inoculation, and fifteen were negative after thirteen months. Only one serum reacted in a dilution of 1 to 1,200 at the end of thirteen months. The addition of lecithin to the vaccine did not influence the local reaction after inoculation, nor did it appreciably affect the formation of immune bodies to the typhoid bacillus. There is, of course, no justification for the conclusion that clinical immunity can be determined absolutely by the measure of immune bodies in the blood, since experience has apparently proved the contrary, a fact which can be accounted for by the latent power of the body cells to react more quickly to a stimulus which has once made them sensitive. That this power lasts for many years after an attack of typhoid fever is well known. It would seem, however, that reinoculation with typhoid vaccine within a year is indicated when exposure to typhoid fever seems imminent.—*Journal of Experimental Medicine.*

New York, November 23, 1912.

AN INSTITUTE FOR THE PSYCHOLOGICAL STUDY OF ANTHROPOID APES.

ACCORDING to the computations of those best qualified to speak, the gorilla, chimpanzee, orang, and gibbon will be practically extinct a hundred years hence. Study of these anthropoids has already rendered such vast service to science that steps should at once be taken to defer as far as possible this period of final extinction, and especially to utilize to the utmost the remaining opportunities for research of all kinds. No effort should be wasted in seeking to acclimate specimens in temperate regions for study purposes, but experiment stations should be established directly in the habitat of the animals.

Rothmann, who discusses this subject in an article in the *Berliner klinische Wochenschrift*, October 18, 1912, regards the Canary Isles as an ideal locality for an experiment station. Not only is the climate well suited to the anthropoids but the islands are readily reached from the European capitals. Gorillas and chimpanzees could be transported readily from Western Africa, their habitat. If the orang and gibbon could not be successfully carried thither and made to thrive, a second station could be established somewhere in the East. Rothmann himself has already taken the initiative in this project. Last spring, upon the occasion of a journey to Teneriffe, steps were taken to procure and care for a consignment of chimpanzees from German West Africa, after it had become apparent that these animals could thrive there without requiring acclimatization.

The next step is to send to the station an expert who will study these animals from the viewpoint of experimental psychology. The aspects of the latter to be covered first are phonation, gesture, comprehension of spoken language, enumeration, perception of color, and education possibilities of the hand. At present the general movement has gone no further than the creation of a committee, headed by Professor Waldeyer. It is not clearly stated by whom this committee was created, nor it duties, nor to whom it is to report. Prominently mentioned in connection with this movement are the German Intercolonial Government, the Provincial Government in German West Africa, and two scientific foundations (Selenka and Plaut). The progress made will evidently depend largely on private means. The movement will not be restricted to psychology, but will include all branches of biological study, not the least being breeding and crossing experiments. That all possible efforts will be made to decide the problem of the evolutional relationship between anthropoids and man goes without saying. Rothmann lays considerable stress upon the belief universal among the savages who have always dwelt with the anthropoids, that the latter are not brutes but men like themselves. This belief appears to argue the existence of traits unknown to investigators.

Of special interest is the point made by Klaatsch, Sergi, and others that Eastern anthropoids have structural peculiarities in common with Eastern primitive man. Just as a similar correspondence is seen between Western anthropoids and the lowest forms of African aboriginal man. This has led to the hypothesis of a double origin of modern mankind. As it is already conceded that the latter is quite unrelated to some of the first men, who became entirely extinct in glacial or other cataclysmic epochs, it is hoped that more light will be shed on the relationship between the first men, modern men, and the anthropoids.

THE RECOMMENDATIONS OF THE SURGICAL CONGRESS.

OF the two recommendations made by the Surgical Congress at its closing session last week, the one calling for public instruction regarding the nature of uterine cancer and the need of early diagnosis and early operation in such cases must meet with the hearty approval of every medical man. Operation for cancer is a desperate remedy, but in the present state of the therapeutics of that disease it is the only one that offers any hope; and therefore until some one of the many workers in that field shall have discovered a specific the knife remains our only resource. Therefore it is very proper that women should be taught the necessity of seeking medical advice at the first sign of any trouble with the pelvic organs. Many times, fortunately, they will learn that the trouble is not serious, but now and again such prompt notice of slight symptoms will lead to the diagnosis of an incipient cancer, and this to early operation and possible cure.

Regarding the second recommendation, namely, that a special surgical degree be established, to be given by the colleges only after a special course of post-graduate study, and that the right to practise surgery, major surgery at least, be granted only to the possessor of such a degree, there is room for considerable discussion. Such a setting apart, and above, of one branch of the medical profession would not be looked upon with entire favor by the general practitioner, and it would not be surprising if any attempted legislation looking to that end aroused a decided opposition within professional ranks. The medical student is compelled, and rightly, to devote a large part of his college course to the study of surgery and surgical anatomy and he might justly claim that his time and his money had been wasted if he is to be debarred from putting such knowledge as he has acquired to prac-

tical use. The internist might also retaliate by demanding that the man with the new surgical degree should be debarred from general medical practice unless he could prove his right to such practice by a supplementary degree obtained by special postgraduate work in internal medicine. It is doubtful whether the needed legislation could be secured, for the tendency is rather the other way. In this State, for example, no distinction is made in the examination between the different schools, therapeutics having been removed from the list of subjects, a knowledge of which is demanded of candidates.

There is much, however, to be said in favor of this recommendation for a special degree and there will be time for its discussion after it has been definitely formulated by the committee appointed to work out the details. The members of this committee are men of high professional standing and of sound judgment and whatever the conclusions of their deliberations may be, we may be sure they will be worthy of the respectful consideration of the profession at large.

TWO EPIDEMICS OF TYPHOID FEVER.

In the Annual Report for 1911 of the Medical Officer of Health of the City of Bristol, England, is given the result of an investigation by B. A. I. Peters of an epidemic of typhoid fever which occurred in that city early in 1911. The fifty-one cases which comprised the outbreak were divisible into three groups, in each of which the source of infection could be traced to a single individual who had recently recovered from an attack of the disease. In each instance the possibility of infection by means of water, milk, or food was carefully considered, and, so far as possible, was excluded. The possibility of "contact infection" has certainly always been recognized, but it is usually met with as the cause of isolated cases. If flies can be acquitted as the carriers in this epidemic, as Peters is inclined to believe, then it is almost a unique instance and deserves such consideration as will tend to prevent the development of like epidemics in the future. One noteworthy fact was that as soon as the cases were reported, inspected, and removed to the hospital, the epidemic ended.

A second epidemic occurred in this country and has aroused a great deal of comment in the public press. It is reported by George W. Stiles, Jr. (U. S. Dept. of Agriculture, Bureau of Chemistry, Bulletin No. 156). Following a dinner held in Goshen, N. Y., at which there were 155 guests, a certain number became ill. Oysters from various sources were included in the menu and 127 persons ate "Rockaway oysters" from Jamaica Bay. Of these 17 developed typhoid fever and 83 suffered more or less from diarrhea. Of the remaining guests there were two taken sick after the dinner with the sort of indigestion which not rarely follows such a function. Other articles on the menu were carefully scrutinized and found blameless so that it seemed certain that the source of infection was to be found in the Jamaica Bay oysters. Stiles then investigated the conditions under which the oysters in Jamaica Bay were grown and "floated." He found that the waters of the bay are dangerously polluted by enormous quantities of raw sewage and was able to demonstrate typhoid, paratyphoid, and colon bacilli in oysters floated in these waters. The raw oyster is a favorite article of food, especially in the cities along the seacoast; it is a good culture medium, and any condition which endangers the purity of the oyster exposes to infection an enormous number of people. It is, therefore, gratifying to note that the Health Commissioner of New York City has ruled that henceforth dealers must prove the purity of the water in which their oysters are fattened in order to retain their permits.

It is essential that every member of the medical profession should consider it his duty to impress upon the minds of his patients the obvious lessons taught by these epidemics. Typhoid fever is preeminently a preventable disease and every case is the result of the negligence of some individual or set of individuals. Hard work will be necessary entirely to eradicate the disease, but it is possible.

ACUTE UTERINE HEMORRHAGE.

Every physician doing obstetrical work has met with serious hemorrhages from an atonic uterus occurring after expulsion of the placenta. Usually the administration of ergot and mechanical irritation of the uterine muscle by massage through the abdominal wall are sufficient to put a stop to the bleeding. Occasionally packing of the vagina is necessary, and still more rarely a radical surgical operation with ligatures of the vessels must be resorted to.

Some years ago Fritsch described a very simple method of dealing with such bleeding, his proceedure consisting in displacing the enlarged uterus out of the small pelvis and pressing it forward against the pubic synchondrosis. This may be done by manipulation through the vagina, and occasionally it may be successfully performed by external manipulation of the abdominal wall. Recently, and quite independent of Fritsch's proposal, Dr. N. Rachinsky has hit upon the same method and has found it very serviceable in several cases of alarming uterine hemorrhage (*Russkii Vrach*, Vol. XI, No. 34). Rachinsky considers that the success of the method is due not so much to the mechanical compression of the uterus against the bone as to the stretching of the broad ligament and the consequent obliteration of the blood-vessels supplying the uterus. With the flabby and stretched abdominal wall of a parturient woman it is quite possible to bend the uterus forward quite over the pubic joint, where the weight of the organ will keep it in this position. Occasionally a suitable bandage or some gauze in the vagina will be necessary to prevent the organ from resuming its former position. In all his cases Rachinsky found that the hemorrhage promptly ceased and the uterus could be safely replaced in a couple of hours' time. This procedure is so simple that he calls the attention of obstetricians to Fritsch's article (*Deutsche medizinische Wochenschrift*, No. 1, 1904) and to his own experience so that the method may be tried.

Random Thoughts on the Surgical Congress.

To the cities in which they are held, the meetings of the Clinical Congress of Surgeons of North America offer an unequaled opportunity of establishing their claims to rank as centers of surgical teaching and progress. In diversity, scope, and number, the clinics of the Congress just ended surpassed those of previous years and the demonstrations in the allied branches of surgical investigation and experimentation emphasized the fact that this city is leading in that work which conduces to substantial progress along scientific lines. The work of the clinics and laboratories was open to the inspection of probably the most critical audience that could be assembled, and the impressions carried away by the visiting members will undoubtedly play a considerable part in determining the degree of regard to be accorded future contributions in the literature of that surgeon or laboratory worker whose work has been so displayed. For the evening meetings the programs were well selected as representing those subjects that are at present arousing the most active interest of surgeons throughout the country. That the speakers were recognized as authorities in their given subjects, the attendance at those meetings was an adequate indication. Whether the visiting members came to this Congress with the idea merely of receiving stimulation through hearing and seeing in a general way that which is considered newest and best in surgery, or of obtaining a brief and concentrated course in some particular branch of surgery, the opportunities were equally great. To the workers in the field of surgery in Greater New York also the Congress was of no little value. Not only was their work reviewed at first hand instead of through the literature, but they had an opportunity never before presented of observing, through the lists of clinics for each day of the Congress, the scope of the work being done in their own community. It is noteworthy that there was little or no undue publicity in relation with the Congress. The newspapers indeed reported the evening meetings and described in greater or lesser detail some of the more notable clinics; but this was merely in the way of legitimate news gathering; the accounts were devoid of sensationalism, as a rule, and antemortem eulogies of individual surgeons were conspicuous for their absence. In this avoidance of réclame the Congress showed itself actuated by a truly scientific spirit.

A Reflection of Medical Activity in the United States.

A current number (October 21) of the *Berliner klinische Wochenschrift* certainly makes no announcement of a symposium of articles by or concerning medical men in the United States; and it is not often that such communications are found among its original articles. We do not look for them there, because the function of this periodical is to reflect the local work of the German metropolis, and to a less extent of the provincial clinics. It is therefore a striking commentary on the importance of the work being done at present in the States that four of the leading articles in this one number chance to be of transatlantic source. The first paper, by Harvey Gaylord of the New York State Institute for Cancer Research, Buffalo, relates to work which has been done in the prevention and cure of piscine cancer. The second article is by Oertel of the Russell Sage Pathological Institute of this city, and deals with a new disease first described by the author in 1904—a lesion of the liver secondary to cardiac stasis, which is unlike nutmeg liver and all other recognized conditions. A third article is by G. A. Friedmann of the Mt. Sinai Hospital, New York, on the clinical association of angiosclerosis in the mesenteric and femoral vessels, of syphilitic nature and apparently cured. Finally an article on organotherapy by Münzer is practically a résumé of Cushing's recent work on the hypophysis.

News of the Week.

A Royal Disease.—It has recently been stated in Russia that the young Czarevitch, whose mysterious illness has caused much alarm, is a sufferer from hemophilia, and it is pointed out that this may almost be called a "royal disease" since it is now more than ever prevalent among the princes of Europe. The late Duke of Albany is said to have succumbed to the disease, which also afflicts the second son of the King of Spain and some of the relatives of the Queen of England and of the Emperor of Germany.

Supervision of Dairies.—The New York Milk Committee has prepared, for presentation to the next Legislature, a bill making the supervision of the milk supply at the dairy obligatory on the State, instead of on the city as at present. The committee believes that the licensing and inspection of dairies, creameries, and milk shipping stations should be done by the State Board of Health; that the State Department of Agriculture should control the health of the dairy cattle and the sanitary conditions of the barns, etc., and of the methods of milk production and handling; and that the City Department of Health should test and inspect the milk as it is received here.

For New Cocaine Law.—The present law governing the sale of cocaine being generally considered inadequate, preparations are now being made to present to the next Legislature an amendment to it. As it stands the law makes the sale of the drug, except on a physician's prescription, a felony with punishment limited to one year's imprisonment and a $1,000 fine, and the possession of it a misdemeanor punishable by six months' imprisonment and $500 fine. It is proposed that the law be amended so as to make the sale of cocaine punishable by five years' imprisonment at least, the attempt to sell the drug punishable by three years' imprisonment, and the mere possession of it punishable by a fine of $1,000 or imprisonment for one year.

Dole for Blind.—The needy blind of New York City to the number of 548 recently received the yearly dole provided for them by the State, amounting to $49 each.

Hospital and College Alliance.—Through the generosity of Mr. George F. Baker of New York, a coalition has been made possible between the Cornell University Medical College and the New York Hospital. It is understood that an alliance similar to that between the Presbyterian Hospital and the College of Physicians will be effected, and that, in consideration of a substantial fund donated to the Hospital to aid its future building projects, the institution gives to the medical school, for purposes of teaching and research, one-half of its entire service, comprising medical, surgical, and children's wards.

in all about one hundred and fifty beds. Cornell has heretofore utilized one-fourth of Bellevue Hospital for its clinical teaching, but the more definite control of a hospital service of its own will enable it to continue, upon much broader lines, the research work for which it already enjoys so great a reputation. The further announcement is made of a gift to the College of a fellowship of $1,000 annually to be allotted for work in medicine in the wards of the New York Hospital.

Carrel Honored.—On November 16, in the Great Hall of the College of the City of New York, Dr. Alexis Carrel was the guest of honor at a reception attended by the President of the United States, the Ambassador from France, the President of the College, and more than five thousand others, including many of the delegates to the Clinical Congress of Surgeons. In acknowledging his reception, Dr. Carrel paid tribute to those who had worked before him, and especially to Dr. Flexner to whom and to the spirit of the Rockefeller Institute his success was largely due.

Resignations from Fordham.—That the dissension in the Fordham University College of Medicine has continued was shown on November 13, by the announcement of the resignations of four members of the Faculty in addition to those already noted, the school thereby losing the services of Dr. Smith Ely Jelliffe, clinical professor of mental diseases; Dr. John B. Huber, professor of pulmonary diseases; Dr. C. R. Keppler, clinical professor of orthopedics, and G. F. Shiels, adjunct professor of surgery. From the University, however, comes the announcement that the appointment of Dr. William F. Healy as Dean of the medical department, to take the place of Dr. James J. Walsh, was ratified at a meeting of the faculty on November 19. At the same meeting the appointment of instructors to take the places of those who resigned with Dr. Walsh was also confirmed, and the new constitution of the medical school was formally put in operation.

"S. C. A. A. News."—For the purpose of keeping its 10,000 members in touch with its work in the field of preventive philanthropy in New York State, the State Charities Aid Asssociation has begun the publication of a monthly newspaper, the *S. C. A. A. News*. The first number, bearing date of November, 1912, is a well illustrated, eight page journal of small size, and contains reports of various county tuberculosis hospitals, and a description of the proposed site for New York City's farm colony for inebriates. There is no subscription list, and the *News* will be sent to anyone interested upon application to the office of the Association, 105 East 22d Street, New York.

Medical Reserve Corps.—The New York Division of the Medical Reserve Corps of the United States Army was formed by the resident officers at a meeting at the Army and Navy Club on November 7. Col. L. Merwin Maus, Chief surgeon of the Eastern Division of the United States Army, presided and read a paper on the purposes of the Corps. The following officers were nominated for 1913: *President*, Henry Clark Coe; *Vice-President*, Thomas Darlington; *Secretary*, Harold Hays; *Treasurer*, H. Sheridan Baketel; *Councillors*, Arnold Knapp, Howard Lilienthal, Clarence A. McWilliams, Eugene H. Pool, and J. B. Rae. The next meeting will be held on Governor's Island on December 5.

Red Cross Christmas Seals.—In a new design the Red Cross seals for Christmas, 1912, have already made their appearance, and are being distributed throughout the country in large quantities. It is hoped that ten million will be sold in New York State alone.

Personals.—Col. William C. Gorgas of the Medical Corps of the United States Army and chief sanitary officer of the Panama Canal Zone, has been awarded the Buchanan medal by the Royal Society of England in recognition of his remarkable administration of the health affairs of the Canal.

Dr. John Cutting Berry of Worcester, Mass., has received from the Emperor of Japan, the Imperial Order of the Sacred Treasure of the Third Class, in consideration of his eminent and disinterested services while in Japan, looking to the promotion of her material well-being, notably his signal contributions to the improvement of medical and sanitary organizations. Dr. Berry was for twenty-one years a medical missionary in Japan.

Hospital Saturday and Sunday.—The report of the Hospital Saturday and Sunday Association shows that during the past year the sum of $116,940.26 was collected and distributed among the various hospitals of the city. Three hospitals, the Neurological Institute, the Manhattan Maternity, and the Jewish Maternity Hospital, were admitted during the year, making a total of forty-seven in the association. The associated hospitals during the year gave 1,950,170 days of hospital treatment, of which 61 per cent. were given without compensation to the hospitals from either the patients or the city.

New Hospitals.—Plans have been prepared for the erection of a new hospital on East 123d Street, New York, for the treatment of deformities and joint diseases. Two floors of the building will be devoted to a gymnasium and mechanical apparatus for the correction of deformities, and there will also be operating and sterilizing rooms, laboratories, complete *x*-ray and photographic equipment, and in the basement a shop for making shoes and surgical appliances.

The Volunteers of America also have filed plans for a hospital which they propose to erect on the lower East Side of New York, to be known as the Volunteer Hospital. The building will front 74.8 feet on Beekman Street, and 56.9 feet on Water Street. The cost is estimated at $65,000.

St. John's Guild.—During the past summer, the Guild cared for more children than ever before. A total of 55,617 patients were carried on the trips of the floating hospital, and for the first time sick children with their mothers were allowed to spend the hot nights on the boat. The seaside hospital of the Guild had the record number of 3,219 days of hospital care. The receipts for the year including $25,000 allowed by the city, were $127,000.

Tuberculosis Work.—The Jewish Consumptives' Relief Society held its eighth annual convention in New York on November 10 to 12. The meetings were addressed by Dr. Abraham Jacobi, Borough President McAneny, Dr. Philip Hilkowitz, and others. The society has a membership of nearly 25,000.

Aid Association.—At the annual meeting of the Aid Association of the Philadelphia County Medical Society held on November 11, the following officers were elected: *President*, Dr. Roland G. Curtin; *Vice-President*, Dr. John R. Schellenberger; *Treasurer*, Dr. John B. Turner; *Secretary*, Dr.

Lewis H. Adler, Jr. The president pointed out the great need for a home for destitute and aged physicians.

Army Medical Corps Examination.—The Surgeon General of the Army announces that preliminary examinations for the appointment of First Lieutenants in the Army Medical Corps will be held on January 20, 1913. Full particulars can be obtained from the Surgeon General, U. S. Army, Washington, D. C., the essential requirements being that the applicant be a citizen of the United States, between 22 and 30 years of age, a graduate of a recognized medical school, and of good moral standing. There are at present thirty-five vacancies in the corps.

Civil Service Examination.—The United States Civil Service Commission will hold an examination for dental interne, men only, on December 11, 1912, for the purpose of filling a vacancy in the position of dental interne in the Government Hospital for the Insane, Washington, D. C., at a salary of $600 per year, with maintenance.

Dedicate Medical Library.—The new building of the Lane Medical Library of the Leland Stanford University, San Francisco, was formally dedicated by President David Starr Jordan on November 3. The library, which contains 40,000 volumes, is a memorial to the late Dr. Levi Cooper Lane and his wife, through whose generosity it was made possible. The new structure in which it is housed was erected at a cost of $125,000, and is as nearly fireproof as it can be made.

Charitable Gifts.—By the will of the late Dr. Arthur Cabot of Boston, the Harvard Medical School received a bequest of $100,000; and upon the death of Mrs. Cabot the residuary estate, estimated at about $500,000 is to go to Harvard University.

The accounts of the estate of the late Mr. George Crocker, which have just been filed, show that Columbia University has received $1,566,635 for the Crocker Special Research Fund to be used in the study of cancer.

The Children's Hospital of Philadelphia has received a gift of $25,000 for the construction and equipment of an operating pavilion in the new buildings planned for the hospital. The gift is made by Miss Hetty King as a memorial to her sister Mrs. Mary Bankson King Wainwright. The pavilion will contain a main operating room and two smaller operating rooms, as well as complete dressing rooms.

St. Luke's Hospital, New York, receives a bequest of $7,500 by the will of Mr. Francis M. Bacon, who died last September at Ridgefield, Conn., for the endowment of a memorial bed.

By the will of the late Mr. Thomas Barden of New York, the following institutions receive bequests: St. Vincent's Hospital and St. Joseph's Home for Consumptives, $1,000; St. Rose's Cancer Hospital, and the Hospital for the Blind, $500 each.

The Society for the Relief of the Ruptured and Crippled of New York and the Home for Incurables, Fordham, receive bequests of $5,000 each under the will of the late Elizabeth F. Noble.

Smallpox Holds Steamship.—The steamship *Barbarossa*, which arrived in New York on November 13 from Bremen, was detained at Quarantine, owing to the appearance of a case of smallpox in the steerage.

Cholera in Turkey.—Startling reports of the spread of cholera among the Turkish troops have been received. Four hundred deaths are said to have occurred in one army camp during twenty-four hours, and the total number of cases at Tchataldja was estimated on November 15 to be about 7,000.

Phillips County (Mont.) Medical Association.—The following officers were elected at the annual meeting on November 5, at Helena: *President*, Dr. W. C. King; *Vice-President*, Dr. H. H. Thompson; *Secretary*, Dr. W. P. Orr.

Chickasaw County (Ia.) Medical Socety.—At the annual meeting held in New Hampton on November 7, the following officers were elected: *President*, Dr. H. D. Fallows, New Hampton; *Vice-President*, Dr. I. D. McKinley, Lawyer; *Secretary*, Dr. Paul E. Garden, New Hampton.

The Late Dr. Newcomb.—The following resolution was adopted at a recent meeting of the Faculty of Cornell University Medical College: "The Faculty of Cornell University Medical College record with deep sorrow the death of Doctor James Edward Newcomb which took place at his summer home, Lake Kushaqua in the Adirondacks, on August 27, 1912. He was born in New London, Conn., August 27, 1857, and had consequently just completed his fifty-fifth year. He was educated at Bulkley School, graduated from Yale University in 1880, and completed his medical course at the College of Physicians and Surgeons in New York City. Subsequently he became interne at Roosevelt Hospital, and since then practised in this City, confining his efforts to Laryngology and Rhinology. He was appointed Instructor of Laryngology at the foundation of Cornell University Medical College in 1898, and in 1911 was made Professor of Laryngology. He was an able and fluent writer, contributing many valuable papers to his special branch of surgery. The high esteem in which he was held by the profession is attested in part by his election to the following societies: American Laryngological, Academy of Medicine, West End Medical, Alumni Roosevelt Hospital, and Hospital Graduates. He was also consulting Laryngologist to Roosevelt Hospital. Although suffering from a chronic ailment he worked bravely; never neglecting a duty and remaining faithfully at his post until the end. Resolved that these expressions of regret be spread upon the minutes of the meeting of the Faculty and that a copy be forwarded to the widow of Doctor Newcomb as a token of the esteem and admiration in which he was held by his colleagues. (Signed) WILLIAM M. POLK, FREDERICK WHITING, ROBERT G. REESE."

Obituary Notes.—Dr. JOHN E. MONROE of Orange, Mass., a graduate of the Medical Department of Western Reserve University, Cleveland, in 1893, died in the Memorial Hospital, Worcester, on November 5, aged 53 years.

Dr. ROBERT FLETCHER, assistant librarian in the library of the Surgeon General's Office, War Department, Washington, died at his home on November 8, aged 89 years. Dr. Fletcher was born in England and received his medical degree from the Royal College of Surgeons in 1844. He came to the United States shortly thereafter, and during the Civil War served as a surgeon in the United States Army. Since 1876 he had been attached to the Surgeon General's library. For many years the work of compiling the "Index Medicus" was in his hands. He was a member of the American Medical Association, and the Medical Society of the District of Columbia, and a fellow of the College of Physicians, of Philadelphia.

Dr. John William Mallet, emeritus professor of chemistry in the University of Virginia, died at his home on November 7, aged 80 years. He was born in Dublin, Ireland, in 1832, and was educated in Germany, receiving the degree of Ph.D. from Göttingen in 1852, and of A.B. from the University of Dublin in 1853. He came to this country in the latter year, and took his medical education at the Tulane University of Louisiana, from which he was graduated in 1868, having served also as professor of chemistry. After holding the chair of chemistry in the University of Texas and in the Jefferson Medical College of Philadelphia for several years, he became professor of chemistry in the University of Virginia in 1885, and served until 1908. During that time he held many important lectureships and was the recipient of many honorary degrees, testifying to the breadth of his knowledge and the value of his researches.

Dr. Edwin R. Dibrell of Little Rock, Ark., a graduate of the Medical Department of the University of Arkansas in 1882, a member of the American Medical Association and of the Arkansas State and Pulaski County Medical Societies, and professor of medicine in the University of Arkansas, died at his home of cancer on October 20, aged 54 years.

Dr. William B. Charles of Hanford, Cal., a graduate of the Medical Department of the University of Louisville in 1887, formerly county physician and city health officer of Hanford, died at his home suddenly on October 18, aged 55 years.

Dr. William C. Steagall of Ozark, Ala., a graduate of the Bellevue Hospital Medical College, New York, in 1860, died at his home after a long illness on October 25, aged 85 years.

Dr. William H. Dorsey of Griffin, Ga., a graduate of the Georgia College of Eclectic Medicine and Surgery in 1897, died suddenly on October 26, aged 42 years.

Dr. Hiram B. Cross of Boston, Mass., a graduate of the Cleveland University of Medicine and Surgery, Ohio, in 1866, a member of the American Institute of Homeopathy, the Massachusetts Homeopathic Medical Society, and the Boston Homeopathic Medical Society, died at his home on November 1, aged 79 years.

Dr. William I. Hamlen of Detroit, Mich., a graduate of the Michigan College of Medicine, Detroit, in 1883, a member of the Michigan State and Wayne County Medical Societies, and formerly vice-president and secretary of the Michigan College of Medicine, died at his home on October 26, aged 57 years.

Dr. John Nutting of Mankato, Minn., died at his home on October 21 from cancer of the throat, aged 78 years.

Dr. Frank L. Hamilton of Chester, Pa., a graduate of the University of Pennsylvania, Department of Medicine in 1893, and a member of the Pennsylvania State and Delaware County Medical Societies, died at his home on November 4, aged 50 years.

Dr. William H. Robinson of Pottsville, Pa., a graduate of the University of Pennsylvania, Department of Medicine, in 1868, secretary of the Pottsville Board of Health, died at his home on November 4, aged 67 years.

Dr. John Thomas Duncan of Toronto, Canada, a graduate of the Toronto School of Medicine in 1882, and attending oculist to the Toronto Western Hospital, died in California on November 3, aged 69 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

PSYCHIATRY AT R. S. M.—IS INSANITY INCREASING?—HEALTH OF CITY WORKERS—THE INSURANCE QUESTION—ACTION AGAINST THE B. M. A.—OBITUARY.

London, November 1, 1912.

The Royal Society of Medicine has inaugurated a new section—Psychiatry—which was opened on the 22d of October, and certainly the Royal Society of Medicine is to be congratulated on having secured as the first president of its new departure Sir George H. Savage, whose long experience of mental disorders is accompanied by other qualifications for the post. He seems to have looked upon the office as somewhat of a burden, for in his opening address he said that lying on a mountain slope, last summer, he could not forget that he had a great responsibility arising from that address, and as he thought of many things, some wild imaginations took possession of him, until he reflected that great discoverers have held imagination to be all-important even in the most mechanical arts and sciences. His responsibility need not have weighed so heavily, after all; at any rate, he has discharged it so well that his address may challenge comparison with most productions of the kind. It embodies a brief survey of his subject and its prospect for the future. It teems with striking thoughts, but so closely knit together that only here and there some may be detached. He paid a tribute to some of the more earnest workers, including Hack Tuke, whose power of work was amazing, and whose Psychological Dictionary he called a mine of wealth, containing many evidences of what younger men often think they originate. Governed by our organized inquisitiveness, we call it science, and collect facts, but are not mere fact-heapers, for in the multitude of facts not knowledge, but confusion, arises. One swallow does not make a summer, but may warn us of its coming; a single case may direct our studies, but is not a base for a theory. So we must define knowledge, but definitions are only for resting on while peering into the indefinite. Death and the dead are definite. We must collect and record, but remember the truth to-day may to-morrow be only partly so. Accepting experimental psychology and psychic analysis, when the practical physician says *cui bono* we reply we must follow truth; an open mind must be cultivated.

Considering on the mountain slope Schäfer's recent address on the origin of life, Sir G. Savage said it left him a believer in something more than the mere chemical theory. All elements, however arranged, were not equivalent to any living thing. The chemist had built up wonderful compounds, called organic, but which did not live.

Another point Sir George maintained, as he has done before, that many mental disorders deserve to be called functional, in so far that they are not represented by any material change in the central nervous tissues. "Nature provides the iron, but man makes the horseshoe for service." As to heredity, he gave his opinion that in some persons there is transmitted a tendency to nervous or mental disorder, but only a certain proportion found in asylums can be proved to have had insane relatives.

The study of the nervous system as a whole was

enjoined, neurology and mental disorder no longer separated. Bodily and mental relationships were exemplified by cases of alternation, as one in Bethlem, with acute mania lasting for weeks, then suddenly becoming sane, but paraplegic, and later on the reverse change returning.

"Waves of thought," said the speaker, "roll on and leave shore lines and raised beaches." At present we seemed on a chemical wave; cells have had their turn, bacteria are having a distinguished career, but the results of both these are, after all, supposed to be chemical products. Internal secretions may be so classed, and the discoveries as to their potency seem very striking; it looks as if every organ had a two-fold relationship: one with the outer world, the other with the self. The central nervous system and its nerves had it with the outer world, but there remained consciousness. Could that result from an internal secretion? It pleased Sir G. Savage to think of it as a byproduct of nervous section, and he could not help seeing in some instances of morbid mental states evidence that such an idea was not altogether wild.

Dr. F. W. Mott read a paper on Tuesday, at the Sociological Society, with a view of showing that the popular opinion that insanity is on the increase is erroneous. Admitting that a greater number of cases are registered, he attributed the increase to the inclusion of the worst forms of imbecility, idiocy, and senile dementia in recent statistics. Further, there was a declining death rate, and fewer discharges from asylums, with the consequent accumulation of cases in the London county asylums, at a rate of 125 to 200 a year for some time past. The excessive use of alcohol and drugs tended to bring out insanity in modern civilization, and it was yet to be found out how far such causes were neutralized by segregating patients. The alarmist statements so often circulated had no foundation in fact, but to failure to study the causes that lay behind an increase in registered insanity.

A conference on the health of city workers has been held, appropriately enough, in the Guild Hall. It was promoted by the Institute of Hygiene, and opened on Monday by the Lord Mayor, who said that during his sixty years' medical practice in the city he found no reason to complain of the air provided for workers. He believed in open fireplaces, for chimneys were excellent ventilators. During his time fevers had practically disappeared from the city, as they had, in fact, from all London, with the improved drainage and water supply. Sir William Bennett, as president of the Institute, explained that it was thought that the habits of individuals working in cities might be influenced by circumstances which should be discussed. That day it was proposed to consider the personal hygiene of the business man. Dr. Olsen said business men were brain, not muscle workers, often hurried or worried, and should take but light luncheon without flesh. Two meals a day was a good system. Dr. C. Gillies said the city men who suffered were highly strung, and the rush of business was increasing. With that pick-me-ups at the chemist's were resorted to. These men could be seen going into public houses early who formerly did not. The resort to narcotics or drink was dangerous, and counsel might well go forth from this conference. Dr. F. Buzzard did not look on business men as unhealthy. Mere rush or sedentary life had less influence than heredity. As to drink, people thought whiskey the safest, and they had been told so by some doctors, and went on increasing the quantity. Every organ of the body suffered. He recommended smaller quantities of food. Exercise used nervous energy as much as brain work. It should only be taken in fresh air. Dr. J. Cahill agreed to this, and that was why golf was the best game for city and brain workers. Dr. Goodhall advised taking time over meals, without business or exciting talk, moderation in everything, and avoiding fads. The chairman, closing the discussion, said much nonsense was talked about exercise, which suited some but killed others. He took as little as possible himself. A tired man should not tire himself further. Drinking between meals he regarded as the most vicious thing in the world, but every man should be left to find out what suited him best. He credited his own good health for the last twenty-seven years to a good breakfast and light luncheon.

The second day's discussion was confined to the health of clerks and warehousemen, though it must be confessed their hygienic surroundings differed but little from those of their masters, and their personal habits were often similar. The same questions therefore arose, and the debate furnished further illustrations of differing opinions. Professor Halliburton took the chair and remarked that pure air in the streets was of little use if the offices were not properly ventilated. He warned against cranks, especially the non-breakfast advocate. A few minutes less in bed and more over the breakfast table would help the day's work. The quick lunch of America was also injurious. Dr. Leslie indulged in statistics of vital force, computed by physiologists as 3,300 foot tons for the average man; of this fully nine-tenths was used for maintaining life, leaving 330 for locomotion, exercise, thought, and action. Two-thirds of this were wanted for the fatigue incident to getting a living—a sort of bank balance, or health capital which it would be dangerous to overdraw. He would pay in two good meals daily and a light luncheon to keep up the balance. Dr. Lister said the health of clerks was no worse than that of other workers, and gave mortality figures in proof. But deficient ventilation must be condemned, as must bad habits and drink. Dr. Alex Haig was rather pessimistic, and told the conference that in thirty years' experience in hospitals in the city, or near it, he hardly met a man who could stand every physiological test of good health. Apparently he did not remember at the moment that hospitals were not just the places to look for such a rarity. He put down degeneracy of the race to improper feeding, and argued that the ills we suffer from are not diseases, but only the outcome of bad feeding. He attributed the fall of Rome to her people taking to eating meat! What about fads after that?

The question of questions with the profession just now is shall we accept the government's revised offer? If it had been the definite sum in cash which the chancellor calculates it may be, I believe there would have been no hesitation. But Mr. Lloyd George's vanity had to be soothed and his defeat concealed, so he has mixed up the sum with balances from other funds. But that has only made many ask, "Is it another trap?" The more so because this week a threat has been put forward that he will start a state service unless his new offer is accepted. Knowing he cannot do so at once, he will begin in a small way—say, a couple of cities—and he is declared to have 100 competent and efficient

men selected from the younger members of the profession, who are ready to begin. Some are laughing at the absurdity of his bluff, others are applying less complimentary words both to his proposals and himself. Meetings are being held all over the country, and there is considerable difference of opinion. On the whole, I am inclined to think an attempt at compromise may be made. The British Medical Association will come to a decision at the meeting a fortnight hence.

Last night, at the dinner of the Irish medical schools and graduates, Sir James Barr, president of the British Medical Association, said they were promised an efficient service, but what they would get was no more like it than the London fog was like sunshine. Those who agreed to serve would only be the riffraff of the profession, and would be ostracized by all others.

Dr. Esmonde, M. P., said no honest, self-respecting man could have taken the first offer, but everyone should consider very carefully whether the new terms should be accepted or rejected. It was easy for the prosperous to say stick out, but he had experienced the difficulty of finding the quarter's rent, and he felt in the interest of the less prosperous some effort for settlement should be made.

The medical members of the Advisory Committee have issued a statement this morning on the intention of the government, which they regard as certain, to try for three years a state service unless the profession accept, and in view of this proposal, without presuming to offer advice, they ask whether it would be wise to refuse to work the act? They evidently think not. Some others seem to think that as the government promise the opportunity of revising after a time, a trial might be made.

A nine days' trial of an action brought against the British Medical Society for libel by the vendor of "sacco" and "lungsava" advertised as a certain cure for consumption ended yesterday in disagreement of the jury, who were therefore discharged. The alleged libel was contained in "secret remedies" published by the association after appearing in the journal. The vendor of the stuff thought the article called him a quack and represented his advertising as fraud. The defence took the line the lawyers so often do, that the words complained of did not bear the meaning attributed to them and related to the system—not the man.

I think the association should have insisted on a bolder plan—declared that a trader in an alleged remedy who had no qualification was a quack and that prescribing for sick people by an ignorant person boasting of being a specialist for chest diseases was a fraud on the sick. It is illegal to practise medicine without a qualification, but illegality is laughed at by the advertising quacks—they know the government will not interfere.

Dr. F. M. Pope, Senior Physician to the Leicester Royal Infirmary, died on October 26 at the age of 56. He qualified as M.R.C.S., 1879, took the M.D. of Cambridge in 1901, and was elected F.R.C.P. 1902. He held various offices in the county including the consultant physician to the asylum, and was regarded as the leading physician in Leicester.

The Perspiration of Tuberculous Patients and Its Infectious Character.—M. Piéry states that the perspiration of a tuberculous individual contains tubercle bacilli. This fact he has demonstrated in 30 per cent. of his cases, including various forms of surgical tuberculosis —*Gazette des Hopitaux.*

2. Pyelonephritis of Pregnancy and the Puerperium. J. W. O'Connor.
3. An Adjustable Knee Support. H. W. Marshall.

1. The Clinical Study of Respiration.—D. L. Edsall states that it is necessary to determine as far as possible, in any pathological disturbance of respiration, whether the disturbance is associated with exhaustion of the respiratory center, or whether it is, on the contrary, due to overstimulation of the center. The treatment would, in the two cases, be the opposite. It may reasonably be suspected that we have in many instances been making an error entirely similar to that which was made for years in treating the circulatory failure in acute infectious diseases with the mistaken idea that it was primarily due to excess of blood pressure, whereas it is usually due chiefly to quite the contrary condition. In respiratory distress one may equally well have been dealing at times with a condition directly the opposite of what we thought we have been treating, and may very often have been treating an overexcited respiratory center by still further exciting it. Likewise it appears that the effects of the respiratory stimulants need, in purely experimental or clinical studies, to be investigated much more accurately than has been done to determine their effect on the amplitude of respiration, as compared with the rate, and to determine their actual influence not merely upon tidal ventilation but, much more important, upon the amount of air that passes in and out of the alveoli. In most of the work that has been done upon the respiratory stimulants their influence upon the actual respiratory function may perhaps have been judged quite as inaccurately as one often judges clinically of the effects of different forms of respiration. Even tracings of the respiration, unless made quantitatively, can give a reliable idea of the effect of a drug upon ventilation only when the effect is so very decided that there is no question of mistake. It is quite possible that one may find that some drugs that are called respiratory stimulants actually lower the efficiency of the function of respiration in some circumstances of disease and even in normal conditions, and the contrary may be true of some so-called respiratory depressants.

2. Pyelonephritis in Pregnancy and the Puerperium.—J. W. O'Connor concludes from his study of this subject that infection of the pelvis of the kidney invariably involves the parenchyma. Owing to its anatomical relations the right kidney is the more vulnerable. The disease is much more frequent than supposed; the author estimates that it occurs once in every 3000 cases. Malnutrition, constipation, and the tonicity of the abdominal muscles are predisposing factors; a tendency to renal abnormalities on the right side, dextrotorsion of the uterus and a predominance of positions in the right oblique diameter favor the infection of the right kidney. Infection by the colon bacillus is the most common type, direct transmission through the intestinal walls being the probable mode of entrance. The pathological picture shows the pelvis and ureter dilated with pus and miliary abscesses in and beneath the cortex. The cardinal symptoms are smarting micturition, chills, fever, nausea and vomiting, pain in the loin and elevation of pulse. The urine is turbid, purulent and albuminous. Tenderness in the region of the kidney is always present. Enlargement of the organ can be demonstrated in about one-fifth of the cases. Abortion and surgical kidney are the most common complications. The diagnosis can generally be made on physical signs and urinary analysis, the differentiation from appendicitis presenting the greatest difficulty. The prognosis is usually good for the mother and less

favorable for the child. Treatment by rest, sedation, catharsis and urinary antisepsis has met with success. The use of vaccines and pelvic lavage, if of any real value at all, entails dangerous delays and, being extremely technical, is beyond the scope of the rank and file of the profession. Early operation in cases that assume a surgical aspect is to be strongly recommended.

1. **Gallstones.**—By P. Syms. (See MEDICAL RECORD, November 9, page 870.)

2. **Direct Transfusion of Blood.**—A. L. Soresi states that transfusion should not be resorted to only when the patient is *in extremis;* surgeons should train themselves in conservative surgery of the blood-vessels by means of experiments on animals before attempting transfusion in human beings; the vein-to-vein method is to be preferred, and the use of a vein of the neck of the recipient is the only physiologically correct method to be adopted, except when not suitable during surgical operations. In the treatment of hemorrhages there must be a distinction between hemorrhages which can be completely checked and hemorrhagic diseases; in the former saline solution should be administered immediately as a first resort and during or before transfusion; in the latter, transfusion should be resorted to before other liquids are introduced into the system, because the blood is used as a hemostatic and should not be diluted; in the greatest number of hemorrhages saline solution is sufficient to save the patient and transfusion should be resorted to only when the surgeon thinks that the hemopoietic organs of the patient are unable to supply, in a reasonable time, the morphological elements indispensable to life. In diseases in which the blood is loaded with poisonous products, transfusion is very useful, provided the central nervous system is not too seriously injured and blood is let out during or before transfusion is resorted to. Transfusion is a great help to patients who are considered bad surgical risks, and must be performed during the operation. A vein for both donor and recipient should be used, anastomosing the distal part of the donor's vein with the proximal part of the external jugular of the recipient. In this way the radial artery is saved and it is easier to find a donor. Obviously there may be cases in which it is advisable to use the radial artery of the donor, and transfusion will be very satisfactory; but, when possible, the vein-to-vein method should be used, the external jugular of the recipient being always preferable.

3. **Perineal Section Under Spinal Anesthesia.**—E. L. Keyes and D. W. MacKenzie call attention to the fact that the marked immediate rise of temperature so characteristic of perineal section done under general anesthesia is absent when the perineal section is done under spinal ansthesia. The authors believe that this single fact renders spinal anesthesia immeasurably superior to general anesthesia for operations upon the male perineum.

4. **The Gwathmey-Woolsey Nitrous Oxygen Apparatus.**—J. T. Gwathmey and W. C. Woolsey summarize the advantages of the Gwathmey-Woolsey apparatus as follows: (1) Absolute and perfect control of the gases flowing at a low pressure is effected. (2) The gases are easily warmed whenever the patient's condition demands it. (3) Small amounts of ether can be added whenever necessary. (4) The apparatus is especially adaptable for endotracheal anesthesia solving the problem of the administration of nitrous oxide and oxygen by this method. (5) An even, automatic flow of gases is assured, thus opening up a new field especially for using the analgesic properties of the gases. The apparatus is of small size and portable.

6. **Operative Treatment of Mammary Cancer.**—J. S. Brown concludes that any breast operation to be radical must sacrifice the pectorales, major and minor, but in some cases the upper clavicular portion of the pectoralis major may be left, and in so doing one insures to the patient a better arm function. In attempting a radical procedure all connecting lymphatic chains should be removed, as has been shown by many observers. This may require wide work, as the lymphatics drain the breast in all directions, even to perforating between the intercostal spaces. No one method of incision is applicable in all cases. It is always necessary to remove large areas of skin, and grafting must be resorted to in a minority of cases. All late cases that are on the borderline between operable and inoperable cases should be *x*-rayed to determine the possibility of metastasis in the long bones. Especially is this true if the patients suffer any neuralgic pains in certain joints.

11. **Mortality of Pneumonia in Alcoholics.**—C. K. Stillman has observed that chronic alcoholism does not of itself alter the mortality figures for lobar pneumonia unless the alcoholism is present to an extreme degree. Chronic alcoholism sufficient to produce delirium tremens may oftentimes exist without affecting a patient's chances of recovery. In fact, in the author's series of free drinkers, there was hardly an individual who had not more or less of the characteristic cerebral excitation, yet this complication alone did not seem to influence the death rate. It thus appears that signs of fairly well marked chronic alcoholism do not in themselves justify a gloomy prognosis. In any given case an attempt should first be made to determine whether or not the patient is a confirmed drunkard. In all others the alcoholic factor need not be too seriously regarded. The generally quoted mortality figures for pneumonia in alcoholics (forty to fifty per cent.) are accurate in the sense that they are drawn from the general run of cases included under the heading of chronic alcoholism. The figures are, however, misleading, since they do not recognize the very important distinction to which the author has directed attention.

2. The Hospital in Relation to Medical Science.—W. H. Welsh notes that from the viewpoint of the various fields of its activity hospital work may be classified as humanitarian, scientific, and educational. The care of the sick and injured is primarily humanitarian, but it is not always easy to convince trustees that the others are also essential functions. The author points out that the furtherance of scientific medicine is also essential to the public welfare. Medicine of to-day is very different from that of former years—it has become more specialized and the hospital has become the laboratory of the clinician, who with this aid only can succeed in solving the great questions in medicine that are constantly appearing. The use of the hospital for educational purposes is the great problem of to-day. The theoretical subjects are outstripping the practical ones and the important thing is to bring the clinical subjects up to the level of the theoretical subjects in medical instruction. The most urgent need is to secure teaching hospitals, and this can be done only when the hospitals belong to the universities. It is for the interest of the patient and the public that such relation should exist.

3. The Special Diet.—H. D. Arnold believes that the average hospital of to-day is inadequately equipped to feed patients properly, according to dietetic principles, and the chief fault lies with the medical staff. He justifies this sweeping statement by saying that the older men commonly direct the action of the staff and their conservatism has hindered progress. There are exceptions to the rule, but he believes it applies to the average hospital. The feeding of patients is an important part of the treatment and constitutes the whole of the treatment in a considerable numer of cases. There should be a skilled dietician and an adequate diet kitchen in every hospital. It is now possible to apply the scientific knowledge of dietetics in practice and every progressive hospital should place its dietary arrangements on an up-to-date basis. Such measures will not only benefit patients but will also be economically profitable.

5. The Physician and the Hospital.—J. B. Murphy calls attention to the fact that the clinical history in many cases is more important in enabling the physician to arrive at a diagnosis than the physical examination or laboratory findings, and yet the newest interne and least-experienced man on the residence staff writes the history. The most incompetent man is given the most important thing to do. To him is assigned the dressing in septic cases and the writing of histories. There is a greater percentage of failures in diagnosis from badly written histories than from anything else; therefore the histories should be written by the senior member of the house staff. The man who is to become junior or senior assistant in the departments of medicine or surgery should remain four or five years, as this length of training is necessary to round out his apprenticeship and to prepare him for his subsequent teaching and surgical responsibilities. The general asepsis and cleanliness of the entire hospital must be looked after as well as that of the operating department. The next important advance in hospital reform will be in the administration of the serum and vaccine therapy. Pathology must be pushed to the top notch; the pathologist is going to play the great rôle in the new therapeutic work.

8. The Medical Superintendent.—H. B. Howard discusses the qualifications needed for the hospital superintendent and notices the more or less prevalent notion that executive ability rather than medical knowledge and skill are requisite. He does not think that a preliminary medical training of the superintendent is wasted and points out many ways in which it is useful and even indispensable to the executive head of a hospital, who must also deputize a large part at least of the actual medical treatment to his subordinates. The medical superintendents of insane hospitals are commonly supposed to be at the head of the medical work and to be expert alienists as well as at the head of the business management. If the staff is to give its best efforts to the treatment of patients it should be relieved from the business details, but it should not have to be overridden in medical matters by a lay superintendent. Medical knowledge is essential in keeping the hygiene of the hospital up to the mark. Every hospital is supposed to exist for its patients and a superintendent who knows most about the medical and surgical work has the clearest view of the needs of the institution and the highest incentive therefore to look out for its efficiency as well as for its economy.

10. Out-Patient Work.—R. C. Cabot makes a plea for the performance of better work in the out-patient departments of hospitals. In certain respects the dispensary fills a more important rôle than the rest of the hospital. The dispensary hits the problem of disease at three most vital points where the wards cannot: First. It roots out the foci of disease in families or neighborhoods, follows home the clues presented in the person of the dispensary patient, and so prevents disease. Second. It checks disease in its incipiency. Third. It deals with chronic cases and keeps the patients from relapsing into a discouraged and vegetative existence. Yet in spite of these three distinguishing marks of superiority, and in spite of the fact that almost all hospitals treat five times as many persons in their dispensaries as in their wards, one still permits the tradition of superficial, slovenly work in dispensaries to go on. The great dispensary abuse—not the abuse of the dispensaries by the patient, but the abuse of the patient by the dispensary—is still in evidence. We tolerate snap diagnoses, treatments that will not bear scrutiny, and records that are a farce. We are content that hospitals should spend at least twenty times as much for the care of a ward patient as they do for the care of a dispensary patient. Some clinics are efficient, especially those in which the treatment can be administered and finished at once. It is the medical, neurological, pediatric, and skin clinics that are relatively slipshod. Hurry, crowding, and a scarcity of assistants prevent creditable work in many instances. There should be in each clinic a fixed ratio of space, staff, and outfit to the number of patients received, as there is in a ward. There is no sense in allowing dispensary work to be a hurried and desperate struggle against time and numbers. It is possible to do as accurate scientific work in diagnosis and treatment at a dispensary as at a private office. This means honest, conscientious, efficient, well-organized, well-supervised work, with the interest of the patient rather than that of the physician or the student always paramount.

19. Muscle-Group Isolation in Treatment of Spasticities.—L. J. Pollock and E. B. Jewell discuss the value of the method of muscle-group isolation introduced by Schwab and Allison for putting out of action the muscles at fault in spastic and athetotic conditions. The isolation is accomplished by the injection of 80 per cent. alcohol into the nerves supplying the muscles concerned, causing a paralysis which is later treated by physiological exercises and educational methods. According to Schwab and Allison there is a gradual return of function without a recurrence of the spasm. Pollock and Jewell, however, combat this claim, and publish six cases supporting their contention. They say: "It is extremely doubtful if we can be assured of return of motor function in every case

subjected to this treatment, and it is preferable to suffer with athetosis and possess function than to be relieved of the athetosis and have function disappear. There is no certainty that the spasticity will not recur after some time, and from our cases it would seem that the spasticity will probably reappear. In cases in which shortening of the contracted muscles has occurred, the procedure is valueless unless supplemented by other surgical measure, as tenotomy, etc. In our opinion there is but one indication for the procedure in the treatment of spasticity, namely, a cross-legged deformity due to spasticity of the adductor groups of muscles occurring in a child, who on account of the deformity is unable to learn to walk. It may be possible in such instances to educate the child to walk during the time that the deformity remains corrected, and in the event of the return of the spasticity, the ability to walk, although hampered by the resulting deformity, may remain. We would particularly warn against the attack by alcohol on any nerve possessing important motor functions, as the ulnar, median, etc."

1. Eugenics: "Unto the Third and Fourth Generation." J. G. Adami.
2. The Importance of Examining the Urine Bacteriologically. W. H. White.
3. The Histology of Experimental Rheumatism. C. Coombs.
4. An Analysis of Injuries to the Bones at the Wrist, Based on the Radiograph Examination of 214 Cases. R. Knox and R. W. A. Salmond.
5. Auricular Fibrillation. C. E. Lea.
6. A Case of Auricular Fibrillation and Pregnancy. C. H. Miller.

1. Eugenics.—By J. G. Adami. (See MEDICAL RECORD, September 21, 1912, page 535.)

2. Bacteriological Examination of the Urine.—W. Hall White concludes that the presence of microorganisms in the urine is of clinical importance, and considers the conditions in which it is of importance. These conditions fall into two groups—those in which there is nothing to direct attention to the urinary tract and those in which there is. In other words, the bacteriological examination of the urine may be of value in two ways: either it may reveal the microorganism which is causing a general infection and which we are able to detect because the microorganism is being excreted in the urine, or it may reveal the microorganism causing local disease of the urinary tract. In various forms of chronic arthritis examination of the urine may show a causative organism, such as the pneumococcus, streptococcus, or colon bacillus. In many of these cases the use of an autogenous vaccine may be of curative value. Staphylococci may appear in the urine in cases of general staphylococcus infection. The same is true of streptococci in cases of streptococcus infection. Colon bacillus infection of the urinary tract may simulate appendicitis; it may cause hematuria; it may produce a chronic illness simulating tuberculosis; and it may give rise to symptoms resembling those of renal calculus. Examination of the urine in cases of cystitis complicating various nervous diseases may reveal the colon bacillus, the therapeutic use of which in the form of autogenous vaccines will usually control the bladder condition. Colon bacilluria which occurs so commonly during pregnancy may be the result of cystitis, pyelitis, or pyelonephritis. No matter how severe the case, medical treatment suffices to effect a cure.

3. Histology of Experimental Rheumatism.—C. Coombs, R. Miller, and E. H. Kettle state that the (1) inoculation of rabbits with streptococci recovered from cases of rheumatic infection has provoked arthritis, carditis, and other lesions. (2) Histological examination of these lesions proves that they are identical with similar changes provoked in rabbits by inoculation with a similar microorganism in the hands of other investigators; and that these lesions include all the phenomena, even the submiliary nodule, found in the rheumatic lesions of man. (3) Such differences as exist between the experimental rheumatic infection and the human variety are to be accounted for by a difference in the mode of entry of the infective agent in the two conditions.

4. Injuries to the Wrist.—R. Knox and R. W. A. Salmond, from an analysis of 214 cases of injuries to the bones at the wrist conclude that the most common injury at the wrist in cases in which the epiphyses have joined their shafts is a transverse fracture one-half inch above the lower end of the radial bone, the lower fragment being displaced backward and with or without a fracture of the styloid process of the ulna, while in cases in which the epiphyses are not yet united the commonest injury is a transverse fracture about one inch above the lower ends of both forearm bones and with both lower fragments displaced backwards.

1. High Blood Pressure: Its Associations, Advantages and Disadvantages. Sir William Osler.
2. The Calculation of Drug Dosage for Children. With Description of a New and Simple Method. W. J. Dilling.
3. Successful Removal of a Tumor in the Adrenal Gland. H. T. Mursell.
4. Some Experiments with Ionic Medication. N. S. Finzi.
5. A Case of Uremia Treated by Morphine. A. H. Carter.
6. Two Cases of Peptic Ulcer of the Esophagus. C. G. Watson.

1. High Blood Pressure.—Sir William Osler propounds the question: What are the conditions in which we see permanent high pressure, and what are its advantages and disadvantages? For practical purposes one may consider three groups of cases: Simple high tension, hyperpiesis, without signs of arterial or renal disease; arteriosclerosis, with the associated high tension, and renal and heart changes; and chronic nephritis, with secondary high pressure, arteriosclerosis, and heart changes. Hyperpiesis signifies simple high pressure without sings of cardiovascular disease. We have learned to recognize an average pressure, as taken with ordinary instruments, and the figures given are usually accepted. There are, of course, great variations, usually temporary, but now and again we meet with individuals whose pressure is permanently high—above 180—without, so far as can be ascertained, arterial, cardiac, or renal disease. Cannon and others have shown that in emotional states there is an increase in the adrenal flow, and this is a factor which has to be considered in the high pressure of modern life. This high pressure is not itself the disease, but a compensatory, salutary state, if not for the man, at any rate for his circulation. That this is so may be proved by trying to reduce it below a certain point. One may, for a time, succeed in doing this, but the pressure goes up again, and the man only feels comfortable when he is allowed to live at a certain high level. The disadvantages of high blood pressure are: (1) Transient cerebral attacks such as aphasia, headache, vertigo, flushings, or an anginal attack, or transient bouts of dyspnea with palpitations. But more serious still is (2) the certainty that sooner or later sclerosis of the arteries will follow. The author refers to two other causes, one of which has a note of personal appeal. There is an old motto, "It is the pace that kills," and nothing is more certain than that the pace of modern life kills many prematurely through the complications of arteriosclerosis. As a rule men under 60 years of age with primary arteriosclerosis have high blood pressure, indeed the highest known records are in this condition. In this group of cases it is well to recognize that the extra pressure is a necessity—as purely a mechanical affair as in any great irrigation system with old encrusted mains and weedy channels. Yet the victims are often robust, energetic men of great vitality. One should be disabused of the idea, if possible, that the high pressure is the primary feature, and particularly the feature to treat. The

two essential factors in maintaining uniformity in a system of land irrigation are keeping the terminal channels free between the rows of cane, and maintaining the drainage. Obstruction in the fields can be overcome by increasing the pressure, to a certain point, but it is cheaper and safer to clear out the weeds. The difficulty is to keep the human irrigation plant free from weeds, the sud that chokes the capillary bed, through which it takes a greater force to drive the fluids. We too often tinker at the pump and the mains, instead of looking for the real seat of trouble in the fields.

2. **Drug Dosage for Children.**—W. J. Dilling concludes that (1) of existing formulæ for the calculation of doses in children from imperial measures, those of Young and Gabius are of little value after the tenth year. Cowling's formula is the best of the older methods. (2) Sir Lauder Brunton's formula for calculating dosage with metric weights gives figures which are somewhat low at all ages and for both sexes; the calculation is also a little elaborate, and is not readily applicable to the imperial system. (3) The method suggested by the author for the metric system $\frac{\text{age} \times 5}{100}$, or for the imperial system $\frac{\text{age}}{20}$, results in doses which correspond closely with those demanded by the average weights of non-adult individuals of both sexes at different ages; the calculation is simple, and the method can be employed for the metric and also for the imperial weight systems.

4. **Ionic Medication.**—N. S. Finzi has found that it is possible to introduce the ions of some substances directly into a joint, even into the cartilages; at any rate of a compartively superficial joint like the knee. Very few ions driven in at the cathode, that is to say, acid radicles, can be traced in this way, but it is possible in various ways to trace certain of the basic radicles driven in at the anode. The penetration of different ions varies enormously, and it is possible to tell from the movements of the needle of the milliammeter whether a drug is entering the tissues freely or not. In using two ions which penetrated the tissues freely, it was found that if the handle of the shunt resistance was moved to a certain point and left there the milliamperage gradually increased, which means that the resistance of the skin had diminished so that the ions were entering in greater number. With ions which precipitated in the epidermis the milliamperage actually decreased after the first few moments, showing an increased skin resistance and a lessened number of ions entering; to maintain the milliamperage at all, the handle of the shunt resistance had to be continually moved in order to raise the voltage. In the case of ions subsequently proved to be deposited in the deeper layers of the skin, an intermediate effect was obtained, the current rising first and falling afterward.

6. **Peptic Ulcer of the Esophagus.**—C. G. Watson reports two cases of this condition which is a rare one. The ulcer in the first case perforated into the left pleura; in the second case no perforation occurred. In the first case a diagnosis of perforated gastric ulcer was made, and in the second a diagnosis of gastric ulcer. In both cases acute abdominal symptoms occurred; laparotomy was performed, and nothing abnormal was discovered. Both cases ended fatally.

Münchener medizinische Wochenschrift.

October 29, 1912.

Pure Culture of the Microbe of Granuloma Venereum.—Martini makes a hasty preliminary announcement of this discovery. He has obtained in pure culture a diplococcus and believes it to be the essential cause of the disease because found in tissue sections, on ulcerated surfaces and deep beneath the latter. Germs from these various localities all stain the same, cultivate the same, and behave in the tissues in an analogous fashion, their tendency being to penetrate inwardly and not to flourish on the surface. Siebert described the organisms in parts as far back as 1907, in specimens brought from New Guinea, and Flu saw them in specimens from Paramaribo in 1911.

Occurrence of Diphtheria Bacilli in the Lungs.—Reye takes up this subject in monographic fashion. Recently accounts have been published of the presence of this bacillus in the blood and cerebrospinal fluid. In the blood it is said to occur in less than 5 per cent. of cases. On the other hand, it has recently been determined that the bacillus gets into the cerebrospinal fluid in at least one-half of all cases. The author has, therefore, in view of these finds, investigated the lungs from the same viewpoint in all autopsies on diphtheria subects at the Hamburg-Eppendorf Hospital. Thus far he has studied from this point of view sixty-seven cadavers of which number forty-three patients died during the period of disease and the rest after the disease proper had run its course. In this combined material diphtheria bacilli were found in the lungs in fifty-six subjects (85 per cent.). In all but six cases of the positive finds other bacteria were present, chiefly erysipelatous streptococci. In the negative cases the microbic finds seem to have been insignificant. The association of the Klebs-Loeffler and Fehleisen bacteria in so many cases (twenty-seven in all) was to say the least striking. The symbriosis of these germs has been remarked before, but seems at present devoid of clinical significance. After all pseudomembrane has vanished we have to contend against the presence of diphtheria bacilli in the lungs. We do not know to what degree these are inimical to the welfare of the subject nor do we know how the lungs, in any event, are to be sterilized.

Seven Cases of Psychoses Cured by Gynecological Treatment.—Orrenau, who appears to be a disciple of Bossi explains his recovered cases by quoting the latter author: there are nervous and psychic affections in women which are conditioned by genital anomalies and affections and which may be cured by restoring the normal secretory activities. Hence all females presenting psychoses should be examined and if necessary treated gyneologically. Psychiatric clinics should therefore have a gynecologic ward and a chief of clinic for the same. To cite one of the seven cases: Midwife, age 40, of sound stock, and had been active professionally in author's clinic; menstruated at 18, scanty and painful; married at 28; husband died ten years later, paretic; woman married a second time to a younger man, was sexually frigid and had been sterile throughout. For 13 years past showed a variety of functional disturbances, including melancholia. Examination showed retrodeviation and pyometra. There had evidently been a long series of disorders dating from congenital antiflexion and dysmenorrhea. The psychic state was becoming aggravated. After a protracted course of gynecological treatment, including cautery and plastic work with use of pessaries the local and psychic troubles appeared to be fully cured. Patient now has normal menses.

Bacteriology of Peritonitis.—M. Fishbein states that peritonitis would seem to be most commonly associated bacteriologically with a combination of the *Bacillus coli* and other organisms, usually staphylococci and streptococci. The origin clinically is usually endogenous, the affections of the appendix being of major importance, the female organs of generation being next in importance. Exogenous peritonitis is becoming exceedingly rare with the improvement of aseptic technique in the handling of wounds and in operative methods.—*American Journal of the Medical Sciences.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS

BY THE INSURANCE EDITOR.

COMPLETION OF THE EXAMINER'S REPORT.

THE RECOMMENDATION.—The report having been completed to this point, the examiner is called upon to recommend the acceptance or rejection of the risk. The form of recommendation varies according to the requirements of different companies, and may be divided into the following classes:

1. In most blanks, a definite "yes" or "no" is required, and any deviation from this simple monosyllabic affirmative or negative answer will usually complicate the matter.

The recommendation should be based largely upon the physical condition of the applicant, there being very few exceptions to this rule.

The question of family history should always be left to the consideration of the home office officials who give decisions on hundreds of family records daily and are therefore more familiar with the subject. When an examiner qualifies the recommendation for acceptance of the risk by some such phrase as "barring the family history," he makes an unnecessary suggestion, as the family history is supposed to be already presented in full detail in the application for the study of the home office authorities. It will complicate the situation still more if the examiner recommends rejection on account of the family history. It would seem a simple matter for an approving officer at the company's headquarters to regard such an answer as final, ignoring the negative answer and accepting the risk when he is satisfied with the family history, disagreeing with the examiner as to the bearing of this part of the report on the insurability of the applicant. This is not a safe practice, however, as the writer can testify from the experience of his own company in several cases in which the examiners advised rejection of the risks on the ground of unfavorable family histories. As the family histories recorded were satisfactory, it was assumed that the examiners had overestimated the value of, what apparently seemed to them, adverse features, and issuance of the policies was approved in each of these cases. Death claims were presented a year or so later and it was then learned that each of the examiners had been in possession of the knowledge of some serious impairment which they would not allow to appear in writing for politic reasons and supposed that they were discharging their obligations to their company by basing their rejections on grounds of a trivial nature. If they had supplemented their report by sending the missing information to the home office, according to the suggestions in a previous section on "Confidential Letters," they would have fulfilled their duty and prevented the unfair losses to the company. There was no redress in these cases as it was decided by the company that the rejection of the examiners, even though the real cause for their action did not appear in the reports, should not have been overruled without further investigation. No application, then, should be finally approved at a home office until a recommendation of rejection based on apparently insufficient reasons has been fully explained by subsequent correspondence with the examiner.

The personal history, also, should be left for the consideration of the home office after being fully recorded in the report. Occasionally there will be some remaining effect of a recent or even remote illness, in which case the examiner may recommend rejection as, in such a case, he is justified in his refusal on account of the present physical condition.

The habits of the applicant may usually be left to the judgment of the medical directors, although they should be reported very carefully in all cases. If, however, the examiner is aware from his personal observation that the applicant is a bad risk on account of frequent intoxication or the use of drugs, he will be justified in recommending rejection.

The term "fair risk" or "average risk" should never be used instead of the concise "yes" or "no" in recommendations in this class. Companies do not limit their business to writing policies for athletes and those who enjoy the perfection of good health; they are quite ready to accept good average risks, knowing that the latter will live out their expectancy as well as the former. When, however, the examiner qualifies his endorsement by the elastic and vague terms "fair" and "average," it is suspected that, in his opinion, the risk is not quite up to the standard and this doubt has to be cleared up through correspondence. The examiner has the advantage of inspecting the applicant personally and must make up his mind definitely whether or not the physical examination justifies the insuring of the risk.

2. In a few companies the examiners are asked to recommend action according to whether in their opinion the risks are "good," "fair," or "poor." When this classification is required, the examiners are usually expected to rate the risks according to physique, general appearance and general record of family vitality. The drawback to this form of recommendation is that there is apt to be a discrepancy between the estimates of different examiners.

3. The examiners are not required to make any recommendation by some companies. This plan has certain advantages, especially to companies which issue rated up policies to sub-standard risks. These companies will probably write some form of policy even though it will differ from the one applied for, and it would, therefore, be manifestly inexpedient to ask the examiner to advise rejection in the case of impaired physical conditions. In this class, the examiners are expected to set forth fully the facts in the personal and family records and to state the results of the physical examination, so that the medical department at the home office may draw its own conclusions.

Investment Insurance.—George W. Hopkins opposes the idea of "investment insurance." He holds that (1) cash surrender values are not "investment values"; (2) cash loan values are absurd in principle and unjust in practice; (3) investment policies involve the risk of loss of large amounts of money paid for investment, not insurance, purposes, if the policyholder dies before his policy matures in ten, fifteen, or twenty years; (4) because investment insurance is full of discriminations and the discriminations nearly always favor the policy which contains the least of investment; (5) because "dividends" are really not dividends at all, and often the companies find it necessary to use the "dividend" funds for expenses.—*Medical Review of Reviews*, October, 1912.

Book Reviews.

Elementary Bacteriology and Protozoology: The Microbiological Causes of the Infectious Diseases. By Herbert Fox, M.D. Director of the William Pepper Laboratory of Clinical Medicine in the University of Pennsylvania, Pathologist to the Zoological Society of Philadelphia, etc. Price $1.75 net. Philadelphia and New York: Lea & Febiger, 1912.

Designed as an elementary text book for nurses and beginners, this small volume has been written with a most commendable restraint. The author has eliminated all unnecessary technicalities and yet succeeds in giving the reader a very clear view of the nature of microorganisms. While it would perhaps be unsuited for the beginner who intends to follow the subject persistently it seems admirably adapted for the instruction of nurses or the laity. The chapter on the subject of immunity is particularly clear and easily understood. In the discussion of the individual organisms special attention is paid to the mode of infection and to the routes by which the infectious agents leave the body, together with the precautions necessary to prevent the spread of the disease. The volume is attractively gotten up and the text is free from typographical errors. It can be highly recommended to training schools for nurses.

Principles of Microbiology. A Treatise on Bacteria, Fungi and Protozoa Pathogenic for Domesticated Animals. By Veranus Alva Moore, B.S., M.D., V.M.D., Professor of Comparative Pathology, Bacteriology, and Meat Inspection, New York State Veterinary College at Cornell University, and Director of the College. Price $3.50 net. Ithaca: Carpenter & Company, 1912.

This volume is described as an outgrowth of a lecture course accompanying laboratory work in bacteriology and protozoology and has been prepared as a text book for veterinary students beginning the study of microbiology. Dr. Moore occupies a high place among American bacteriologists and he has evidently put his best thought into this work. Although somewhat elementary in character, the most important facts are given and the essential principles explained. The principal laboratory methods are described and the relation of the several species of microorganisms to animal disease is rather fully discussed. The book is attractively published and should make a valuable addition to the veterinarian's library.

Landmarks and Surface Markings of the Human Body. By L. Bathe Rawling, M.B., B.C. (Cant.), F.R.C.S. (Eng.); Surgeon with Charge of Out-Patients, Demonstrator of Practical and Operative Surgery, Late Senior Demonstrator of Anatomy at St. Bartholomew's Hospital, Late Assistant Surgeon to the German Hospital, Dalston; Late Hunterian Professor, Royal College of Surgeons, England, etc. With thirty-one illustrations. Fifth Edition. Price $2.00 net. New York: Paul B. Hoeber, 1912.

The excellence of this volume lies largely in the beauty and clearness of the illustrations. The colored plates illustrating the topography of the great body cavities and the photogravures showing the surface markings of the different regions of the body cannot possibly be improved upon. The text is brief and well arranged for didactic purposes, the black-face side references to the illustrations being a happy feature. This volume may be recommended to the student, general practitioner, and surgeon as a safe guide, the popularity of which is amply attested by the five editions through which it has already run.

Burdett's Hospitals and Charities, 1912. Being the Year Book of Philanthropy and the Hospital Annual: Containing a Review of the Position and Requirements, and Chapters on the Management, Revenue, and Cost of the Charities. An exhaustive record of hospital work for the year. It will also be the most useful and reliable guide to British, American, and Colonial hospitals and asylums, medical schools and colleges, nursing and convalescent institutions, consumption sanatoria, religious and benevolent institutions, and dispensaries. By Sir Henry Burdett, K.C.B., K.C.V.O. Author of "Hospitals and Asylums of the World"; "Cottage Hospitals: General, Fever, and Convalescent"; "Burdett's Official Nursing Directory"; "The Nursing Profession"; "Helps in Sickness and to Health"; "The Relative Mortality of Large and Small Hospitals," and editor of "The Hospital." Price 10/6. London: The Scientific Press, Limited.

The object of the publication of this now well-known volume is well described on the title page, and on the whole it fulfills what it claims there to fulfill. In a special chapter the author refers to the British National Insurance Act and the influence it may exert upon the revenue and future interests of the voluntary hospitals. A number of matters intimately concerned with hospital work, such as the training of nurses and the cost of administration of hospitals, are well dealt with in separate chapters. In short, the book is an adequate vade mecum for those who desire information concerning hospitals and kindred subjects in any part of the English-speaking world. Sir Henry Burdett, however, has a bone to pick with the managers of some American hospitals who will not send accurate returns with regard to their institutions. Generally speaking, the information contained appears to be reliable and sufficiently full, and the Hospital Annual is coming to be, in its way, indispensable. Mistakes occur here and there, as for instance, putting down the name of Hughlings Jackson as on the staff of the National Hospital for the Paralyzed and Epileptic, when he has been dead for some little time, but as said before, generally speaking, the information appears to be accurate.

The Practitioner's Encyclopedia of Medicine and Surgery in All Their Branches. Edited by J. Keogh Murphy, M.C. (Cantab.), F.R.C.S., Surgeon, Miller General Hospital for South-East London; Senior Assistant Surgeon to Paddington Green Children's Hospital. Price $7.00. London: Henry Frowde, Hodder & Stoughton; New York: Oxford University Press, American Branch, 1912.

This is a single-volume encyclopedia of medical science arranged by subjects rather than alphabetically. Such an arrangement is not so inconvenient in a one-volume work as it would be were there several volumes, for the index, which is very well made, enables the reader to find the subject he wants without undue trouble or loss of time. It has its inconveniences, however, in that the classification is not altogether satisfactory or scientifically accurate. For example, under the section on infectious diseases caused by bacteria, we find discussed such very doubtful cases as smallpox, chickenpox, scarlatina, measles, hydrophobia, and syphilis. The last is not caused by bacteria, and we have no proof that the others are; indeed, the general belief is that some or most of them are of protozoan nature. In the section on diseases due to vegetable parasites other than bacteria, actinomycosis alone is considered, the very important blastomycosis receiving no mention. There are numerous omissions also in other sections; Malta fever and angina pectoris, for example, being mentioned only casually in the discussion of other subjects. The subjects that are considered, however, are well treated—and there are many of these. They are discussed succinctly, but for the most part in all necessary fulness and very satisfactorily.

The Theory of Schizophrenic Negativism. By Professor Dr. E. Bleuler, Professor of Psychiatry, University of Zurich; Director of Burghölzli Asylum; translated by William A. White, M.D., Superintendent of the Government Hospital for the Insane, Washington, D. C. Price $0.60. New York: The Journal of Nervous and Mental Disease Publishing Company, 1912.

This is a monograph on a most complicated phenomenon of mental pathology, namely, the tendency on the part of the individual to react in a manner opposite to what one would expect. The predisposing causes are ambitendency, which sets free with every tendency a counter tendency; ambivalency, which gives to the same idea two contrary feeling tones and invests the same thought simultaneously with both a positive and a negative character; the schizophrenic splitting of the psyche, with the result that the most inappropriate impulse can be transferred into action just as well as the right impulse, and that in addition to the right thought or instead of it, its negative can be thought, and the lack of clearness and imperfect logic of the schizophrenic thought in general which makes a theoretical and practical adaptation to reality difficult or impossible.

Children—Their Care and Management. By E. M. Brockbank, M.D. (Vict.), F.R.C.P., Honorary Physician Royal Infirmary, Manchester. London: Henry Frowde, Oxford University Press; Hodder & Stoughton, 1912.

This is an eminently practical and simple guide for the young mother and even for the physician in the management of infants and young children. The methods advocated by the author are in accordance with orthodox teachings; there is nothing spectacular or obtrusively "original." The artificial feeding of infants is described with equal regard to the rules of percentage feeding and the practical facilities of the home. The vexing problems of the diet of nursery children are carefully considered.

Special Article.

REPORT ON VITAL STATISTICS AND HEALTH REPORTS OF NEW YORK CITY.

BY THE PUBLIC HEALTH, HOSPITAL AND BUDGET COMMITTEE OF THE NEW YORK ACADEMY OF MEDICINE.*

The Objects of the Report.—The objects of this report are threefold: (1) To analyze briefly the scientific value of the reports and statistical tables of the New York Department of Health in order to suggest desirable improvements; (2) to impress the medical profession with the importance of complete and exact, promptly issued vital statistics, and of their service to science as well as to administration, and, finally, (3) to urge upon the city the necessity for appropriating adequate means for the reorganization of the present Bureau of Records of the Department of Health into a Bureau of Vital Statistics, which should be charged in addition to the present duties of the Bureau of Records with the scientific arrangement and interpretation of the city's vital statistics and prompt publication of the health reports.

I. *The Bookkeeping of the Public Health Movement.*—Vital statistics, or demography, may be figuratively described as the most reliable barometer for measuring social pressure. It constitutes one of the few instruments we have for accurate recording of social movements and tendencies. It is authoritatively claimed that "there is almost nothing more important in the entire field of statistics than vital statistics, because of its direct bearing upon the health and consequent welfare of the people."† Dr. Newsholme defines it as "the science of numbers applied to the health registration of communities and nations."‡ It forms an indispensable basis for the proper guidance of the public health movement and for a rational administration of a health department.

The Advisory Committee of Statisticians, appointed by the New York City Department of Health to make a study of the city's vital statistics, have, in their report, aptly defined vital statistics as "the bookkeeping of the health movement. Correct and thorough statistical data are as essential to the wise administration of the Health Department as bookkeeping to the conduct of business."§

From the scientific point of view vital statistics are of great importance. The unique opportunity scientific men have for medicosociological studies in this city of great numbers with its large variety of racial elements, diversity of occupations, and habits of life, has never been exploited. Not even the first skirmish of the field has been made. The great laboratory for eugenic research has not hitherto been utilized, except, perhaps, in a casual way. In spite of the much discussed question of so-called "race suicide," no numerical studies of this phenomenon have been made in this city. The fecundity of marriage among the various racial and economic elements of the population; the distribution of stillbirths among the various social classes; the effect of illegitimacy on infant mortality; the influence of the age of parents upon the vitality of their children; the effect of consanguinity upon the fertility of marriage; infantile diseases in relation to the age and occupation of parents; births in relation to occupation of mothers; the relation of mortality to the density of population; the proportion of males and females at birth in relation to the ages of parents, their race, and economic status; the influence of immigration upon birth, death, and morbidity rates; immunity from, or susceptibility to, disease of certain races or occupational groups in the population; all these and many other matters of vital interest have never been studied nor current beliefs regarding them put to a statistical test.

II. *The Basis for Reliable Vital Statistics.*—The two indispensable conditions for correct vital statistics are: First, the correct enumeration of population and the reliable scientific estimates of population during intercensal periods, and, second, a complete and detailed registration of births, marriages, sicknesses, and deaths.

These two requirements must be fulfilled before any reliable results can be obtained. They are very closely interwoven, as deaths, births, marriages, and sickness, for purposes of comparison in points of time or place, must be expressed in ratios to the unit of population.

III. *The Bureau of Records: Its Growth and Duties.*—1. *Duties of the Bureau.*—Section 1179 of the New York charter provides that there shall be two bureaus in the Department of Health, that of the Sanitary Superintendent and that of the Registrar of Records. In the latter bureau there "shall be recorded, without fees, every birth, marriage, and death, and all inquests of coroners which shall occur or be taken within the city of New York." The duties of the Bureau of Records are more complicated than the wording of the charter would indicate. First, the bureau receives and keeps on file all birth, marriage and death certificates, prepares and maintains a complete registration of physicians and midwives practising in the city, issues burial permits, makes searches of birth records for school and employment purposes, makes transcripts of said records, and recommends for prosecution violations of the law as to the filing of certificates of marriages, births, deaths, and stillbirths. Then the bureau issues weekly, monthly, and annually a detailed summary of all the births, deaths, and marriages correlated with sex and age composition of the population; it computes birth, marriage, and death rates, and also collects and tabulates information gathered by other divisions of the department relating to the health conditions of the city.

2. *The Staff of the Bureau.*—The staff of the bureau is composed of the Registrar of Records, who is a physician, and of five assistant registrars, one for each borough, who are also physicians. Clerks and tabulators make up the remainder of the staff. The bureau has not a single statistician.

3. *The Growth of the Work of the Bureau.*—With the constant large increase of population, the work of the division has grown greatly. The number of marriage, birth, and death, certificates, the issue of burial permits and transcripts, and the making of searches of birth records has increased considerably within the last decade, as seen from the following table:

Year	Marriages		Births		Deaths		Searches		Transcripts	
	Total	Per Cent. Increase Over 1900	Total	Per Cent. Increase Over 1900	Total	Per Cent Increase Over 1900	Total	Per Cent. Increase Over 1900	Total	Per Cent. Increase Over 1900
1900	32247	....	81721	..	70872	..	25132	....	21989	....
1901	33447	3.8	80735	*1.2	70720	*.2	26361	4.9	23296	6
1902	36207	12.2	85644	4.7	68112	*3.8	27340	8.8	23025	5
1903	38174	18	94755	15.9	67864	*4.2	36074	43 5	28673	30
1904	39436	22	99555	21	78060	10.1	68824	174	36468	66
1905	42675	32	103880	28	73714	4	88395	252	35833	63
1906	48355	49	111722	36	76203	7.5	90964	262	39085	78
1907	51097	58	120720	47.7	79205	11.7	98504	293	42788	95

*Decrease.

4. *Appropriation for the Bureau of Records.*—The appropriations for the bureau have been increasing with the work, but the increases are very much lower than those allowed in the other divisions of the department for the same period. This has enabled the bureau to continue on its beaten track, but has not allowed for any expansion in other directions which seem urgently desirable. Last year, following the recommendations of a special Committee of Statisticians appointed by the Department of Health, a request was made that the Board of Estimate and Apportionment appropriate $45,000 for an enlargement and organization of the bureau. This money, owing to other very heavy increases in the budget for 1912, was not voted. The salary cost of the bureau for the last decade was as follows:

Year	Money Expended in Salaries	Per cent. Increase Over 1900	Year	Money Expended in Salaries	Per cent. Increase Over 1900
1900	$38,654	....	1906	57,850	50
1901	40,022	4	1907	61,576	59
1902	41,150	6	1908	65,885	70
1903	40,343	4	1909	61,654	60
1904	42,356	10	1910	68,110	63
1905	53,245	38	1911	62,075	61

§Monthly Bulletin of the Department of Health of the City of New York, July, 1911. pp. 153-154.

IV. *New York City Vital Statistics.*—1. *Their Contents and Volume.*—The tables of the last annual report of the Department of Health *i.e.* for 1909 do not differ from those of previous years, except that some of the former tables were omitted in 1909 in accordance with the decision of the Department of Health to reduce the size of its annual reports. The 1908 report of the Bureau of Records was spread over 352 printed pages with only 18 pages of very simple descriptive matter; that for 1909 occupies but 87 pages, of which 22 contain descriptive matter and special tables. The discontinued tables were those giving (1) the deaths of males and females (each separately) by age, and cause of death in each borough; (2) the mortality according to cause, by weeks and age, with annual rates per 1,000, with meteorology, and number of deaths in public institutions, which was a very valuable table, and (3) a number of retrospective tables. All of the data of 1909 is comparable, however, with the reports of former years.

2. *Comparison of the New York Tables of Vital Statistics with Those of Paris and London.*—Comparing the New York tables of vital statistics with those of the city of Paris, one may at once notice that the Paris tables are much more complete, that they give very much more detail and more bases for correlation, especially with regard to births and marriages than do our tables. The Paris tables, for instance, divide births into living and stillborn, then they classify the two according to the legal status of the children and the age of the mother; they give the duration of pregnancy in the cases of stillborn children by the age of the mother and the number of previous births; they classify legitimate children, living and stillborn, by the sex of the children, age of the parents, duration of marriage, and according to the differences in the ages of the parents; they give the relation of age to fecundity; they report marriages by conjugal status before marriage and by the degree of consanguinity of the husband and wife, and so on. The New York report has only two tables for births and one for statistics of marriages. The most complete of all are the mortality tables, although here also there is great opportunity for improvement, especially along the lines of greater correlation and better interpretation of facts. In this respect the London vital statistics excel. The analyses contained in the reports of the Public Health Committee of the London County Council are most instructive and illuminating. They give a very clear picture of the existing demographic and health conditions. To begin with, all the information is given by sanitary areas, the city comprising 20, such districts varying in size from 18,000 to 350,000 inhabitants. The birth rates for each sanitary area are expressed as proportions to every 1,000 persons living, and as proportions to every 1,000 married females, aged 15 to 45. Tables are given indicating the fertility of women and the relation of fertility to social conditions. Statistics of deaths are similarly given by sanitary areas, and for each both the crude death rate and the death rate corrected for differences in the age and sex constitution of the population of the several sanitary districts are given. The most detailed, however, are the tables bearing on infant mortality. The deaths are classified by causes and by very minute age groups; by weeks for the first month of life, and by months for the remainder of the year. Infantile mortality is correlated with overcrowding, and special tables for the first 12 months of life are prepared. The principal epidemic diseases also find a very ample statistical description.

3. *The Scientific Value of the Tables.*—The demographic tables of this city present the minimum of information necessary for general administrative purposes. They are utterly inadequate as a guide for social or legislative action, and are of little use for scientific purposes. They do not throw any light upon such vital problems as the relation of morbidity and occupation, vitality of children, and the age of parents, the influence of illegitimacy on infant mortality, the relation of stillbirths to the occupation of mothers, the incidence of disease among the various elements of the population, etc. The cosmopolitan character of our city suggests a large number of questions of relation of race to various social phenomena, but in three instances only, where classifications are given by country of birth (instead of race or mother tongue) do our tables give any information on the matter, and, moreover, such a classification as "Austro-Hungarian" mothers (pp. 210, 220), for example, is utterly meaningless.

Furthermore, our marriage, birth, and death rates are crude rates, *i. e.* they express the average proportion of all deaths, births, and marriages in a unit of population, viz., 1,000. For general purposes the crude rates are satisfactory, but for a closer study of social conditions many factors which influence the death or birth rates must be eliminated before the force of other causes can be accurately determined or measured. If death rates, for instance, are to be employed as a meaure of the healthfulness of two places, the elements of age, occupation, and sex distribution must be eliminated, as some occupations are healthier than others, and as the mortality of females is at nearly all ages lower than that of males. Such correlated rates serve very often as a safeguard against erroneous conclusions, as will be illustrated in another section of this report. The New York City mortality tables contain correction for one single matter only, and that is the domicile distribution of the deceased by boroughs. By corrected mortality rates is meant there "that the death rate of each borough is corrected by the exclusion of the death of residents of the other boroughs occurring within its limits and the inclusion of the deaths of residents of the borough occurring in other boroughs."* Such corrections should be made as a matter of course and the name "corrected" not applied to it, as it may be misleading.

V. *Information Which the Bureau of Records Should Furnish in Its Annual Report.*—This section is not intended to give a detailed outline of all the tables which should be included in the statistical report, but simply to indicate the main divisions which seem to be essential to a comprehensive report of the demographic conditions of the community.

1. *With Regard to Marriages.*—In addition to the information given in classifying marriages by months, method of solemnizing, with three subdivisions of religious marriages, conjugal conditions at day of marriage, and color, the following statistics concerning the contracting parties should be given:

(1) Race or Nativity.—This would give us an insight into the degree of intermarriage among the various elements of population, also among the natives of different parts of the country. Is immigration tending to promote matings of dissimilar and unrelated blood, or is the tendency in the other direction? We could then trace the fertility of such marriages from the birth tables.

(2) Residences.—The residence unit in the marriage table should be made smaller than a borough. For scientific purposes the residence distribution of mates has great interest. Dr. Davenport reproduces in his book† a clipping from a Brooklyn (N. Y.) newspaper, giving the announcement of marriage licenses on a certain day in the spring of 1911, which shows the frequency of marriages between persons from the same address. To what extent does selection and not chance and propinquity govern the marriage phenomenon?

(3) Age, Education, and Occupation.—Marriages of minors should be given separately. Do we at present have in our society any evidences of educational and occupational selection, or are marriages contracted in an entirely haphazard way? What is the relation of selection, as far as we can measure it, with divorce?

(4) Length of Widowhood and Divorce.—Is there any relation between former conjugal condition and the marriage rate?

(5) Divorces by age and occupation of consorts, length of married life, and the number of children.

(6) The General and Corrected Marriage Rate.—The crude marriage rates should be continued for purposes of comparison with former years. A marriage rate corrected for women of marriageable age should be computed for ascertaining the actual fecundity of the population and for future and more exact comparisons.

2. *As to Births.*—The present tables of the Bureau of Records with regard to births should be amplified by tables giving the births by the months in which they occurred, by races, age of both parents, and their occupations.

Stillbirths and illegitimate births should be similarly classified, with the addition, in the case of stillbirths, of duration of pregnancy, occupation of mother, and length of work during pregnancy, if the woman was regularly employed at some occupation.

The tabulation basis should in all cases be smaller than a borough.

In view of the fact that venereal diseases are at present reportable, the number of cases of syphilis, by age, in a district should be put in close juxtaposition with the number of stillbirths in that district.

3. *As to Deaths.*—As has been stated above, our mortality tables already contain a great deal of important information. This information could be made more valuable by changing the arrangement of it and adding more material, so as to afford better means of comparison and correlation. Causes of death should, in addition to age groups, be subdivided with reference to occupations and the racial elements of the population. On the death cer-

*Annual Report of the New York City Bureau of Records, 1909, p. 244.

†Dr. C. B. Davenport, "Heredity in Relation to Eugenics," N. Y., 1911, p. 201.

tificate the occupation of the deceased is usually given. If this information could be made available and presented in accordance with some standard classification of occupations, say, as that of the last Federal census, much information of great importance and value could be obtained. As it is, we have no information on the relation of occupation, disease, and mortality, with the exception of a few private monographs. Deaths and suicides should be classified according to the conjugal condition of the deceased, and death rates should be correlated with social conditions. It would be extremely important to ascertain whether the effect of social conditions on mortality is as distinct in New York as it is in London. In London the death rates from all causes—from the principal epidemic diseases, from diarrhea, from phthisis, and from other diseases—vary in an almost inverse ratio with the social condition of the population. The better the social condition, the lower is the mortality from all causes. Is this true in New York, and if so, to what extent?

Infantile mortality should be registered and published by small, uniform tabulation areas; the age subdivisions, for the first month of life at least, should be given by weeks; the causes of death of infants should be minutely subdivided; the deaths of babies and the mode of feeding should be correlated; the relation of infantile mortality and overcrowding indicated, and the influence on the infant mortality rate of general and contagious hospitals for children, and of other public institutions caring for babies, clearly presented. Moreover, in addition to tables of mortality, life tables for the total population should be periodically constructed. Our life tables need correction from time to time, and by increases in the average longevity the influence of sanitary progress could be gauged.

4. *As to Morbidity.*—There is no way of accurately ascertaining the extent of general morbidity in a community. One approximation is furnished by causes of death and the prevalence of contagious and reportable diseases. Another source of information is contained in the hospital and dispensary records. If these could be classified and presented annually in the vital statistics report, much light would be thrown, not only upon the extent of morbidity in the community, but it would also serve as a guide to the city and to charitable institutions, as well as to charitable individuals, in their disbursements for additional hospitals. A classification of hospital and dispensary cases by occupations would throw light upon the relation of disease and occupation.

With regard to a better sanitary control of infectious diseases, the areas representing a unit of tabulation should be made uniform and much smaller than a city ward, and the principal diseases should be classified by sources of infection whenever known, as it is being done in London with reference to scarlet fever, for instance, where the following sources of infection are reported: previous case in family or house, infection by friends or neighbors, school, return cases, visiting hospitals, and other sources.

VI. *Statistical Methods.*—In order to be valuable, statistics must be exact and prepared in accordance with modern scientific methods, the tables must be carefully planned and arranged in such a way that no wrong inferences can be drawn. This has not been done in the past and therefore at the present time we are woefully lacking in a reliable basis for the preventive campaign and for social action in regard to health matters.

1. *Importance of Corrected Rates.*—For purposes of comparison the ordinary crude rates, computed on the basis of the frequency with which a phenomenon occurs in a certain fixed number of cases, say 1,000, are unsatisfactory. They very often lead to entirely wrong conclusions. In the case of Ireland, for instance, the crude birth rate has been declining for a number of years. This was attributed to the diminished fertiliy of the population. Dr. Newsholme and Dr. Stevenson,* analyzing the figures to their elements, demonstrated that the crude birth rate was utterly unreliable as an index to the fertility of the Irish women. Birth rates are influenced by four factors: (1) The number of women of child-bearing age in a given population; (2) the proportion of those who marry; (3) the age at which they marry, and (4) the natural fertility of the women. To establish the natural fertility of the women the other three elements affecting the birth rate must be eliminated before a proper index can be formed. By eliminating these elements it was found that the declining crude birth rate in Ireland was not due to a lower fertility of the population, but to the lower proportion of married women at child-bearing age, due to emigration.

Our city birth, marriage, and death rates are crude rates, and their main value is limited to general administrative purposes. For more detailed and intensive studies the rates must be corrected for certain factors.

2. *Need of Caution in Interpretation.*—Professor Chaddock, in his paper on "Sources of Information Upon the Public Health Movement,"* presents a number of very interesting illustrations showing how incomparable quantities are often compared and how erroneous conclusions are consequently reached. The report of the U. S. Department of War for the year 1899, for instance, analyzes the health conditions of the soldiers in the Philippines, and finds that the death rate among them compares favorably with the death rates of the population of Boston and Washington. This comparison is inconclusive, since soldiers are a selected, healthy class of men between the ages of 18 and 30 years, while the general population of cities is composed of people of all ages, infants and old men, healthy and sick. Many more examples drawn from various parts of the statistical field could be cited to illustrate the lack of satisfactory bases for many deductions, but this may suffice to prove the need of the skilful application of all safeguards and scientific methods to the guidance of such an important matter as the public health administration. The complex social problems of our city require constant and keen analysis of all the recorded data. Our present analyses, owing to the limited size of the staff of the Bureau of Records, are incomplete and fragmentary; they should have much broader bearings, be bolder and more intensive.

3. *Concentration of All the Statistics of the Department of Health in One Bureau.*—At the present time statistical data relating to work done and results achieved are corrected and tabulated in each separate division of the Department of Health, and this work is often performed by clerks to whom this tabulation is incidental to their other duties. This arrangement is not conducive to exactness and uniformity of work, nor to promptness in preparing reports and making them coherent and correlated. All the statistical work could be done better and more safely when performed under the direction of one bureau.

4. *Unit of Tabulation.*—The statistical information of the city is, in most cases, tabulated according to boroughs, and in some cases according to city wards, the boundaries of which were laid out long ago, and which are too large and uneven in area and in number of inhabitants. The wards of Manhattan differ in size from 78 acres (Second Ward) to 8,050 acres (Twenty-fourth Ward). The wards, moreover, do not coincide with social and racial groupings of the city population.

The unit of sanitary administration should be smaller than a ward and more elastic, more adaptable to the shifting of the population. The 40-acre tract units of the last Federal census to be published for this city present an excellent opportunity for the adoption of a new tabulation basis. For some purposes the 40-acre tract unit would be too small. In such cases a larger unit comprising a number of the smaller ones could be adopted, but for some other purposes the small basic unit would be of great assistance to efficient health administration.

5. *Need of a Local Population Census.*—As has been already mentioned, the first desideratum for complete vital statistics is a correct count of the population. As the Federal census is taken every ten years, the population of the city is estimated during the intercensal years, a method which can never be exact, especially when we try to estimate the distribution of the population by occupations, races, city areas, etc., and when it is applied to such a dynamic community with so large a bulk of immigration as New York City. The last police census in the city was taken in 1895. It showed the distribution of population by sex and age in Assembly districts and city wards. It also computed the density of population by wards. In 1905 the Department of Health took a census of the population of the greater city, but the results were never tabulated, and the vital statistics of the last decade were computed on estimates of population. It is highly desirable that a local census by the Police Department be taken every ten years and its ramifications made broader than in 1895.

VII. *Cooperation of the Medical Profession.*—1. *Careful and Uniform Registration.*—Of equal importance to a complete count of the population is a complete registration of marriages, births, deaths, and reportable diseases. Physicians are responsible for the registration of certain diseases, deaths, and a very large majority of births. On the accuracy of their reports the value of vital statistics depends. No valuable results can be obtained unless the medical practitioners making out the death and birth certificates take the trouble to answer all the questions carefully. Similar to a standard classification of causes of

*"Decline of Human Fertility," Journal of the Royal Statistical Society, Vol. LXIX, 1906.

*"The Public Health Movement," p. 61-86, published by the American Academy of Political Sciences, Phila., March, 1911.

death, the Department of Health should adopt a standard classification of occupations and races by mother tongue. The following of these classifications might involve some loss of time on the part of physicians, but as scientific men and citizens they would undoubtedly realize the importance of exact registration to science and to the health administration of the city, and would therefore readily adopt the uniform system, especially when it is realized that with respect to the scientific value of our vital statistics we are almost a generation behind the leading European countries.

2. *Statistical Instruction in Medical Colleges.*—Physicians have not been trained to appreciate the value of vital statistics. Medical colleges of this city have never offered full courses in the principles of statistics and their application to medicine and demography. In these days, when the physician is becoming more of a social factor than ever before, the need of his having a knowledge of statistical methods is constantly increasing. The branches of administration in which the professional knowledge of the physician is required are broadening, and the medical colleges should equip their students for their new opportunities, impressing upon them the value of scientific demography to the public health movement.

3. *The Medical Press.*—The medical press has hitherto given very little space to the consideration of the scientific value of public health reports. It often reproduces statistics without discussing their accuracy or significance. The health reports are rarely, if ever, analyzed and their contents or methods criticized. They constitute, perhaps, the only class of publications, public or private, which is free from the refreshing and invigorating current of vigilant, careful, and scientific scrutiny. It would be a great help and stimulus to the public health movement and to the city health administration if their reports and publications received more publicity and constructive criticism.

VIII. *Recommendations of the Advisory Committee of Statisticians of the Department of Health.*—The Department of Health Advisory Committee of Statisticians, mentioned above, realized the shortcomings of the present New York vital statistics and emphasized inadequacy of the present bureau and its staff to undertake the work on a larger scale. They accordingly advised last year the reorganization and enlargement of the bureau on scientific lines commensurate with the growth and needs of the city. All of this was incorporated in the budget estimates of the Department of Health for last year.

The Advisory Committee of Statisticians made their report in June, 1911, and they recommended the subdivision of the Bureau of Records into three sections: (1) That of Records, (2) of Research, and (3) of Publicity.

(1) The Division of Records to be charged with their present duties as outlined above.

(2) The Division of Research to be responsible for the scientific work of the bureau, for the preparation of tables, correlation of data, comparing results with former years and other places, and pointing out to the department the desirable lines of action.

(3) The Division of Publicity to be responsible for the publications of the bureau and for the general education of the public in health matters.

The Advisory Committee of Statisticians estimated that the additional cost of the enlarged and fully equipped bureau would amount to $40,000 yearly in salaries.

The recommendations of the Advisory Committee of Statisticians of the Health Department have the full approval of our committee. The present Bureau of Records has an inadequate force of trained statisticians and inadequate means to enable it to undertake the work on a large and scientific scale indispensable for public health and for a rational administration of the Department of Health. New York City should have a fully equipped and a scientific Bureau of Vital Statistics, and should, in this respect, set an example to the rest of the country. This year, witnessing the International Congress on Hygiene and Demography, is highly appropriate as a starting point in the accomplishment of such an end. Although we are not prepared to express any opinion on the rates of salaries to be paid to the men in charge of the work, as suggested in the estimates of the Advisory Committee of Statisticians, we want to emphasize here that these must be high enough to attract men of high qualifications, intelligent to plan investigations, and able to give proper interpretation to and analysis of figures. The value of statistics was depreciated in the past because of the laxity with which they were gathered, and because of the unsoundness of generalizations derived from them by men ill qualified to make proper use of them.

IX. *Publications of the New York City Health Department.*—The Department of Health publishes at the present time annual reports, weekly reports, monthly bulletins, and special studies carried on by the various divisions or by individual officers of the department. The quarterly reports have recently been discontinued.

1. *The Annual Reports.*—(1) Contents.—In former years the annual report was a stout, two volume publication with a lot of detailed description of the work of each division, numerous photographs, diagrams, reproductions of blanks used in the routine work of the department, and a number of monographs prepared by employees of the department, too extensive to be published in medical journals or magazines. The annual reports contained a great deal of detailed and superfluous information. In 1909 the size of the report was, with no harm to its value, cut from 1,234 pages, which was the size of the two volume 1908 report, to one volume of 305 pages.

(2) Lack of Careful Editing.—The editing of the reports has been negligent. The reports lack unity and congruity. Certain records of one year are often incomparable with similar records of former years. Information on some points is lacking, while on others it is repeated several times. In the section on the Child Hygiene Division we find in the report for 1909 the same table reproduced (pp. 181 and 183), once under the caption of "Communicable Diseases of Eye and Skin," and again under "Eye and Skin Diseases." What is worse than the repetition, however, is the fact that the first table reports 14,621 cases of miscellaneous diseases, while the other (on the next page) reports 179,545 such cases. The reader is left to guess which of the two reports is correct. By careful editing the report could be still further reduced with no curtailment of essential descriptive information. Many of the tables which are scattered throughout the report could be advantageously included in the report of the Bureau of Records, and correlated with other demographic data.

(3) Delays in Publication.—The annual reports contain a great deal of essential and highly interesting information, which is, however, rendered almost valueless (except for retrospective purposes) by the late issuance of the publications. At the time of this writing, early in September, 1912, the report for 1909 is the last available. For three years we have been without information as to the work of the department. This shortcoming, which is shared by all the publications of the Health Department, is a matter of great public concern, and the department should be able to find a way for remedying it. The delay is attributed to the large amount of "red tape" involved in the present arrangement for printing, whereby every report intended for publication must go for approval to the Board of the City Record, to the Department of Finance, and to some other departments before it reaches the printer. It is claimed that the reports leave the press in the same roundabout way. Without attempting to locate the responsibility for the deplorable delays, one questions the wisdom of issuing at all reports which appear so late, especially the weekly and monthly ones, which are intended for current information.

2. *The Weekly Reports.*—The weekly reports have a small circulation and are designed principally for physicians and others actively interested in the health of the community.

These four page leaflets give first a summary of deaths, births, and marriages by boroughs, then cases of infectious and contagious diseases by weeks for a period of fourteen weeks, and deaths first by principal causes and by large age groups, then by causes of death more minutely specified and by smaller age groups. The fourth page of the report reproduces a summary of deaths for the last fourteen weeks, with a computed annual rate per 1,000, meterology, and the number of deaths in institutions. The reporting of diseases by city wards was recently discontinued.

Aside from the question of the need of reporting chronic diseases by weeks, the question of the advisability of publishing these weekly summaries suggests itself when we consider that since January of this year the average delay of issuance has been twenty-three days, in some cases over a month. These delays are the more striking when compared with those of other weekly publications. The weekly reports of the U. S. Public Health and Marine Hospital Service reach New York five days after the date of publication, and the weekly reports of the Chicago Department of Health reach New York six days after the date of publication. The Chicago weekly report is always two weeks ahead of the New York report.

3. *The Monthly Bulletins.*—The publication of the monthly bulletins was begun in January, 1911. This bulletin contains, in addition to tables of vital statistics, descriptive articles and notes intended "for the instruction of the public and for the information of physicians and others concerned in public health work, to whom an account of the methods, aims, and accomplishments of the department may be of interest." It is undoubtedly a very instructive and interesting bulletin, but its value is diminished by its

double aim, to be scientific and to reach the general public. Hence, alongside of discussions on the "logical basis of Dr. Nott's hypothesis," we have a piece of poetry on "swatting the fly." The bulletin reaches and instructs a certain class of citizens in the community, but it does not reach the general public, and, like other publications of the department, it appears much too late.

4. *Monograph and Reprint Series.*—The department has recently established these two series. The first is to deal with certain problems of the department's work, the second is to disseminate in a standardized form reprints of papers on health matters which have been prepared by the department officers and published in medical journals. Six numbers of the monograph series have already appeared.

5. *Collected Studies from the Research Laboratory.*—In these studies are published the results of the work carried on by the bacteriological laboratories of the Department of Health. The studies are intended for professional men.

6. *Lack of Contact with the General Public.*—From this cursory review of the Department of Health publications we can see that the number and kind of publications are entirely sufficient for the description of the work and methods of the Department of Health, and that they are chiefly intended for physicians, social workers, and a certain class of the public. None of them is designed for the education of the masses or to supply what is considered the most effective weapon in the public health campaign. The Advisory Committee of Statisticians expressed the same opinion when they said that "the department has most inadequate and ineffective means of contact with the public, from whom it must derive its support, and through whose active cooperation alone it can achieve the largest results."*

It seems advisable to enlarge the edition of the weekly report and change its character. Most of the vital statistics given there could be omitted and relegated to the monthly bulletin; statistics of cases of contagious diseases reported, cases in hospitals, and deaths from contagious diseases should be left in, while cases of chronic diseases could be reported monthly in the bulletin. The space thereby gained could be used for popular and interestingly written information on various vital and timely topics; infantile diseases and milk stations in summer time, pneumonia in the fall, contagious diseases and school hygiene in winter, etc. Short reports of the main weekly activities of some divisions of the department could be reported there, and results of food and milk inspections could be given weekly. It would be a live and interesting publication, which the newspapers would be glad to reproduce regularly, and in this way a needed contact between the department and the public would be established. Arrangements could also be made with newspapers published in foreign languages for the periodic translation of the reports. In this way the great masses of immigrants would be reached. The reports could also be distributed among schools, clubs, libraries, churches, and settlements. The additional cost of the publication would not be very great, as, with the cooperation of the press, the report would not need to be spread broadcast in leaflets, but through the daily and weekly journals. In this way a broad and effective educational influence of the department would be secured for the good of the community.

SUMMARY.

1. Vital statistics is the bookkeeping and accounting of the public health movement and a guide for administrative, legislative, and social action.

2. The New York vital statistics are collected and tabulated by the Bureau of Records of the Department of Health. This bureau is, in addition, charged with many other duties, and its staff is inadequate for a detailed, intensive presentation of the vital statistics of the city.

3. The information contained in the reports of the Bureau of Records is insufficient and loosely correlated. With regard to the classification of the material and the statistical methods pursued, the New York reports are inferior to those of Paris, and with regard to the interpretation and analysis of the statistics, they are much inferior to those of London.

4. The reports fail to tabulate essential information contained in the marriage, birth, death, and sickness records which would throw important light upon many sanitary and social problems of the city.

5. Much of the statistical information of the various divisions of the department is prepared independently by the several divisions, published separately, and not correlated with the essential data of the report of the Bureau of Records.

6. The tabulation areas of the reports of the Bureau of Records are boroughs, and in some instances city wards. In many cases these bases are inadequate for administrative, social, or scientific purposes.

7. The two indispensable conditions for proper vital statistics are a correct count of the population and a correct registration of marriages, births, and deaths. The first requirement is met by frequent censuses. In this city, outside of the Federal census taken every ten years, we had a police census in 1895 and a Board of Health census in 1905, the data of the latter having never been published. Hence our rates are based on ten year estimates. As to the second requirement, the registration of births in this city is still incomplete, and in the registration of deaths there is no standard classification of occupations or of races by mother tongue, which would insure uniform, reliable, and scientific information.

8. Physicians have not yet fully realized the importance of correct vital statistics, and the medical colleges and press have not laid sufficient emphasis upon its significance.

9. The Bureau of Records needs reorganization and a larger, well trained scientific staff. The recommendations of the Advisory Committee of Statisticians, appointed by the Department of Health in 1911, for a subdivision of the bureau into a Division of Records, a Division of Research, and a Division of Publicity, are highly commendable.

10. The various publications of the Department of Health give a full description of the work of the department, but the delays in their publication detract a great deal from their value, especially for current administrative and social purposes.

11. The annual reports are usually several years late, and bear many signs of careless editing. The weekly reports have been, on an average, three weeks behind the time. The monthly reports also share in that shortcoming.

12. None of the publications of the Department of Health is designed to educate the masses of the people. They are of service to physicians and students of administration and sociology, but do not constitute a connecting link between the department and the general public.

RECOMMENDATIONS.

1. That the Department of Health reorganize and enlarge the present Bureau of Records in accordance with the recommendations of the Advisory Committee of Statisticians made in 1911, and subdivide the bureau into three divisions, of Records properly, of Research, and of Publicity.

2. That the Board of Estimate and Apportionment appropriate the money necessary for the enlargement of the Bureau of Records in the interests of efficient administration and the public health movement, and that the salaries fixed for the responsible officers of the bureau be such as to enable the department to secure well trained men for the positions.

3. That the work of the reorganized bureau be undertaken on a comprehensive scale and in accordance with modern scientific methods.

4. That all the statistical work of the department be done under the direction of the Bureau of Records to secure accuracy and uniformity of method, and that the records be promptly available.

5. That the reports of the Bureau of Records be published independent of the annual report of the Department of Health and be ready for distribution early every year.

6. That the city undertake a local population census every ten years beginning 1915, and that the forty acre tract unit of the last Federal census be made the basis for tabulation.

7. That the medical press give more analysis to public health reports and vital statistics and impress the profession with the importance of exact vital statistics, urging them to cooperate with the Bureau of Records in making prompt, careful reports.

8. That the medical colleges instruct their students in the methods and principles of medical and vital statistics.

9. That the Department of Health make greater efforts to issue promptly its annual, weekly, and monthly reports.

10. That the weekly report be changed from a purely statistical sheet to an educational pamphlet intended primarily for the general public, and that arrangements be made with the newspapers of the city for periodical reproduction of the essential parts of the report.

11. That more and better means of contact between the Department of Health and the public be established in the interest of efficient administration and of the public health movement, and that the public receive regularly information regarding the department's most vital functions—food and milk inspection, prevention of disease, and care of babies and school children.

Society Reports.

CLINICAL CONGRESS OF SURGEONS OF NORTH AMERICA.

Third Annual Session, Held in New York, November 11-15, 1912.

(Special Report to the MEDICAL RECORD.)

(*Concluded from page 920.*)

Thursday, November 14—Fourth Day.

THE PRESIDENT, DR. EDWARD MARTIN OF PHILADELPHIA IN THE CHAIR.

THIS meeting was held in the Brooklyn Academy of Music where the Congress was the guest of the Kings County Medical Society.

Problems of Obstetrical Practice.—Dr. W. W. CHIPMAN of Montreal, Canada, Professor of Gynecology and Obstetrics in McGill University read this paper. He stated that he proposed to attack the simple problems of obstetrics and felt that perhaps he should apologize for the elementary character of his paper. The interest in clinical teaching had recently greatly increased and this was especially true of obstetrical teaching. Practical obstetrics, however, deserved a very moderate amount of congratulation; in fact, it ran a bad third to both medicine and surgery. They had been too much inclined to regard natural parturition as a physiological process identical in the countess and in the cow, and to forget that there were many factors which modified the physiological process and made it a pathological one. The price of motherhood was still cruelly high; this was due among the lower classes to poverty, improper nutrition, and overwork, while in the upper classes it was due to indolence and luxury. Who was to blame that in Canada and the New England States 500 women died yearly and 5,000 were condemned to invalidism? Where the practice was imperfect the training was at fault. The fault lay in the teaching or, rather, want of teaching. Barely one-half of the medical schools of this country had been pronounced acceptable by the Council on Medical Education of the American Medical Association and only six really adequately equipped for clinical training in obstetrics. A recent graduate in Canada had informed him that his training had consisted in being permitted to witness two normal deliveries at a distance of 10 feet. In some of the other schools they were permitted to witness twelve confinements at an equal distance. These men were well trained, not as obstetricians, but rather as observers. There was some truth in the boast of the general surgeon that it was safer to undergo a laparotomy than to bear a child. Brilliant surgical achievement had dazzled the vision of many of their number so that they had failed to study the needs of the general practitioner; obstetrics was their most important need. He sometimes thought it would be better to banish the so-called classical surgery from the college curriculum. Dr. Chipman then criticised rather severely a recent article on the management of normal labor for recommending too frequent examinations of the patient and the pushing back of the cervix over the advancing head. These examinations were regarded too much as routine and matters of course and this was dangerous teaching. The problem of the management of normal labor was the oldest and the commonest in the practice of medicine. He preferred the term "spontaneous parturition" as wider and more comprehensive, since the proper management of normal labor should begin long before the actual crisis of labor set in. The physician should, in every case in which he was engaged before hand, make a visit to his patient six weeks previous to the date set for delivery. This should be done in all cases, but it was especially demanded in women gravid for the first time. At this visit the physician should make a careful palpation to note the size and position of the fetus and should make accurate measurements of the pelvis. No internal examination was needed at this time. At this time the head should be low and lying straight in the pelvic axis. If the child was found in this position it should be left alone. They should by no means forget to examine the urine as to specific gravity, albumen, and sugar. Dr. Chipman said he would pass over the first and second stages of labor, but would only remind them that the physician should come prepared, so far as asepsis was concerned, as though he were to attend a surgical operation. After the child was delivered ample time should be given for the uterus to recover; in the meantime the fundus should simply be guarded by the quiescent hand, but there should be no manipulation. The expulsion of the placenta was a physiological process. One might bring about the final expulsion of the placenta by asking the patient to bear down or by the use of a slightly modified Credé method. Very gentle massage might be permitted but no traction on the cord. A retained placenta was common enough but an adherent one was rare. The two ideals in the teaching of obstetrics were cleanliness and a masterly inactivity. Each man must master for himself a practical technique and so provide the solution of 80 per cent. of the problems he would meet. In regard to the problem of the unengaged head at the third stage of labor when the membranes were still intact or only recently ruptured, he said the gravity of the situation depended largely upon whether the patient was a primipara or not. In a primipara with the head riding above the brim of the pelvis and a great disproportion between the pelvic outlet and the head, the indications were quite definite, but it was the borderline cases that were more common and more difficult to manage. If the true conjugate was barely equal to the biparietal measurement of the head of an average child delivery might be effected, but in the case of a primipara with a conjugate vera of 9 centimeters and the first stage of labor completed the situation was serious and the physician might well say "If I had been aforetime here, this would not have happened." A visit a month or six weeks before would have disclosed the conditions and the obstetrician would have had time to consider what was best to be done. Since it was too late for this they had to confront conditions as they were. The bladder should be emptied and the fetal heart examined, under anesthesia a more careful examination of the parts should be made and the pelvis measured. If the conjugate vera was 11 centimeters, whether juxta minor or flat made no difference, delivery might be accomplished by molding the head if the child was small. The size of the head might be determined by Mueller's method of impression or Monroe Carr's modification. The total results of the examination might reveal a head slightly overlapping and in normal position. In such a case the first injunction was "Do not hurry." Statistics showed that 80 per cent. of these cases ended in spontaneous delivery. The better result obtained by midwives in such cases was due to their not knowing enough to interfere. In these cases the Walcher position might be an advantage together with slight pressure downward and backward on the head. The genupectoral position might also be employed. Another point was that they should avoid version; podalic version was for the expert. This procedure was useful within narrow lemits but was not for the average practitioner. A pubiotimy or cesarean section was scarcely to be undertaken outside a hospital. If the head did not descend axis traction forceps might be used with the patient in the Walcher position; force should not be used and the issue would soon be decided. If the head did not advance a living child could not be delivered. The fault was grave if this happened in any instance, but it was altogether unjustifiable if it happened the second time to the same woman.

Radical Operation for Cancer of the Uterus, Viewed from the Standpoint of (a) Permanent Cure, (b) Temporary Relief.—Dr. THOMAS S. CULLEN of Baltimore read this paper. The early recognition of cancer of the body of the uterus had led to such excellent results that its consideration was not necessary. In two-thirds of the cases there was no recurrence. In cancer of the cervix it was difficult to determine the cases that were operable. There were numerous advanced cases where the cervix was freely movable that were still operable even though the cancer had reached the ligament. In advanced cases it was an advantage to examine the patient under an anesthetic. While he had never used vaginal hysterectomy he would not hesitate to do so in the case of very fat or cachectic women. For several years he had done the cautery operation before opening the abdomen. Dr. Cullen described his operation, which was patterned after that of Wertheim, and illustrated it by lantern slides. They had been using a heated operating table which he thought was a great factor in conserving the vitality of the patient during the operation. They also conserved the patient's strength by not using the Trendelenburg position until the patient was under the anesthetic and first stage of the operation completed. Sometimes they removed the pelvic glands and sometimes they did not; every enlarged gland was not necessarily cancer. The extent of time employed in removing glands must depend upon the condition of the patient. It was a good plan to stimulate the patient before signs of collapse appeared. In order to find out

all they could as to the results of radical operation in cancer of the cervix, Peterson, Taylor, and Tausig had sent out letters to many operators and the results of the information gained had been published. The most evident fact ascertained was the entire absence of dependable statistics and the universal feeling that patients were not seen early enough. Tausig collected one series of 60 cases of whom only 14 were living after the five-year limit, but there were no operative deaths. Neil reported 70 cases of whom 20 per cent. were free from recurrence five years after operation. The investigations of the American Gynecological Society among the surgeons of the South showed that the majority of them had never done the radical operation. There was a failure to follow up the patients and only in a few instances were the statistics of any real value. After a radical operation, even in favorable cases, it was very difficult to give a forecast of the end results. When the growth was of the granular type one might look for a return. It had been stated that recurrences after operation made the condition of the patient more deplorable than though no operation had been performed. This had not been his experience, though in some cases in which he had operated he would not have done so had he known beforehand the extent of the disease. It was difficult to lay down any rule as to the advisability of an operation but with the terrible outlook for the patient most would gladly take a chance if there were only two chances in one hundred. He thought the Continental surgeons had better results than those in this country, because the women had more children, worked harder, and therefore were not so fat. The women had also learned to seek aid earlier, and, again, the surgeons were more accustomed to the operation and therefore did it more skillfully; one had performed the operation fifteen times in one month. In this country nothing but occasional sporadic efforts had been made to enlighten the public in regard to the early symptoms and the advantage of early operation in cancer of the cervix. The public had been taught the necessity of operation in appendicitis and now accepted it without question; they had been taught the necessity of and the means for fighting tuberculosis, and now they should be taught in regard to cancer. The public should be taught that cancer was a local lesion capable of cure by extirpation and not a blood disease. Under proper conditions the surgeon could save from 20 to 25 per cent. of those attacked by this disease. He thought the radical abdominal operation would give the best results but his feelings were expressed by the remark of Peterson that his experience in 11 advanced cases had not made him any more confident that the next patient would survive the operation or would be cured. Apparently favorable cases were apt to turn out to be grave. In a series of 48 cases in which he had operated there were 13 living after the five-year limit.

The Wertheim Operation.—Dr. WILHELM WEIBEL of Vienna, Austria, First Assistant to Professor Wertheim, read this paper. He said that Wertheim had been performing this operation since 1898, and a description of the operation by Wertheim was published in the American Journal of Obstetrics and Diseases of Children, of August, 1912. In describing the operation Dr. Weibel used lantern slide illustrations. He called special attention to the method of handling the ureter by placing the finger between the ureter and the uterine vessels and thus protecting it from being ligated. He said that they had never found cancer in glands of normal size. The ureter was sometimes imbedded in cancerous parametrium and there were some who preferred to resect it, but he did not favor this procedure, as cancer seldom attacked the ureter. The bladder was sometimes fixed and here he advised resection. In only a few cases was it necessary to resect the rectum. In 25 per cent. of their cases there were cancerous glands and nearly all of these died of recurrence. In a series of 863 cases at the Vienna Clinic from 1898 to 1907 operation had been refused by 36; there had been 447 inoperable cases; the radical operation was done 380 times; after operation 8 died of intercurrent disease and there were 160 recurrences. The results at the end of five years showed a mortality of 43 per cent., including primary deaths. The absolute efficacy of the operation had been 19.5 per cent. operative mortality of the first 100 cases was 30 per cent. In the following 400 cases it was 15 per cent., and in the last 175 cases it had been 9 per cent. The operability in the first 250 cases was 42 per cent.; in the next 251 cases, 52 per cent., and in the last 175, it had been 55 per cent. If the glands were hard and located high up along the aorta the cancer was inoperable. Fixation of the bladder was an unfavorable symptom. An exploratory operation might be necessary in making a decision. The greatest objection to the abdominal operation was the high mortality. The great reduction that they had succeeded in making was not due to the selection of cases so much as to better technique, more care in regard to the anesthetic, and other little refinements in handling these cases. It seemed that the prognosis was not so good in younger women as in those past the menopause. In recurrence little could be expected. Cancer statistics were only good when all the results were known. When they could not trace a case it was put down to recurrence.

Cautery in the Radical Treatment of Cancer of the Cervix.—Dr. X. O. WERDER of Pittsburg read this paper. He stated that in these radical operations his technique had undergone many changes. His first 19 cases were operated upon entirely through the vagina, but he was now using a combined vaginal and suprapubic operation. The operation was preceded by curettage of the cancerous surface. With the thermocautery he made an incision around the cervix and carried it up between the bladder and uterus. The peritoneum was not opened. Douglas sac was opened posteriorly. Wherever the wound did not look black and leathery the cautery was applied the second time. It was also applied to small bleeding vessels but the large vessels were sutured. The abdominal part of the operation was practically a pan-hysterectomy, but the broad ligaments were clamped and burned instead of ligated. In using the cautery he had never had but one injury to the ureter. The cautery was applied to the affected portions of the parametrium where the heat from the cautery destroyed microorganisms and penetrated further than could be reached by the knife alone. The removal of the iliac glands was a routine measure, but the regional glands were not disturbed because, according to Wertheim, with multiple gland involvement only five of his cases were alive after five years. He was very skeptical in regard to the alleged advantage of removing the glands. He had done the radical cautery operation in 78 cases. The primary mortality had been 5 per cent.; operability 39 per cent. There were 18 cases that survived the five-year limit and 13 were well at the present time. Among the recurrences two were after more than six years and two after five years. In all of these cases the clinical diagnosis had determined the treatment and only once had they resorted to an exploratory operation. Their primary mortality of 5 1-10 per cent. certainly compared favorably with results obtained by others. There had been no serious infections; sepsis was a large factor in causing the high mortality from radical operations. He did not attribute the absence of sepsis to the preliminary curettement but to the cooking process to which the parametrium was subjected. As there was very little loss of blood the danger of heart shock was greatly diminished. Age was an important factor as affecting recurrence; it seemed that lymphatic extension was much more rapid in the young and that women who had passed the menopause were much less liable to recurrence.

Dr. ROBERT L. DICKINSON of Brooklyn, in discussing Dr. Werder's paper, said that Dr. John Burns of Brooklyn had performed these radical operations with the electrocautery some years ago but his outfit was so elaborate that it was difficult to duplicate. The advantages of the deep dry roast have been shown and it was now possible to secure a simple and practical apparatus such as was on exhibit for inspection after the meeting. It was not impossible of argument that most of the cases that were curable could be cured by the lesser operation. The radical operations should only be done by very expert surgeons after a long experience. As a rule he believed in the cautery for the lower part of the operation and the suture for the upper part, but he had done the complete extirpation with the cautery.

Extended Radical Operation Through the Vagina for Uterine Cancer.—Dr. GEORGE GELLHORN of St. Louis, Mo., read this paper. He said that researches had shown that the recurrences in cancer of the uterus had been shown to take place in the parametrium and as a consequence simple hysterectomy had lost all precedence. He had used the Schauta operation with some slight modifications. By this operation, the details of which were given in Schauta's monograph on this subject, the greater part of the vagina and the parametrium were removed together with the uterus. Dr. Gellhorn described and illustrated with lantern slides his method of dissecting the vagina so as to form a cuff which was stitched and drawn out of the wound, thus preventing contact with cancerous tissue. He showed how he exposed the parametrium and dissected the ureter under the guidance of the eye. The two parametria were excised close to the pelvic wall. The

ligaments were fastened extraperitoneally. The Schauta operation was practically unknown in this country and was not popular. The technique of the vaginal operation was a *terra incognita*, but if a surgeon wished to claim the distinction of a specialist he should be familiar with every method used in his specialty. It was surprising how much of the pelvis could be exposed by the Schauta method. They could not afford to adapt the patient to one method of operating. The abdominal method was unsuitable in very fat women, in those past the age of sixty, in the cachectic, the emaciated, and those having heart disease. The mortality of the vaginal operation was lower than that of the abdominal. Wertheim had obtained a mortality of 18.5 per cent., and Doederlein of 17 per cent. Schauta and Franz had shown an operation mortality of 11 per cent. Cancerous glands were found in about one-third of the cases and here it had been admitted that operation was practically useless; removal of the glands in other cases was unnecessary. The two methods did not differ in their essential principles; they complemented each other and one should choose the operation suited to the individual case. In early cases and in the squamous celled variety the vaginal method was preferable. Where the uterus was not movable the abdominal method should be chosen. Pregnancy, fibroids, tubo-ovarian tumors, etc., were for the abdominal method. The surgical axiom that in dealing with cancer one should cut only in healthy tissue existed only in theory; these were times when they had to place the knife almost on the line of demarcation. In such instances they were liable to have recurrence and the state of the patient was worse than though she had not been subjected to the operation. His experience with recurrences was that they were much less amenable to treatment. He did not believe that they should persist in an excessive radicalism. In cases that had been operated upon the recurrence was more apt to be complicated with a mixed infection. The days of radical partisanship were past and he believed that the abdominal operation had served a purpose in focusing their attention of this subject and that it still had a place in surgery, that it was the operation of choice in advanced cases.

Dr. Howard C. Taylor of New York, in discussing these papers, said that the operation for carcinoma might have any one of three ends in view. It might be undertaken to save life, to prolong life, or to make life more agreeable. The operation with the highest percentage of cures was not necessarily the one of choice but the one with the highest percentage of operability. Any deficiency or interference with function was ignored and any risk was taken as giving the patient the only possible chance of life. However, there was a risk beyond which it was not right to go. In the largest percentage of cases Wertheim's operation was the one indicated. The risk was not so great that it could not be undertaken. He had done it and did not hesitate to take the risk. He had witnessed the work in Schauta's clinic and was surprised at the accessibility of the parts and the amount of tissue that was removed. Beyond question this operation did not remove as much tissue as was removed by the abdominal method. It was much more difficult than the Wertheim operation. However, he preferred the vaginal operation in the case of very fat and cachectic women, or those with marked prolapse. The great need was better statistics. Each man should follow his own cases and then they might learn the proper position of these operations in America. Another problem that confronted them was that of getting the patients early in the course of the disease. The great difference in the statistics between this country and the Continent was that they got their cases earlier abroad. In this country many were operated on only to prolong life and give some comfort. In order to get the cases earlier, women must be taught the early symptoms of cancer of the uterus and that operation was the only cure. In Germany and Austria they considered cases inoperable that would have been operated upon here. Dr. Taylor said he thought the time had arrived for the inauguration of a campaign of education on the subject of cancer and he wished to submit the following resolutions: *Be it Resolved*, That the time has arrived when, if the surgeons of America are to do their duty to the citizens of this country, a campaign of publicity should be at once undertaken to bring to the attention of every woman in this country the early symptoms of cancer of the womb and to point out that if the cancer be detected in its early stages it can often be cured. *Be it further Resolved*, That this society at once appoint a committee of five, to be named by the president, to disseminate this information. *And further*, That this committee be instructed to write or have written, articles to be published in the daily press, or the weekly or monthly magazines, as may prove most expedient. *And further*, That they report their progress at the next annual meeting.

In accordance with these resolutions the president appointed Drs. Thomas S. Cullen of Baltimore, Howard C. Taylor of New York, C. Jeff Miller of New Orleans, F. F. Simpson of Pittsburgh, and E. C. Dudley of Chicago.

Friday, November 15.—Fifth Day.

The Early Days of Clinical Surgery.—Dr. Stephen Smith, having been introduced as the guest of the society, told of the beginnings of clinical surgery at Bellevue. He said that in 1840, when he began the study of medicine, Dr. James R. Wood made an effort to introduce the clinical study of surgery and met with much ridicule. It was gratifying to him to have lived to see the day when the advantages of clinical surgery were recognized. If he had his way he would not only put medical students into hospitals as internes but would put them into the wards as nurses; they would then become acquainted with every possible emergency. He compared the surgery of those days, when anesthetics were not used, with that of the present time and said that at that time they were as much amazed at the work of Mott and Rogers as they of the present time were amazed by the operations for the transplantation of kidneys or bone, or perhaps as they would soon be by the transplantation of brains. Dr. Smith also drew a vivid picture of the results of a neglect of asepsis in those days and compared it with the present, when, according to report, a prominent physiologist sent to Bellevue for a specimen of pus to exhibit to his class and was told that there was none in the institution.

The Treatment of Lateral Curvature of the Spine.—Dr. E. G. Abbott of Portland, Me., read this paper and illustrated it with lantern slides. He said that from the point of view of the orthopedist if one or more movements of any portion of the body were lost, this constituted a deformity. If the movements of flexion and abduction were lost in the foot a club foot resulted; the spine was not unlike the foot. It was capable of bending as far to the right as to the left in the normal individual, and if this motion did not reach to that of the normal individual, the spine was crooked. If a club foot was operated upon and brought to the correct anatomical position and held by a fixed dressing until union took place, when the dressings were removed the deformity would almost immediately recur, but if the foot was put in extreme flexion and adduction until healing took place and then held in the same position by a steel appliance, the result would be a cure. Physiological lateral curvature was a position frequently assumed during the activities of daily life and pathological lateral curvature was the same so far as the position of the spine was concerned. Following the analogy of the club foot the logical treatment was to place the spine in an overcorrected position. To accomplish this overcorrection, Dr. Abbott had devised a gas pipe frame in which was suspended a hammock. The hammock was shaped so that the head and feet were elevated and the head was supported by a strap under the occiput. Straps were applied around the body of the patient and by means of a windlass attached to the frame so adjusted as to bring pressure to bear in opposite directions. They were adjusted so the spinal deformity was overcorrected. The shoulders were treated in a like manner. Dr. Abbott then applied a plaster jacket to the patient with the spine in the over corrected position. After wearing this jacket for the length of time that the individual case might require, it was removed and replaced by one in which the patient's spine was in the straight position. A window was cut in the jacket over the seat of the deformity so that there was no undue pressure at this point and the physician could watch the progress of the case. By means of lantern slides Dr. Abbott showed the different stages of the procedure as applied to a girl, 19 years of age, with an old lumbar lateral curvature of five or six years' standing, which was made perfectly straight at the end of eleven months. In the treatment of club foot every surgeon realized that the after treatment was more important than the operation and that the corrected deformity must be followed up for two years. The same was true in lateral curvature; some appliance should be worn which might be removed for exercise and to meet this demand Dr. Abbott had devised a celluloid corset. In ordinary cases it was worn a year, being removed twice daily in order that the patient might perform certain exercises. For the first six months this corset was worn day and night and then during the day only. In many instances it might

have to be worn for a longer time. There were many cases of lateral curvature of the spine that could not be cured. It was possible in severe cases to overcorrect the deformity so that the overcorrected result would be worse than the original deformity. This method was not applicable to deformities resulting from tuberculosis, but would be found effective in lumbar and dorsal curvatures and even in upper dorsal and double curvatures.

Dr. JOHN RIDLON of Chicago said that in his opinion Dr. Abbott had done one of the greatest things yet accomplished in the realms of surgery. When he first read Dr. Abbott's paper on this subject about a year and a half ago he was very skeptical. In his long experience he had treated lateral curvatures in different ways and had secured very few cures. He had obtained better results with Lovett's method than with any other until he had tried that of Dr. Abbott. He had visited Portland to see Dr. Abbott work and felt that he had accomplished the impossible. Since that time he had treated 23 cases by the Abbott method and had had some cures. Some of the cases thus corrected and overcorrected could not have been cured by any other known method. He had not been successful in correcting lateral curvature in the upper dorsal region as had Dr. Abbott, nor had he been successful with the double curvatures. He had been very successful, however, with cases of a single curve in the lower two-thirds of the dorsal region. He had used the method with satisfaction in the scoliosis of infantile paralysis.

Dr. ROYAL WHITMAN of New York said that he could not agree with some of the statements that Dr. Abbott had made. Since Dr. Abbott had published his article in June, 1911, he and his associates had been testing his method; they had followed Dr. Abbott's directions as nearly as possible. They had had under treatment an average of 40 cases during the summer and their results did not seem to justify Dr. Abbott's claims. Club-foot offered no adequate comparison. Many of the high dorsal curvatures and sharp angulations of the ribs offered great resistance to treatment. Certain cases had been rapidly corrected but as rapidly relapsed. He thought the attitude in which the patients were suspended was undesirable and the patient very uncomfortable. Sleep was disturbed and respiration interfered with, and the pain was renewed every time that the pressure was renewed. He felt sure that they had not made more than the average number of mistakes that any one would make in the application of a new method. The corset had to be worn too long and he felt sure that moderate lateral curvatures could be reduced more easily by extension and gymnastic exercises. He nevertheless thought the thanks of the profession were due Dr. Abbott for the new interest that he had awakened in the subject.

Surgery of the Bones and Joints.—Dr. JOHN B. MURPHY of Chicago made this address. He divided his subject into three divisions as follows: (1) Fractures in the neighborhood of the joints; (2) diseases of the joints which were complicated by fracture; and (3) diseases of bones which had regenerated after partial destruction. He called attention to those fractures which were most common but which gave the most evil results. Colles' fracture was always produced by falling with the pressure upon the anterior surface of the hand and not on the back of the hand; it always resulted in this definite way. The question arose, How should it be reduced? By traction and this was the only definite way to accomplish this if proper results were to be had. In order to make this reduction the bones should be unlocked and for the after care use a splint of any particular kind. If the fracture was properly reduced it would remain reduced. It was only necessary to place on plaster-of-Paris, up and down, and place the limb in a handkerchief and let the patient go. Dr. Murphy presented pictures showing the results of his treatment. In many cases there occurred a Volkmann's contraction. Why? Because the arm itself was not used as a splint. Dr. Murphy described the operation he did and emphasized the importance of picking up the periosteum without opening the joint, not a difficult thing to do. Another interesting picture he showed was of a fracture at the elbow which occurred nine years before the photograph was obtained, and in this case there was a failure in extension and an incomplete bony ankylosis. An attempt was made to elongate the tendon after dividing the capsule clear across. The fibrous portion of the capsule was inelastic and, of course, would not fracture. He had had as many as twenty-five or thirty cases of Volkmann's contraction to deal with. In this condition the mischief was usually done within twenty-four hours; there was a traumatic myositis with swelling, tenderness, etc. This should be written about in all papers dealing with injuries of the joints. Dr. Murphy presented another picture of a boy who had talipes equinus from birth. He was twenty years of age. The result of his operation was the production of a perfect normal relationship. Another picture shown was one of fracture at the shoulder joint which was very interesting in illustrating the errors that were made in interpreting the *x*-ray pictures. These pictures, in his opinion, were the most difficult to read because they were so often deceptive. Another picture shown was one of internal luxation of both bones of the forearm. In another case the *x*-ray did not reveal anything at all in the way of any pathological condition about the shoulder; it did not show that the head of the humerus was not in the glenoid cavity at all. The diagnosis of fracture had to be made on the physical signs alone. At operation the head of the bone was found to be completely out of the glenoid cavity. Pictures of Pott's fracture were shown, a fracture of the lower portion of the fibula, the interosseous ligaments being injured and with a luxation of the foot outward, not inward. In cases of Pott's fracture it should be borne in mind that from six to eight weeks are required for repair of the injury. Dr. Murphy showed pictures of fractures about the knee, particularly that of the impacted type. He also showed photographs of ununited fracture of the femur. In dealing with these latter it was absolutely necessary that the strictest asepsis should be employed. In cases of inflammation of joints there were but two tissues that really became inflamed, the synovial membrane and the bone or bones. It was the former that should be especially considered in the treatment of these inflammations. It was interesting to note that its tensile strength or power was from 100 to 140 pounds. When a joint became infected the endothelial cells were destroyed and this was followed by ankylosis. The joint should not be opened unless there was a streptococcus infection present; these cocci were the ones that destroyed the synovial membrane. Every day they met with cases of arthritis which began with a chill and which, as a rule, resulted in a certain amount of destruction of the synovial membrane. If these cases were studied with care it would be found that those that began with chills were cases of pyemia; when there were no chills they were instances of rheumatism so-called, which was not rheumatism but mild infection. In these arthritides, whether multiple or single, that began with a chill one often found one, two, or more joints affected. The first thing to do in these cases was to apply a Buck's extension apparatus; this would relieve the pressure and pain and morphine would not be required. The second thing to do was to aspirate the joint if there was much tension. And the third thing that might be resorted to was injections remembering the fact that the fluid in the joint was a very good culture media. Dr. Murphy showed some pictures illustrating the evils that resulted from draining these joints and the bony union which had occurred without drainage. In cases of ankylosis of the hip, an end to be desired oftentimes, the importance of keeping the limb in proper position was emphasized. There were more deformities following arthritis than from fractures. After arthritis there were many cases of metastatic inflammations. Why were they not recognized? Because the joint never became involved during the active and early period of the infection unless there was a streptococcus infection. He asked them to recall the fact that when they were in the dissecting room and the finger was cut, nothing serious was looked for even if the axillary glands became involved. One never became infected with the Neisser bacillus before the age of eighteen as a rule. After that time frequent cases of infection occurred. There was no danger in these cases from metastases before the seventeenth day. In cases of diphtheria there was no danger of metastases until the membrane came off. Dr. Murphy then exhibited a number of pictures of bone transplantations and called attention to the fact that in fractures there might be imperfect union even though the fragments were in perfect apposition. This was probably due to a lack of osteogenetic force in the line of union, and the insertion of a fresh bone graft would result in perfect union.

Dr. GEORGE E. BREWER said the paper had been one of great interest and to discuss it would be a work of supererogation. They had received a great lesson and should thank Dr. Murphy for his interesting paper.

Prostatectomy.—Dr. E. S. JUDD of Rochester, Minn., read this paper. He advocated the suprapubic operation and described the method in use at St. Mary's Hospital. He stated that the posterior lobe of the prostate was a separate structure, separated from the anterior lobe by

a fibrous capsule and that, furthermore, a primary carcinoma rarely had its beginning anywhere but in the posterior lobe. The posterior lobe could be enucleated with the finger, unless the tissues were unusually tough, from the prolonged use of the catheter. The operation was done in the usual way. He preferred to have the bladder empty and did not open the peritoneum unless it happened accidentally, when it apparently made no difference in the results. There was no bleeding if the enucleation was done within the capsule. He sutured the bladder without providing for drainage after having first made sure that there were no blood clots retained. The suprapubic route was the anatomically correct approach; it did less damage to other structures; interfered less with other functions, and was more certain to result in a cure. The perineal operation was much more difficult no matter what method was employed.

Dr. J. Bentley Squier of New York said that an attempt to discuss the paper was futile as he gave his unqualified assent to the suprapubic operation whether for the relief of urinary retention or of obstruction. He believed it was customary to sew the bladder without drainage, but his experience had been such that he had not thought it wise to continue this method. Drainage was considered a good measure in either surgical procedures and it seemed to him that it was in this. Pulmonary embolism was a danger after any surgical operation but especially so after prostatectomy.

Suture of Vessels.—Dr. Alexis Carrel gave a brief demonstration of his method of blood-vessel anastomosis which he illustrated by lantern slides. Only a small incision was necessary. The tube was a silver one plated with gold and sterilized in paraffin. It was introduced by a specially constructed dilator with two branches. The tube was fixed by ligature. The procedure looked exceedingly simple, Dr. Carrel stated, but was in reality a very delicate operation.

Election of Officers.—The officers elected for the next year were: *President*, George Emerson Brewer of New York; *Vice-President*, Dr. W. W. Chipman of Montreal, Canada; *General Secretary*, Dr. Franklin H. Martin of Chicago; *General Treasurer*, Dr. Allen B. Kanshiel of Chicago; *Chairman of the Committee on Arrangements*, Dr. E. Willis Andrews of Chicago. Chicago was selected as the next place of meeting.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Pennsylvania State Board of Medical Examiners.

December, 1911.

(*Concluded from page 876.*)

OBSTETRICS.

1. How would you treat a case of prolapse of the cord?
2. Give the management of a normal case of labor.
3. Name the conditions during labor indicating an anesthetic.
4. Give a description and the causes of false and true labor pains.
5. Describe the technique of the high forceps operation.
6. What are the sources of septic infection during labor, and what means would you take to prevent it?
7. What are the early symptoms of ectopic gestation?
8. State the causes and proper management of rigidity of the os uteri in labor.
9. Name a method of treating labor at full term when complicated by placenta prævia.
10. Give the possible complications and treatment of twin labor.

SURGERY.

1. Give the details of an operation for phimosis.
2. What symptoms would warrant the exploration of the brain?
3. Describe the operation of tracheotomy.
4. Describe in detail the conservative surgical treatment of open comminuted fracture of the tibia.
5. What condition of a stump would warrant amputation?
6. What symptoms would require the operation of salpingectomy? Outline the palliative and operative treatment of infection of the fallopian tubes.
7. Describe in detail an operation for the radical cure of oblique inguinal hernia in the male.
8. Describe in detail an elective amputation of the leg.
9. Name three forms of fracture that might occur about the elbow joint, with the appropriate splints for the treatment of each.
10. Describe the treatment of carbuncle.

HYGIENE.

1. What hygienic measures should be followed to prevent malarial infection?
2. Give the dietetic and hygienic management of acute rheumatism.
3. Describe a method for the disposal of excreta in the absence of sewerage system.
4. Outline the hygienic management of a case of scarlatina in a private residence.
5. What instructions should be given a patient with pulmonary tuberculosis to prevent the communication of the disease?

ANSWERS.

OBSTETRICS.

1. *Treatment of prolapsed funis* consists in: (1) Not rupturing the membranes prematurely unless there is some positive indication; (2) postural treatment, in which the woman is placed on her back or on the opposite side to that on which the cord lies, with hips and pelvis elevated, or the knee-chest position may be adopted; (3) reposition of the cord, either manually or with some form of repositor; (4) speedy delivery, by forceps or podalic version.

2. *Management of normal labor. During the first stage* a rectal enema of soapsuds with turpentine (℥i) should be given, and when the os is dilated to the size of a silver dollar the patient should be placed in bed, lying upon the side toward which the fetal back looks. If the pain is severe, chloral hydrate (gr. 15) may be given every half-hour for 3 doses.

During the second stage, examinations should be made every 10 or 15 minutes. In multiparæ, the membranes may be ruptured with the finger or with some aseptic instrument. Care should be taken not to injure the child's scalp or the lower uterine segment. The pain may require the administration of chloroform or ether, but not to the extent of complete anesthesia. The expulsive force of the abdominal walls may be increased by directing the patient to pull upon a sheet firmly secured to the foot of the bed. Attempts may be made to prevent laceration of the perineum by making firm backward and upward pressure against the occiput during the pains; by restraining voluntary expulsive efforts during the pains; and by securing expulsion of the head between the pains. The head should be supported when born; the eyes should be cleansed with sterile water; and if the cord is coiled about the neck, it should be loosened or slipped over the head. Delay in delivery of the shoulders may be overcome by stimulating the uterus by friction through the abdominal wall or traction. The cord is ligated and cut when pulsation has ceased, and the child is placed by the mother's side with its face turned away from the maternal discharges.

During the third stage ℥i of fluid extract of ergot is administered and irritation of the uterus by friction through the abdominal wall is practised for 10 or 15 minutes. If the placenta is not expelled by this time, the uterus is firmly grasped between the thumb and 4 fingers and compressed. Firm pressure is then made from above downward and backward in the direction of the pelvic canal. This usually causes delivery of the placenta. A vulvar pad of salicylated cotton and carbolized gauze and an abdominal pad and binder are then applied." (Gould and Pyle's *Pocket Cyclopedia.)*

3. *Anesthetics* are used in labor to lessen suffering produced by labor pains; to lessen the pain attending obstetric operations; to relax the uterus when its rigid contraction interferes with version; to promote dilatation of the os uteri; to reduce excessive nervous excitement which may interfere with progress of early stage of labor; to relieve eclamptic convulsions and mania; in cases of uterine inversion to relax the constricting cervix and so facilitate replacement; in bipolar version to lessen pain of introducing the hand into vagina; in precipitate labor to suspend action of voluntary muscles and retard delivery; in all cutting operations upon the abdomen; and sometimes in sewing up a lacerated perineum when many sutures are required. (From King's *Obstetrics.)*

Dangers: It lessens the efficiency of the uterine contractions; it predisposes to postpartum hemorrhage; and, if given too freely, may be followed by headache, nausea, and vomiting.

4. *False labor pains* are slight, occur before labor, do not cause dilatation of the os, do not produce a "show." They

are the normal intermittent contractions occurring in pregnancy, and may be further caused by a loaded rectum.

True labor pains gradually increase in frequency and severity, occur during labor, cause the os to dilate, produce a "show." They are due to commencing labor.

5. "The Simpson, the Tarnier axis-traction, and the Sawyer forceps are the instruments most often used. They may be used as tractors, rotators, levers, or compressors. They are indicated when there are lessened expulsive force, increased resistance, threatened fetal or maternal life, certain acute and chronic diseases, and abnormal positions and presentations. They should not be used when the os is undilated, when the head is not engaged, except in placenta prævia, when the membranes are unruptured, when the disproportion between the child's head and the parturient canal is too great, or in impossible positions and presentations. Before applying the instruments they should be sterilized, preferably by boiling; and the patient anesthetized and placed in the lithotomy position. Two fingers of the right hand are introduced into the vagina; the left blade of the forceps is then held almost perpendicularly by the left hand, with the tip of the blade opposite the vulva; the tip is introduced into the vagina, passed along the floor toward the sacrum. The blade is rotated outward in its long axis in order to escape the promontory of the sacrum. The right blade is introduced in a similar manner. To facilitate locking one of the blades must be rotated forward. If the head occupies the right oblique diameter, as in L. O. A. and R. O. P. positions, the right blade must be rotated; if it occupies the left oblique diameter, the left blade must be rotated. Traction is made in the direction of the pelvic axis until the perineum is well distended. The perineum is then protected by one hand, while the face is swept over it by an upward movement of the forceps. In posterior positions it is necessary to remove the instruments after the head is drawn down to the pelvic floor; after anterior rotation is secured they may be reapplied. If the occiput rotates into the hollow of the sacrum the hands should be depressed as the face is swept out under the symphysis pubis." (*Pocket Cyclopedia.*)

6. The aseptic management of normal labor aims to *prevent* infection. The prophylaxis consists in throrough disinfection of the *patient*, the *physician*, and the *instruments* and *appliances* employed. The simplest method is as follows: The *patient*, at the beginning of labor, takes a tepid bath and is well scrubbed all over with soap and water. Then an enema of soap and water to empty the bowel; after the action of which, the external genitals, thighs, buttocks, and abdomen are carefully washed with a 1:2000 bichloride solution, special attention being given to overlook no fold or fissure of the surface. The vaginal douche, of 2 per cent. creolin solution, or the weak solution of bichloride of mercury formerly used before labor, has been abandoned, unless there be some already existing infection, when it may be used. The normal vaginal mucus is itself germicidal in some degree, as well as a useful lubricant, and should therefore be allowed to remain undisturbed. Moreover, washing out the vagina exposes the woman to some danger of infection from an unclean syringe. The *physician*, before making any examination or doing any operation, removes his coat, bares the arms to above the elbows, when the hands and arms are thoroughly scrubbed with soap, water, and a stiff nail-brush. Scrape the under surface of the nail-ends and the fissures surrounding the nails with some pointed instrument, not sharp enough to scratch, and having washed off all soap in some clean water, immerse the hands and leave the arms in a 1:2000 bichloride solution, and continue this last washing for ten minutes." (King's *Obstetrics.*)

Nothing should come in contact with the genitals of the patient that is not sterile; and examinations should be as few as possible.

7. "When ectopic gestation exists there are: (1) The general and reflex symptoms of pregnancy; they have often come on after an uncertain period of sterility. Nausea and vomiting appear aggravated. (2) Then comes a disordered menstruation, especially metrorrhagia, accompanied with gushes of blood, and with pelvic pain coincident with the above symptoms of pregnancy. Pains are often very severe, with marked tenderness within the pelvis. Such symptoms are highly suggestive. (3) There is the presence of a pelvic tumor characterized as a tense cyst, sensitive to the touch, actively pulsating. This tumor has a steady and progressive growth. In the first two months it has the size of a pigeon's egg; in the third month it has the size of a hen's egg; in the fourth month it has the size of two fists. (4) The os uteri is patulous; the uterus is displaced, but is slightly enlarged and empty. (5) Symptoms No. 2 may be absent until the end of the third month, when suddenly they become severe, with spasmodic pains, followed by the general symptoms of collapse. (6) Expulsion of the decidua, in part or whole. Nos. 1 and 2 are *presumptive signs;* Nos. 3 and 4 are *probable signs;* Nos. 5 and 6 are *positive signs.*" (*American Text-Book of Obstetries.*)

8. RIGIDITY OF THE OS may be due to neurotic conditions, to early rupture of the bag of waters, to ineffective uterine contractions, to premature onset of labor, to constipation, to scars on cervix; it is not unusual in elderly primiparæ. *Treatment:* This consists in administering hot vaginal douches; giving chloral, or a narcotic; or the administration of an anesthetic and forcibly dilating the os and delivery by forceps.

9. *Treatment of placenta prævia, at term:* (1) Introduce one or two fingers within the os (the hand being in the vagina) and dissect the placenta from the uterine wall for about three inches from the os uteri in all directions, pushing it to one side if necessary. (2) Rupture the membranes, and if there is an unfavorable presentation turn the child and make the breech engage in the os; or, if the head presents forceps may be used if speedy delivery is necessary. The strength of the woman is then the main point to be cared for, and if in a reasonable time the uterus seems to be incompetent, the child may be delivered by art. In some cases of central placenta prævia, where rapid delivery is required, cesarean section may give good results for mother and child. (Landis' *Obstetrics.*)

10. *Possible complications of twin labor* are: Compound presentations, malpresentations, twisting or coiling of the umbilical cords, locking of the two heads, or locking of one fetus with the other. Compound presentations or malpresentations may require version or forceps or manipulation; coiling of cords requires ligation of cord in two places and cutting the same between ligatures, followed by rapid delivery. Locking of the heads generally requires craniotomy of the second child, with forceps delivery of the first, and subsequent extraction of the body of the second child.

SURGERY.

1. The operation for phimosis is circumcision. "Asepticize the parts. Grasp the foreskin and the mucous membrane with two forceps, draw the prepuce forward, catch the skin (at the point it is desired to cut) horizontally between the arms of the handle of a pair of scissors, and cut off the redundant prepuce. Retrench the excess of mucous membrane by cutting around with scissors one-quarter of an inch from the glans, stitch the skin to the mucous membrane with catgut, and dress with sterile gauze." (Da Costa's *Surgery.*)

2. Anorexia, vomiting, vertigo, headache, slow pulse, Cheyne-Stokes respiration, epileptiform convulsions, apoplectiform attacks, pyschic disturbances, muscular twitchings, choked disc, optic neuritis, and various focal symptoms.

3. *Tracheotomy.* (The high operation.) "The patient is placed on the back with a narrow pillow under the neck. Chloroform or cocaine can be used as anesthetics. An incision, one and a half inches long, is made downward from the cricoid cartilage, keeping strictly in the mid-line. The incision is deepened till the tracheal rings and isthmus are exposed. Enlarged veins give trouble during this stage if there is dyspnea. A director-hood is thrust into the trachea, and the point of a knife is slid along the groove to open the trachea from below upward. The patient is allowed to cough for a few minutes while the wound is kept open with dilating forceps; then the tube is tied in" (*Aids to Surgery.*)

4. "In the treatment of compound fractures the main object is to render the wound aseptic and to give efficient exit to the discharges. For this purpose the patient should in all cases be anesthetized, the limb shaved and thoroughly purified, and the wound enlarged and thoroughly washed out with some reliable antiseptic. It may be advisable to excise torn and dirty fragments of skin, muscle and tendon, especially when dirt has been ground into them. Loose fragments of bone are removed and portions denuded of their periosteum may be taken away lest necrosis should ensue; where fragments retain any considerable connection with the soft parts they may be left without fear. When a sharp end of one of the fragments is protruding through a small opening in the skin it is first purified thoroughly before attempting its reduction and then replaced, after enlarging the wound in the skin, or a portion sawn off. Hemorrhage is dealt with in the usual way, and the fragments are placed as nearly as possible in their normal position. If the fragments can be brought ac-

curately into position it is well to fix them by some mechanical appliance; but where the ends of the bone are much comminuted the small portions must be arranged in position as well as possible, and no attempt made to wire them. A good-sized drainage-tube is inserted, and, if need be, counter-openings are made; the external wound is closed or not, according to circumstances, and dressed, and suitable splints are then applied. Under such a régime the majority of cases do well. Immovable apparatus may be used after a time, windows being left in the plaster casing to allow wounds to be dressed." (Rose and Carless' *Manual of Surgery.*)

5. *Re-amputation* may be necessary when the stump shows signs of malignant disease or gangrene, in some cases of conical stump and severe neuralgia of the stump.

6. *Salpingectomy* is indicated in purulent salpingitis, the symptoms of which are as follows: A dragging sensation in the neighborhood of the affected tube; colicky pain, which is increased on exertion or even on standing; abdominal tenderness; menstrual disorders, as amenorrhea, metrorrhagia, dysmenorrhea, menorrhagia; dyspareunia; there may be septic symptoms and peritonitis; sterility generally ensues. On examination there will be found a fullness in Douglas' pouch and one or both lateral fornices; in these latter will be felt either the tubes, distorted and possibly adherent, or a sausage-shaped tumor, which is very painful; the uterus is retroverted or retroflexed, and may be bound down by adhesions; there may be an intermittent expulsion of pus, accompanied and preceded by a burning pelvic pain. There will be a leucocytosis.

The treatment of the acute form consists in rest in bed, free purgation with Rochelle salt (5i every hour) hot vaginal douches, and hot applications to the abdomen. If the symptoms become more severe celiotomy is indicated. The chronic form may be treated during the menstrual period by rest in bed, free purgation, hot vaginal douches; local applications of iodine to the cervix and vaginal vaults, and glycerin tampons. If these measures fail removal of the tube and ovary and replacing the retroverted uterus, etc., are necessary.

7. Many operations are practised, but Bassini's is the most useful. An incision, 2½ inches long, is made over the inguinal canal, exposing the structures of the cord and the external oblique. The external oblique fibers are split from the apex of the external ring to expose the canal. The sac is found, opened, emptied of its contents, and isolated from the structures of the cord up to the internal ring. If the hernia is irreducible, the intestine is freed and returned to the abdomen, omentum being ligatured and removed. The neck of the sac is then transfixed and tied with silk, and the fundus removed. The stump returns to the abdomen, three of four stitches are then passed through the conjoined tendon and arched fibers of the internal oblique and transversalis muscles above, and the deep part of Poupart's ligament below. These are tied behind the cord. The external oblique is then sutured in front of the cord, leaving just sufficient opening for it to pass through without pressure. The skin is then closed by a continuous stitch. The patient should be kept in bed for three weeks, and should not exert himself for at least six weeks. If the wound has suppurated, or if the case is one in which the abdominal muscles are weak, it is advisable that a light truss should be worn afterward for six months." (From *Aids to Surgery.*)

8. In Sedillot's "method of *amputation of the leg* the point of the knife is entered a finger's breadth external to the spine of the tibia and carried outward, grazing the fibula, and is brought out as far as possible to the inner side; a flap three or four inches in length is then cut from within outward; the extremities of the incision are next united by an incision across the inner side of the limb, involving the skin only; any remaining muscular tissue is next divided and the bones are sawed. The long external flap is then brought over the ends of the bones and fastened to the edges of the incision on the inner side of the limb. Ashhurst modified this operation by cutting the long external flap from without inward, and made also a short internal flap in the same manner. By either method the resulting stump is a good one, with the ends of the bones covered by the tissues of the external flap." (Wharton's *Minor Surgery.*)

9. (1) *Intercondyloid fracture* (T-shaped, or Y-shaped). This requires complete extension on a straight splint for three weeks, followed by passive motion; and then an internal angular splint for two weeks. (2) *Fracture of the olecranon process.* If there is very little displacement, a broad strip of adhesive plaster should be placed around the lower third of the arm. If there is much displacement the arm should be extended moderately, and a splint extending from axilla to finger tips applied anteriorly. (3) *Fracture of the external condyle.* This requires an internal angular splint; or the elbow must be flexed and fixed in this position and the arm placed in a sling so arranged as to support the elbow. This must be continued for a month or more.

10. The *treatment of carbuncle* is excision in those cases in which the carbuncle is favorably situated; the wound is allowed to granulate under antiseptic dressings. In other cases the honeycombed mass should be opened freely by crucial incisions, and as much of the necrotic tissue as possible removed by forceps and scissors. The wound should then be disinfected with peroxide of hydrogen and bichlorid of mercury solution, 1 to 1,000, and dressed with warm antiseptic fomentations. The constitutional treatment is that of sepsis. (From Stewart's *Surgery.*)

HYGIENE.

Malaria is transmitted through the bite of an infected mosquito (*anopheles*). Individuals should use mosquito netting round their beds and wire gauze in doors and windows, so as to keep out the mosquitos as much as possible. All pools, stagnant water, etc., where mosquitos may breed, should be removed. All mosquitos, larvæ, etc., should be destroyed as far as possible. By staying indoors during dusk and darkness, opportunities for infection may be avoided. Occasional fumigation with formaldehyde or sulphur is also efficacious.

2. In *acute rheumatism*, the patient must be kept in bed; some advise his lying between blankets; he should wear flannel; the room should be airy, well ventilated but free from draughts. Milk, either alone or modified, should form the basis of the diet; plenty of water should be taken. Light broths, soups, vegetables and fruits are allowed; meats, highly seasoned foods, alcohol, tea and coffee should be used very sparingly or not at all.

3. Where there is no sewerage system a privy vault may be used.

A sanitary rural privy consists of a "small watertight pit, not drained but roofed over to exclude rain, and so arranged that the excreta and ashes become thoroughly mixed. For this purpose either the ashes must be thrown in through the closet seat, which may be hinged so as to be lifted *en masse*, or else a "shoot" or sloping slab must conduct one or the other to a common point. The floor should be smooth, and raised a few inches above the level of the adjoining ground.

"The contents ought to be removed at fixed short intervals, and the work should be done at night or early in the morning so as to minimize the nuisance." (Whitlegge and Newman.)

4. The patient must be isolated; no one but the physician and nurse must enter the room; the physician should put on a large washable gown when he goes in, and remove it on leaving, at the same time washing his hands in a disinfectant; the nurse, when she leaves the sick room should also remove her clothes and put on others, at the same time disinfecting herself. Special care must be taken during the period of desquamation. At the termination of the disease everything should be disinfected; toys, and books, etc., are better burned.

5. The patient should be duly impressed with the communicability of his disease; he should be particularly warned about the disposal of sputum, the use of handkerchiefs, etc.; he should cover his face when sneezing or coughing; kissing should be prohibited. Rooms should be well ventilated, and frequently cleansed. Clothes and bedclothes should be boiled or disinfected before being sent to the laundry.

The Action of the X-Rays in Leucemia.—A. David and R. Desplats state that in studying this subject one is obliged to take account of the destructive action of the *x*-rays in large doses as well as of their stimulating action in small doses. The former action is not consistent with what has been observed by the authors and by others in the blood and tissue changes occurring in leucemia as the result of the action of the *x*-rays. These changes are to be explained rather on the basis of the stimulating action of the *x*-rays. The spleen and the hemopoietic organs are stimulated so far as their deficient functions are concerned, particularly the leucocyte-destroying and hemopoietic functions. This stimulation is proportional to the dose of the *x*-rays and to the functional capacity of the tissues subjected to the action of the rays. This conception does not contradict the theory that leucolysins are present in the circulating blood. But one may regard these leucolysins as the products of secretion of macrophages emanating from the hemopoietic organs.—*Archives d'Eléctricité Médicale.*

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

TREPANATION NEOLITHIQUE, TRÉPANATION PRE-COLOMBIENNE, TRÉPANATION DES KABYLES, TRÉPANATION TRADITIONELLE. By Dr. Lucas Championniere. 131 pages, with 32 illustrations; paper. G. Steinheil, Publisher, Paris.

ARTERIOSCLEROSIS. By LOUIS M. WARFIELD, A.B., M.D. 220 pages; illustrated; cloth; price $2.50. C. V. Mosby Company, Publishers, St. Louis.

PHILADELPHIA GENERAL HOSPITAL REPORTS. Vol. VIII; 1910. Edited by David Riesman, M.D. 357 pages; cloth.

METROPOLITAN WATER AND SEWERAGE BOARD. Eleventh Annual Report. December 31, 1911. 244 pages; cloth. Metropolitan Water and Sewerage Board, Publishers, Boston.

LES PRODUITS BIOLOGIQUES MÉDICINAUX. By P. BYLA and R. DELAUNAY. 466 pages; cloth. Société de Editions Scientifiques et Medicales, Publishers, Paris.

ELECTRICITY IN GYNECOLOGY. By May Cushman Rice, M.D. 159 pages; illustrated; cloth. L. I. Laing & Co., Publishers, Chicago.

DIE GROSSSTADT ARBEIT UND IHRE HYGIENE. By Dr. B. Laquer. Vol. IX. No. 8. 30 pages; paper; price 1 M. Carl Marhold, Publisher, Halle.

KLINIK FÜR PSYCHISCHE UND NERVÖSE KRANKHEITEN. Vol. VII. No. 2. By Robert Sommer. 192 pages; illustrated; paper; price 3 M. Carl Marhold, Publisher, Halle.

DER GERICHTLICH-MEDIZINISCHE NACHWEIS DER WICHTIGSTEN GIFTE. By Prof. Dr. Hermann Hildebrant. 70 pages; paper; price 2 M. August Hirschwald, Publisher, Berlin.

CEREBELLAR FUNCTIONS. By Dr. André Thomas. 223 pages; illustrated; paper; price $3.00. The Journal of Nervous and Mental Disease Publishing Company, Publishers, New York.

FIFTH SCIENTIFIC REPORT ON THE INVESTIGATIONS OF THE IMPERIAL CANCER RESEARCH FUND. By E. F. Bashford. 94 pages; illustrated; paper; price 5s. Taylor & Francis, Publishers, London.

PRACTICAL EUGENICS. By WILLIAM J. ROBINSON, M.D. 93 pages; cloth; price 50 cents. The Critic and Guide Company, Publishers, New York.

DEUTSCHE ZEITSCHRIFT FUR CHIRURGIE. Festschrift. By Prof. TH. KOCHER. 818 pages; illustrated; paper. F. C. Vogel, Publisher, Leipzig.

THROMBOSER OG EMBOLIER EFTER APPENDICIT-OPERATIONER. By P. BULL. 92 pages; paper. Steen'ske Bogtrykkeri, Publisher, Kristiania.

SEXUAL IMPOTENCE. 4th Edition. By VICTOR G. VECKI, M.D. 394 pages; cloth; price $2.25 net. W. B. Saunders Company, Publishers, Philadelphia.

SYMPTOMS AND THEIR INTERPRETATION. By JAMES MACKENZIE, M.D., LL.D. 304 pages; cloth; price 7/10. Shaw & Sons, Publishers, London.

PELLAGRA. By STEWART R. ROBERTS, S.M., M.D. 272 pages; illustrated with 81 special engravings and colored frontispiece; cloth; price $2.50. C. V. Mosby Company, Publishers, St. Louis.

SURGICAL AFTER-TREATMENT. Second Edition. By L. R. G. CRANDON, M.D. 831 pages; with 264 original illustrations; cloth; price $6.00 net. W. B. Saunders Company, Publishers, Philadelphia.

COLLECTED PAPERS BY THE STAFF OF ST. MARY'S HOSPITAL (MAYO CLINIC). 603 pages; illustrated; cloth; price $5.50 net. W. B. Saunders Company, Publishers, Philadelphia.

Miscellany.

Gil Blas on High Living.—B. M. Randolph presents an extract from *Gil Blas,* the masterpiece of Lesage, the French novelist of the eighteenth century. The latter depicted in Dr. Sangrado a type both comic and serious, whose advice on the results of high living is practically in accord with present-day teachings, particularly in reference to the production of arteriosclerosis and premature senility.

"Away I went, therefore, for Doctor Sangrado," says *Gil Blas,* "and brought him with me, a tall, withered, wan executioner of the sisters three, who had done all their justice for at least these forty years. This learned forerunner of the undertaker had an aspect suited to his office: his words were weighed to a scruple; and his jargon sounded grand in the ears of the uninitiated. His arguments were mathematical demonstrations; and his opinions had the merit of originality. After studying my master's symptoms, he began with medical solemnity: 'The question here is to remedy an obstructed perspiration. Ordinary practitioners, in this case, would follow the old routine of salines, diuretics, volatile salts, sulphur, and mercury; but purges and sudorifics are a deadly practice. Chemical preparations are edged tools in the hands of the ignorant. My methods are more simple, and more efficacious.' 'What is your usual diet?' 'I live pretty much upon soups,' replied the canon, 'and eat my meat with a good deal of gravy.' 'Soups and gravy!' exclaimed the petrified doctor. 'Upon my word, it is no wonder you are ill. High living is a poisoned bait; a trap set by sensuality to cut short the days of wretched man. We must have done with pampering our appetites; the more insipid, the more wholesome. The human blood is not a gravy. Why, then, you must give it such a nourishment as will assimilate with the particles of which it is composed. You drink wine, I warrant you?' 'Yes,' said the licentiate, 'but diluted.' 'Oh, finely diluted, I dare say,' rejoined the physician. 'This is licentiousness with a vengeance. A frightful course of feeding. Why, you ought to have died years ago. How old are you?' 'I am in my sixty-ninth year,' replied the canon. 'So I thought,' quoth the practitioner; 'a premature old age is always the consequence of intemperance. If you had only drunk clear water all your life, and had been contented with plain food, boiled apples for instance, you would not have been a martyr to the gout, and your limbs would have performed their functions with lubricity. But I do not despair of setting you on your legs again, provided you give yourself up to my management.' The licentiate promised to be upon his good behavior."—*Old Dominion Journal of Medicine and Surgery.*

The Collection of Disputed Claims.—T. F. Reilly notes that in most States claims for services must be filed within two years. The physician must prove that he has been employed and that his services were accepted. Parents and guardians are responsible for their children under age. One must show in court the date of visits, and the amount should be charged up each day under the visit mark. This is not always insisted upon, but it is a safe thing to do. When the patient has died and has left an estate the physician should file the bill with the executors, who will arrange for its payment. If the patient had no relatives or executors the claim should be filed with the public administrator, who will pay the physician if there is anything left after the undertaker's bill is paid. Employers are not responsible for service rendered to employees, unless they personally order it. When the physician has attended a patient through his last illness, and after death the friends come to the doctor with an insurance certificate to be filled out, the latter should make up his mind if the friends are likely to pay the bill. If not he should take the certificate to the undertaker and both of them can arrange to be paid as soon as the company pays the claim. In some instances the physician can find out from the company the precise time when they will settle and he can then be present. "No patient is too poor to treat. Do not send the poor patient or any other one to a dispensary in order that he may save the expense. Get the experience and the gratitude yourself. No patient who goes to the hospital or a dispensary ever afterward has the same regard or respect for you as before, because there the personal worship or idolatry is lost, and he realizes that other men are just as clever as you are, or perhaps other patients that he meets will convince him of the superiority of some one else. Whatever the reason may be, he never has quite the same confidence in you. Once a patient gets free treatment he is like the rest of us who, when we once get free tickets for a theater or railroad journey, never afterward feel like paying for similar services. If you can do absolutely nothing for the patient, send him to one of your young friends who is struggling to get experience in that particular specialty. He will be glad to treat him for the experience, or for a very small fee. The patient will appreciate it as a favor."—*New York Medical Journal,* October 26, 1912.

The Physician in World Politics.—One of the most noteworthy features in the present era of political reconstruction is the increasing prominence of the physician as a leading figure in world politics. This has been exemplified in the recent upheaval in China and is evidenced in the present work of reconstruction in Portugal. In both cases it seems to be recognized that the physician's experience with the ills of humanity gives him a peculiar fitness for larger service to the State. In Portugal, not only were the foremost revolutionary leaders physicians, as were the principal officers of the provisional government, but the present leaders of the most influential political parties are medical men. The former Minister of Justice of the Provisional Government of Portugal, Dr. Affonso Costa, now heads the Democratic party which includes the Socialist and laboring groups. This party includes half of the senators and deputies in the Portuguese Parliament. Dr. Costa is the author of the Church and State Separation Law and other measures. Dr. Antonio José d'Almeida, another medical man, is chief of the Evolutionists, the conservative element in Portugal. Dr. Almeida controls the "extreme right," as distinguished from the extreme left, or ultra-radical Democratic party headed by Dr. Costa. The Unionist party, a compromise group halfway between the extreme radicals and the ultra-conservatives, is headed by Dr. Brito Camacho. These last two parties, with the Independents, the political organization of the secret society, "Carbonario," comprise the conservative element, which is at present in control. The Portuguese Cabinet, however, is a coalition, and includes three Democrats, two Evolutionists, and two Unionists.—*Medical Review of Reviews,* September, 1912.

THE PSYCHOLOGY OF THE GAMBLING HABIT.

A STUDY OF SUSPENSE IN GAMING, THE DRAMA, AND THE EXPERIMENTAL SCIENCES.

By J. LEONARD CORNING, M.D., LL.D.

NEW YORK.

THE spell wrought in the mind by hazard is as old as humanity itself. Whether called into being by battle, the stock market, or the roulette table, the enchantment remains the same. When asked what were his emotions on the eve of an impending battle, an officer of distinction replied that they were "Precisely the same as those I used to feel when laying a tremendous stake." The essential similarity between the feelings aroused by the more strenuous phases of stock speculation and those called forth by games of hazard has been frequently pointed out. Indeed the notion has long since obtained a footing in the idiom of the street. Games of hazard seem to be indigenous among all races. Neither savagery nor civilization has been proof against their wizardry. In India, Egypt, China, Africa; in Greece, Rome, Germany, and England; in France, Russia, and even the United States, games of chance have never lacked for votaries.

At various times, and under incitement more or less obscure, gambling has spread like a contagious insanity throughout an entire country, infecting all, regardless of class, sex or condition. During the advanced decline of the Roman Empire, gaming was universal among rich and poor alike. At various times, extraordinary exacerbations of the passion have occurred among the French; and in Germany, both in ancient and modern times, gambling, though less universally indulged in, has been widely practised. In England the propensity is traceable from the most ancient times to our own day. The stakes among the wealthy were frequently enormous; while among the poor the amounts risked, though actually less, were proportionately greater. That the moral damage to individuals and to the community as a whole was great in all countries, is attested by numerous reliable commentators, some of whom have been at some pains to point out the analogous evils following outbreaks of unbridled speculation. Nor were the judicial and legislative authorities lacking in appreciation of the malign influence exerted upon society by an excessive gratification and a useless and degrading application of the instinctive love of hazard. Laws of the most stringent character were enacted against gaming both in England and the more important countries of continental Europe; but the fact that these laws have been powerless to stamp out the practice is the best proof of how firmly the propensity is rooted in the instinctive life of the race.

Not much has been written on the purely psychological phases of gambling. Most of the literature, widely scattered and some of it difficult to procure, deals largely with the historical and anecdotal features of the question. Neither space nor the purposes of the present writing permit an extensive gleaning from these sources. Enough—if we are to credit the chronicles—that men have always disclosed a willingness to wager almost anything at the gaming table; and that women—so runs the story—have lagged little if at all behind their male companions, staking, when hard pressed, even the more essential parts of their apparel on the turn of a card or a throw of the dice.

What is the underlying psychology of phenomena of this kind? Certainly the question is by no means answered by assuming the desire for gain with a minimum of effort to be the sole motive, as is commonly though not invariably done. Avarice no doubt is constitutional, as it were, with some persons, and this quite irrespective of their economic situation in the world. To such individuals the prospect of laying hold of their neighbor's possessions even at the risk of parting with their own, involves, to put it gently, a unique and considerable fascination. It was of these—of their sordid faces, of their covetous gestures, of their glowering, avid eyes—it was of these gentry, no doubt, that Aristotle was thinking when he referred to gamesters as no better than thieves. Were these and their congeners the only victims of the caprice of hazard, society could perhaps afford to let them go their way unmoved. Unfortunately, there are other specimens far from ignoble, many of them, though for the most part not less vehemently infatuated, who swarm about the gaming table.

What—being in many instances neither predatory nor yet very poor—what urges these people to the gaming table, and what keeps them there? Surely inordinate greed is not responsible for their coming, nor can it be held to be the sorcery which enchains them. Where, then, lies the witchery? Some writers have found the explanation in the excitement caused by the alternation of hope and fear. Nor can it be denied that this alternation is the important factor in games of hazard. Yet it is necessary to remember that still other forces are at work; that, in a word, we have to do not only with hope, but fruition; not only with fear, but with loss and sometimes despair. Here the affective contrast is as wide as could well be imagined. And, as if this were not enough, the widely disparate moods, obedient to the capriciousness of chance, are, as already intimated, rapidly alternated, victory following defeat and vice versa, so that a new composite erethism is engendered, an erethism which knows neither respite nor repose. To help to an appreciation of what is here implied, the writer ventures to introduce a diagram. (Fig. I.)

Is there any similarity in the manner of its pro-

duction between suspense as it is met with in gaming, and suspense as it occurs in certain of the Arts —the Drama, for instance? A moment's consideration will show that in certain respects a resemblance of this kind is certainly traceable. Take melodrama—the old kind—replete as it is with

Fig. 1.—Diagram showing suspense curves in gambling. Note that the height is somewhat greater than the depth, and that there is no logical termination, the erethism continuing after cessation of play.

thrills and "gory interjections." Here plot is everything, the delineation of character but a subordinate concern of the playwright. The sympathetic element represented, let us say, by hero and heroine, and the antipathetic by the villain, are aggressively apparent. There are no half people; all are either devils or angels. The hero desires the heroine in marriage; the villain feels the same way—entrance of the exciting force. Were the hero, however, to realize his wish too easily or too quickly, there would be little drama and less suspense. Obstacles, or subsidiary actions (machinations of the villain or his friends, etc.), are accordingly introduced. Thus by play and counter-play the action of the play is retarded, suspense is maintained, and excitement augmented. Neither the hero nor the villain is allowed the upper hand for long. For a space, the hero seems about to triumph; then down he goes, and up goes the villain. And so the process is repeated and the play progresses, arousing and maintaining in the spectator a kind of palpitating suspense—a sort of see-saw of uncertainty.[1] Such tension, however, nature being what it is, cannot be indefinitely maintained; and hence in due course the hero runs away with the heroine (climax); the villain being unable to catch him, is himself caught and comfortably hanged; while the hero and heroine, as befits the truly virtuous, are duly amalgamated (dénouement).

In an entertaining little book on the elements of dramatic construction, published more than twenty years ago,[2] Hennequin observes that "The most important means of arousing interest (in the drama) is suspense. Keep a listener in doubt as to what is coming ,and he cannot help but listen. Suspense is the nervous system of the drama. In some form or another it must exist throughout the entire progress of the story. At various points of the story, generally at the close of each act, it may be partially relieved; but it must always be done in such a way as to give rise to new suspense, or to leave one or two particulars still unsettled. Not until the last moment of the story should every item of doubt be cleared away."[3]

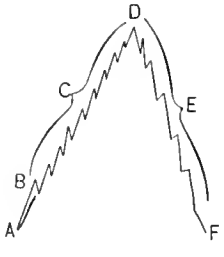

Fig. 2.—Diagram showing suspense in a play with a single major climax. A, beginning of the action; AB, exposition; C, growth (play and counter-play) suspense; D, climax; E, fall; F, dénouement.

The appended diagrams (Figs. 2, 3, 4) show the management of suspense in plays of one or more climaxes.

While the morbid craving for a maximum of excitement with a minimum of effort, confirmed as it is by habit, plays a conspicuous—nay, the chief

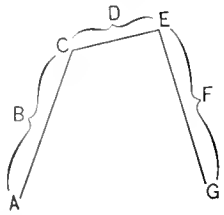

Fig. 3.—Diagram showing suspense in a play with two climaxes. A, beginning of play; B, D, suspense (B, play and counter-play to first climax C; D, play and counter-play to second climax, E); F, fall; G, close.

—rôle in the bewitchment of the gamester, it can scarcely be denied that abnormally emotionalized ideas of success exert at least a contributory influence. Hence the suspense curve of gambling is somewhat greater in height than in depth. (The writer begs to refer once more to Fig. I.) Confirmation of this view is afforded by the fatuous attempts of those who play for low as well as high stakes to establish a "system" or theory of the game whereby success shall be rendered more certain. To the average outsider, untrammeled by the fascination of gaming and alive to the impossibility of fore-reckoning the infinite vagaries of hazard, their efforts seem to betoken a singular obliquity of mind. This tendency to rationalize where premises are quicksilver and logic thrown away is a characteristic peculiarity of the gamester. Thence arise quixotic feelings of confidence, intensified, perhaps, by various superstitions, of which gamesters are known to cherish a variety; and these in turn tend further to increase the height of the suspense curve.

Among such superstitions, "Rouge et Noire"[4] gives the following: "To turn your back on the moon when playing for money portends ill luck; to lend money is unlucky; to play on borrowed money is unlucky; playing with money first laid on the altar Christmas night is lucky; some gamblers believe that they can cheat luck by going from table to table or playing at certain intervals. . . . The approach or touch of a hunchback is held to be a sign of luck." Among savages, whose addiction to gaming has already been referred to, the belief in luck is apparently universal, and to gain its countenance they have recourse to philters, fasting, and

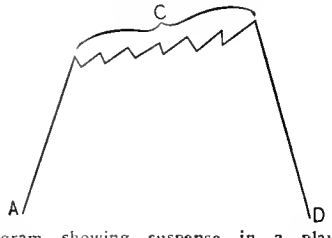

Fig. 4.—Diagram showing suspense in a play with several climaxes; A, beginning of play; C, succession of climaxes, arranged in rising gradation so that suspense is progressively increased; D, dénouement.

an astonishing variety of ceremonious cajoleries.

Of contributory effect in heightening excitement in the gamester should be mentioned the magnitude of the stake, and the influence of its loss or gain on his welfare and future destiny. The importance of this element is obvious, and has been accentuated

by even the most superficial writers on games of chance. Not so fully appreciated is the erethistic influence of a neurotic temperament. Over and above the predisposing rôle played by such a temperament in heightening the excitement of gaming, the present writer is convinced that to

FIG. 5.—Suspense curve in a series of experiments undertaken for the solution of a major problem. There is no progressive rise (in suspense), the only increase in height being at the close. Failure would entail a corresponding fall.

it is largely to be charged those more extreme manifestations of the gaming impulse that so frequently result in the permanent undoing of the subject and the humiliation and misery of his dependents. Still more disastrous is the craving when it develops in those already afflicted with some form of neurotic derangement. Danville and Sollier[5] have published two instances of this kind, in which the presence of a neuropathic element was easily made out. In the first, the impulse to play was comparable with an hysterical attack; in the second, with the morbid craving of dipsomania. Here, the passion to play assumes the dimensions of true mania; the motiveless, irresponsible, and at times furious excitement of the subject impressing even those without psychiatric knowledge as essentially insane. It may be noted in this connection, that the gaming habit is not infrequently associated with paranoid conditions, a fact overlooked or but slightly accentuated by most writers.

From this commentary we may pass to the consideration of a group of activities in which, while at times there is considerable suspense, great demands are made upon perception, reason, inductive and deductive, and imagination as well. Nowhere are these activities more in evidence than in the experimental sciences, including invention and, to some extent, original work in the domain of astronomy and the higher mathematics. Is there anything at all comparable with the suspense so characteristic of gaming and that met with in those who devote themselves to these disciplines? With due allowance for temperamental differences, and excluding for purposes of comparison those pursuits which, while they imply some power to observe, require a minimum of interpretative subtlety, it may be granted that a certain degree of analogy is really traceable. That a long period of brooding and experimentation undertaken for the solution of a considerable problem may at times be accompanied by a high degree of suspense, is abundantly attested by the history of discovery and invention. Obviously the importance of the problem; the success and failure of the individual experiments undertaken for the purpose of its solution, and the rapidity with which one experiment follows upon another, will largely determine not only the degree but, to an extent, the character of the emotional erethism. (Figs. 5 and 6.) But conceding this as a general statement, it is not to be forgotten that in a certain proportion of research work there will be time sufficient for more or less recovery from the excitement, pleasurable or painful, of each experimental venture; and time is an all-important element in the rehabilitation of the emotional mechanism. The suspense curve will, therefore, be undulating rather than abrupt.

It is precisely in this that the suspense of experimentation and invention differs so widely from that of gaming, in which so little time elapses between the separate coups that recovery, even to a limited degree, is impossible. Moreover, there is the further difference that in experimental work there is apt to be a definite conclusion; either the end is attained, or the problem is for the time being, or perhaps definitely, abandoned. A logical conclusion, as already pointed out, and consequently repose, is also attained in the drama; and there is besides a considerable lapse of time between the separate parts of the action. Nothing of the kind, of course, is possible in games of pure hazard; there is no logical sequence, neither are there any intermissions, and hence in the nature of things there can be no logical conclusion. That the inveterate gamester carries his excitement away from the table, has it with him in fact most of the time, is therefore hardly the riddle that it is popularly held to be. Still, the very admission that despite his losses he returns again and again, carries with it the suggestion of an addiction, a compelling force, a deranged mechanism; so that, recalling the physiology of the emotions, as we now understand it, one is inevitably moved by a desire to win to a conception, however provisional, of the morbid physiology implied by the habit of the gamester.

While in the present state of knowledge attempts in this direction can scarcely be expected to rise much above the level of tentative approximations; still, something, the writer is fain to believe, may be done to satisfy the desire to rationalize, and this without any very glaring violation of the canons of common sense. A glance at the opinions now prevailing regarding the physiology of the emotions will help in an attempt of this kind. Two principal theories, each having advocates more or less, should be considered. According to the first and older conception, the mind (brain) "feels" in a definite way immediately upon excitation, whether from without or within. Only subsequently does this "feeling" (emotion) manifest its presence by purely nervous phenomena (discharges). On the other hand, it is maintained, notably by James and Lange, that the body itself reacts primarily in a definite way to a given stimulus; that the mind becomes aware of this bodily perturbation ("feels it"), and that this feeling, whether of tension or relaxation, is the emotion. For, as James observes, "If we fancy some strong emotion, and then try to abstract from our consciousness of it all the feelings of its bodily symptoms, we find we have nothing left behind, no 'mind stuff,' out of which the emotions

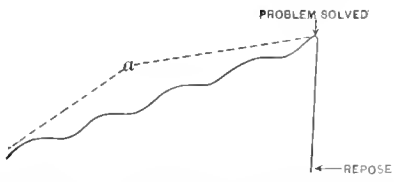

FIG. 6.—Suspense curve in a series of experiments, each of which eventuates in an obvious step towards solution. The progressive rise of the suspense curve is shown at a.

can be constituted, and that a cold and neutral state of intellectual perception is all that remains."[6]

If it be granted that the position of James and Lange is well taken, and in the writer's opinion it is open to fewer objections than any other, we may conceive the genesis of an emotion to be somewhat

as follows: A sensation, auditory, visual or what not, or a perception, or an idea, gives rise in the brain (cortex) to an impulse which is disseminated centrifugally to the motor apparatus. Muscular contraction ensues, and it is the sensations due to contraction of the muscles, transmitted to the sensorium by the centripetal system of nerves, to which vasomotor, visceral, and other sensations are added, that give rise to the emotion.[7]

Now, as already sufficiently accentuated, the emotions in gaming are aroused or rather racked in a unique and extreme fashion. That in time the affective functions, motor, vasomotor and sensory, must inevitably become erratic, disharmonized, seems a wholly warranted conclusion. Here, then, are all the psychoneural elements necessary to the establishment of addiction; and it is a matter of surprise to the writer that an implication so apparent should have been so widely overlooked.

From the foregoing considerations, it is easy to understand why those who are the chronic victims of the gaming habit are so little fitted for the routine that enters so largely into the activities of common life. This inefficiency of the gamester has long been recognized; and his restless, feverish nights, with their succeeding days of futile, maundering wistfulness, have provided texts for the diatribes of the moralists. Not much, in view of history and the practically universal love of hazard, can be accomplished by such fulminations. Nor has drastic legislation, however much it may have helped to mitigate it, sufficed to suppress the gaming evil. Of more promise, perhaps because more rational, would be a systematic attempt to spread abroad a knowledge of the essentially morbid nature of the gaming habit; while at the same time frankly recognizing the legitimacy of the love of hazard when properly applied, as in the building up of new industries, war, games of skill and the like. A considerable approval of the drama of the better sort should likewise be expressed, since through its mechanism both a logical progress and a logical ending are made possible, while at the same time suspenses is maintained without undue racking of the emotions.

While this is doubtless true enough, it is nevertheless not to be forgotten that however much the intellect and the imagination are concerned in the making of a play, its enjoyment by the spectator is relatively a passive one. Quite the opposite is true of the experimental sciences, the pursuit of which makes a constant demand upon the active resources of the mind. Here, too, as already intimated, there is suspense, but without those sharp alternations so characteristic of gaming. There is, moreover, the further merit of a possible enlightening or useful outcome, the consciousness of which cannot fail to bring its own meed of satisfaction. Unfortunately, though the present age has been aptly characterized as "the scientific age," science and invention are not for all; nor in view of the average make-up of human intelligence, are they ever likely to be so.

From the foregoing analysis, it may be fairly assumed that—

1. In its more extreme manifestation, the gambling habit may disclose many of the attributes of a true psychosis.

2. This is especially true of the habit as observed in neurotic individuals, or those in whom the psychotic impetus is enhanced by paranoid or hysterical coincidences.

3. While many persons are led by a desire for diversion to indulge from time to time in games of hazard, there is always more or less danger, especially in the case of idle, excitable, unbalanced persons, of the gradual establishment of addiction.

4. It is the rapid alternation of opposing emotions that provides the chief suspense and major excitement of gaming. Herein is likewise to be found the source of its chronic allurement. A contributory though subordinate enhancement of suspense is discernible in the stake.

5. The suspense curve in the drama is less sharp by far than in gaming. In other words, there are fewer alternations, and consequently there is less racking of the emotions in a given length of time in the former than in the latter.

6. Of original work in the experimental sciences, it may be confidently stated that while suspense is an ingredient far from insignificant, it is brought about not by rapid affective oscillations, not by an emotional riot of to-and-fro as in gaming, but by far more gentle undulations than even those met with in the drama.

7. Since the suspense in games of pure hazard is brought about in an arbitrary manner, without any noteworthy participation of the intellect; and since, moreover, habitual gaming tends to engender distaste and even to unfit its votaries for concentrated mental effort, the practice is to be condemned on psychopathological grounds, if for no other reason.

8. While the love of hazard appears as an indigenous and even highly useful quality in the history of the race, nothing is more certain than that from time immemorial it has been shunted, as in gaming, from its true sociological intent.

9. The gaming habit in its more exaggerated forms, especially when complicated by neuropathic adjuncts, is rather an affair of psychopathology than of morals.

10. Disssemination of knowledge regarding the essentially morbid nature of the gaming habit, coupled with a dispassionate and explicit account of its inroads on mental efficiency, should help, it would seem, to a rational prophylaxis.

Much has been said and written about the facial expression of the gamester, and not a little of this commentary has crept into fiction. Thus we hear of the "gambler's face," implying thereby a certain "hardness" of visage; a hardness which, however apparent, can nevertheless scarcely be regarded as an exclusive adjunct of those who habitually indulge in games of hazard. Still, it cannot be denied—and this is an interesting and revealing circumstance—it cannot be gainsaid that there is usually a vast difference in facial expression between those in whom suspense is brought about by the drama or the pursuit of the experimental sciences, and those in whom it is produced by gaming. And more striking, it may be observed parenthetically, than even this disparity, is the contrast in the expression of the face between those who gamble and those whose efforts are directed to literature and the arts.[8]

Facts of this kind are their own commentary.

THE PRO AND CON OF MAINTENANCE OF THE RETRO-AURICULAR OPENING AFTER THE RADICAL MASTOID OPERATION.*

BY SEYMOUR OPPENHEIMER, M.D.,

NEW YORK.

IN the majority of cases of chronic suppuration of the middle ear associated with mastoid disease that require operation, no question arises as to the advisability of closing the retro-auricular incision, for the conditions present are such that it is to the best interests of the individual that this be done, but there are a certain number of cases associated with varied and often extensive pathological changes in the temporal bone, in which the question of maintaining an opening behind the auricle must remain debatable, and it is these infrequent cases that it is desired to discuss here.

Many German otologists seem to prefer the permanent posterior opening in nearly all instances of the radical operation, while a somewhat small number maintain drainage in this way for an indefinite period until the parts have become covered with healthy epidermis and no evidence of a recurrence of the suppuration is discoverable. Others endeavor to obtain primary union of the incision in practically all cases and treat the osseous cavity through an enlarged external meatus. A problem like this, however, cannot be answered in a general manner, nor is any one method applicable to all classes of cases, for in all instances the individual conditions present must be carefully considered and the determination to maintain a more or less permanent postauricular opening, or, on the other hand, an immediate closure of the operative field must be determined by the changes found in the temporal bone at the time of operation.

While it is highly desirable to obtain primary union after mastoid evisceration, yet this is not always possible on account of the difficulty of obtaining precise information as to the complete removal of all diseased tissue, but in the majority of cases modern plastic methods, adapted to widening the cartilaginous external canal, allow of the after-treatment through this channel and therefore the incision behind the ear can be closed either primarily or within a short time after the mastoid operation. In a general sense, however, primary union in contradistinction to the maintenance of a permament postauricular opening, is indicated in the presence of carious osseous tissue and profuse development of granulations in the mastoid interior, when one is sure that all these diseased structures have been removed by whatever operative procedure has been employed and when the loss of bone substance does not involve large areas in the direction of the occiput or does not extend far upwards in a superior direction. The progressive development of these various plastic methods as just mentioned, has released many cases from the necessity of having a permanent auricular sinus, as in those instances where at the time of operation the tissues of the posterior canal wall can be used to line a portion of the newly formed osseous cavity in the temporal bone, so that the production of a large meatus is accomplished and this orifice can be maintained of sufficient size thereafter, the necessity for the maintenance of the former condition with its many obvious disadvantages can be dispensed with.

Undoubtedly, therefore, as the result of two factors, that is the development of methods more closely approaching the ideal in the absolute removal of all the diseased tissue in its entirety and the still higher development of plastic methods upon these tissues, the necessity for the permanent opening even in a very small number of instances will be still further eliminated and it is to be hoped that in the future this question will not arise even in severe cases of cholesteatomata. The main disadvantage of the retro-auricular opening for the patient is from a cosmetic aspect, as in all cases it is most unsightly and especially so immediately following operation, and while at a later period considerable contraction of the soft tissues takes place, yet at the best it is far from being as inconspicuous as the scar obtained in other ways. In men this is especially so, as it is impossible for them to cover at least partially the opening in the bone by their hair.

A marked disadvantage from a more practical point of view is the greater length of time required in healing the parts by this method, so that the patient is kept from his occupation often for a period covering many weeks or months, and the bandage must be worn for a much longer period of time than is the case when the mastoid wound has been sutured and early union has taken place. From the economic aspect, this procedure can in no wise present any advantages over that of immediate closure of the wound and treatment following through the canal, but other sides of the question must be considered and often what may be designated as the vital necessities of the patient must for the time being outweigh any other disadvantages.

As at the present time the main necessity for the maintenance of the posterior opening is in those extensive instances of diffuse cholesteatoma of the mastoid region, where it is seemingly impossible at times to remove the proliferating epithelial masses in their entirety, as they are intimately associated with the microscopic recesses in the osseous tissue and it would seem that in order to obtain a permanent cure in such cases, the post-auricular opening is a necessity.

Many otologists, especially the Continental ones, believe that the opening of the exposed middle ear and its accessory cavities should be maintained until the osseous parts are covered with a healthy cutaneous lining. Burnett, on the contrary, is of the opinion that this is not necessary when the

* Presented at the seventeenth annual meeting of the American Academy of Ophthalmology and Otolaryngology, at Niagara Falls, Sept. 23, 1912.

cholesteatomatous cavity is not of very large dimensions, and he says it is more rational thoroughly to remove the cholesteatoma and heal the bone cavity from the bottom without a permanent fistula. Vulpius believes it neither desirable nor necessary for the cure of this intractable and often dangerous affection to retain a permanent opening, as nature never indicated such a procedure; and Jansen as the result of a very large experience, closes the wound when there is an associated cholesteatoma in the mastoid even though lateral sinus and dura mater are exposed in order that the patient may the sooner return to work.

On the other hand, equally competent observers believe that the reverse of this procedure is the proper treatment in cholesteatoma. Politzer states that the opening should be maintained in certain cases, but he does not think that the opening can prevent the regrowth of the cholesteatoma in those parts of the middle ear not visible through the fistula. Schwartze believing that this affection can be permanently relieved only by the maintenance of a broad fistula behind the auricle, as in nineteen cases of this disease, fifteen treated by maintaining the retro-auricular opening entirely recovered, while the other four cases not so treated broke down and the epithelial proliferation redeveloped as soon as the wound was closed. The findings of Reinhard are especially valuable in this connection, as his experience showed that in cholesteatoma of the antrum, if the opening is maintained by implantation of the integument of the mastoid process into the wound, no return of the disease would ensue, while in those cases where such an opening is not maintained, the affection will develop again and further endanger the life of the individual.

The time when the posterior opening should be closed in such cases of cholesteatoma where a so-called permanent opening has been maintained, will depend entirely upon the condition of the epithelial lining of the eviscerated cavity, for should the least trace of the affection be in evidence, it will be apparent that to close the wound whether it is of several months' or several years' duration in the presence of the heaping up of epithelial masses, would endanger the entire result of the original operation. It is essential therefore in determining when such surgical procedures should be adopted for closing the retro-auricular opening that all traces of cholesteatomata or diseased tissues whether osseous or otherwise, should have entirely disappeared and remain absent for several months at least before such measures can be applied.

As the natural tendency of soft tissues over an osseous cavity is to contract and diminish the size of the opening, it is essential that much care be exercised in maintaining a large opening commensurate with the size of the underlying bony cavity, and this can be accomplished by frequently packing the mouth of the cavity with gauze, in order that epithelial development be retarded or prevented at the edges of the wound. If this be followed out in the majority of instances so that epidermization of the edges of the wound is prevented, it can be maintained at any size required for an indefinite time and when it is desired to close the wound in order to obtain a better cosmetic effect, by omitting the tampons, it will more or less rapidly close in many instances without having recourse to one of the various plastic procedures used for this purpose.

A more or less permanent opening in the mastoid process is indicated as already shown, when cholesteatoma is present in extensive areas in the temporal bone so that large osseous sections are destroyed and a large cavity extending in a posterior and superior direction results, and also when the dimensions of the antrum have been markedly increased by disease processes in the same direction. While if there is a very large loss of tissue in the mastoid process in its vertical portion, as the result either of cholesteatoma formation or of other destructive processes, other things being equal, a permanent fistula behind the auricle will be an advantage in more rapidly healing the parts than if an attempt be made to obtain early closure of the soft tissues over the mastoid process. The maintenance of a fistula behind the auricle for an indefinite length of time is of great importance when, in conjunction with chronic suppurative otitis media, symptoms are present indicative of an intracranial complication so that it is necessary as part of the radical operation to expose either the sinus or the cranial dura mater or both, as under such conditions primary closure of the wound is, of course, inadvisable for fear of subsequent infection of these important tissues; but when the danger of such infection has passed, it may then be advisable to close the mastoid wound by freshening the edges of the soft structures and suturing.

When there are any indications of the development of perichondritis of the cartilage of the external auditory canal, so that it will interfere with the formation of flaps to aid in filling in the large osseous cavity, it is wisest, for a time at least, to treat the cavity through the patulous mastoid opening instead of closing it at the time of the primary operation. It has been the custom of Grunert and Zeroni in performing the radical operation, to allow the post-auricular incision to remain open at first, so that in case furuncles or perichondritis of these parts develop, with the consequent cicatricial and inflammatory narrowing of the canal preventing proper treatment of the osseous cavity, careful inspection and care could be given by way of the mastoid opening and thus obviate the necessity for subsequent reopening should such not infrequent complications ensue.

In various affections of the middle ear and mastoid which partake of the nature of specific granulomata and are accompanied by more or less extensive destruction of both the soft tissues and especially the osseous structures, such as are seen in tuberculosis and in the so-called lymphatic subjects, the maintenance of a permanent opening behind the auricle is undoubtedly indicated in many of such individuals who come to the radical operation. The rationale of such a procedure must be obvious, for while the aim of the operation should be to remove the diseased structure in its entirety yet such an ideal can be but rarely accomplished from the very nature of the local pathological changes present in the individual case and especially from the peculiar lack of resistance on the part of the patient which allows of the progressive and subsequent destruction of tissues. For these reasons, it becomes necessary to allow an exit which will in no manner obstruct free drainage for the discharge of infected pathological products, and as this object cannot be obtained in a satisfactory manner even through an enlarged external auditory canal, it is essential that the post-auricular opening be maintained for this purpose.

In the majority of cases of chronic suppurative

otitis media uncomplicated with sinus or intracranial involvement in which the mastoid process is also involved to a greater or lesser extent, the maintenance of a permanent aural opening is, in my judgment, seldom indicated, as the diseased tissue can be thoroughly removed and the important subsequent treatment carried out through the widened external aural canal in a most satisfactory manner, as has been shown by many operators.

In a series of eighty-three radical operations the posterior opening was maintained in five. These cases recovered with an auditory canal larger than before the operation, which permitted free inspection and treatment of every portion of the large osseous cavity. In this connection the statistics of Holmes are of practical interest as in 115 operations which he performed he did not find it necessary to leave in any instance a post-auricular opening.

In such cases as it is desired to maintain a permanent retro-auricular opening, the operation of Passow presents decided advantages, as the healing of the wound cavity seems to be rather more rapid than by other methods and there is a decided freedom from recurrence of the suppuration if the steps of the operation be carried out with proper technique. It also presents the advantages of allowing free access to the middle-ear cavity for purposes of observing the changes that are taking place and for necessary cleansing; and of considerable value is the fact frequently noted, that free access of air is obtained, so that the parts are kept in as dry a condition as possible. In carrying out this procedure, the usual radical operation is performed and all the diseased structures are carefully removed; into the cartilage of the external auditory meatus a right-angle slit is then made with a sharp, narrow knife and the quadrilateral flaps thus formed are stitched into the bone cavity so as to form a covering for its ceiling. A quadrilateral flap of sufficient size is then dissected up from the cutaneous covering of the mastoid process behind the auricle and is turned into the osseous cavity so as to form a dermal lining for its floor, so that large areas of epithelial covered tissue are at once placed in the cavity and, if the conditions are favorable, in a surprisingly short time the cavity becomes covered with a dry, non-secreting epidermic layer of tissue.

It is especially in chronic suppuration that Passow recommends this operation, as by leaving the free opening behind the ear and by stitching the skin flaps deep in the osseous cavity, complete epidermization is soon obtained with a cessation of the suppuration. Of course, as with all more or less permanent fistulæ behind the auricle, this operation also possesses decided disadvantages, but these should be carefully considered in the individual case, and before any procedure is carried out it is essential that all sides of the question be most carefully considered. The disadvantages of the Passow operation are those common to all such procedures, the most conspicuous being the disfigurement produced, but in this procedure this is not as marked as in some other operations for the same purpose, as the opening contracts during the after-treatment and finally becomes slit-like in character rather than a large oval opening, becoming oval or round in shape only when the auricle is pulled well forward; and at any time, when so desired, it can readily be closed by a plastic operation.

On account of the disadvantage produced by the disfigurement of any large opening behind the auricle, it should be closed as soon as is consistent with the cessation of pathological changes within the osseous cavity.

At the same time the cavity should be under observation for a sufficient length of time until one is convinced that there is not the slightest evidence of heaping up of epithelial masses in any of its parts and that the slight exfoliation that often takes place can be as easily removed from the enlarged meatus as it can from the post-auricular opening.

45 East Sixtieth Street.

EFFECT OF PRESENT PREVENTION ON THE SPREAD OF CONSUMPTION.

By THOMAS J. MAYS, M.D.,

PHILADELPHIA, PA.

It seems that the extensive measures which have been put into active force during the last ten or fifteen years, with a view of stamping out pulmonary consumption, have been in operation long enough to give some rational account of their influence on the spread of this disease. With the object, therefore, of giving a fair and impartial interpretation of the effects of this movement, the writer, through the liberal generosity of the health departments* of the most populous cities of this country, has been enabled to collect a large mass of statistics bearing on the progress of this disease, and from this it is believed that certain well-defined conclusions may be drawn in regard to this problem.

The cities which are comprised in this list are New York, Chicago, Philadelphia, Boston, Buffalo, St. Louis, Baltimore, Pittsburgh, New Orleans, Milwaukee, Cincinnati, Cleveland, Louisville, Washington (D. C.), Providence, Indianapolis, Reading (Pa.), Springfield (Mass.), New Haven, Worcester, Hartford, Haverhill, Nashville, Richmond, St. Paul, Lowell and San Antonio (Texas), in all embracing a population of about 16,000,000. These statistics will be presented in two tables, which give the dates of the enforcement of disinfection measures and the per mille decrease or increase of the death rate of consumption for each city, before and after the introduction of these measures. The first table includes those cities, the records of which cover a period of thirty-seven years from 1875 to 1911, while the other includes those which only cover periods varying from eighteen to thirty years.

The Normal Diminution Rate of Consumption.—In analyzing statistics of this disease, it is important to bear in mind the cardinal point that no estimate of its death rate is worth the paper on which it is written, unless the fact is recognized that pulmonary consumption has been as a rule gradually diminishing in probably every city from its earliest record to the present time, and long before the current preventive measures had been called into existence. In other words, its history shows that its death rate declined independently of any specific preventive measures, chiefly because of improved general sanitary conditions brought about by wise legislation. Let us inquire, then, into the status of this normal reduction rate of consumption before the prevention measures of the present era came into play, as indicated by the statistics of the various cities which are brought under consideration. Before the year 1894 little, if anything, had

*To these the writer's warmest thanks are due for their kind interest and prompt responses.

been done in this direction. Hence, by dividing the records of all those cities which extend over the whole thirty-seven-year period, and which are thirteen in number, into equal parts (taking 1893 as the central year, as has been done in the following table) the first half will demonstrate the diminution rate in the ante-prevention period, which is called the normal rate of decrease; while the second half covers the time during which the prevention measures were in active operation, and this period will show whether the latter has had any perceptible power to accelerate the normal diminution rate, or not. This differentiation in the diminution rate of consumption before and after the year 1893 is shown in each of the thirteen cities in the following table:

TABLE 1.*—STATISTICS OF CITIES COVERING 37 YEARS, FROM 1875 TO 1911.

Names of Cities	Years in which Prevention Measures Were Begun to Be Enforced	Normal Diminution Rate per Thousand in First Half of Period (From 1875 to 1893)	Death Rate per Thousand in Second Half Period (1893-1911) When Preventive Measures Were in Active Operation
1. New York	1894	25—	29—
2. Chicago	1902	13—	2+
3. Philadelphia	1902	16—	16—
4. Boston	1900	24—	32—
5. Buffalo	1900	36—	6—
6. New Haven	1901	26—	19—
7. Reading	1905	22—	40—
8. Providence	1905	17—	36—
9. St. Louis	1905	23—	17—
10. New Orleans	(not given, but very recent)	22—	14—
11. Washington	1908	34—	17—
12. Cincinnati	1906	14—	3—
13. San Antonio	1909	17—	35—
Total		289	262 Net increase of 27 per mille

*The difference in the death rate between the first and second half of the whole period in each city is obtained by getting the average death rate of the first seven years (1875-1889); that of the middle seven years (1890-1896); and that of the last seven years (1905-1911). The difference between the first and the middle average expresses the increase or decrease in the first half, and the difference between the middle and the last average basis expresses the increase or decrease in the second half. The minus (—) sign indicates a decrease, and the plus (+) an increase. The same principle is followed in computing Tabel II, although on account of the lack of the requisite number of years in the whole record, a six instead of a seven year period had to be taken for the average base.

From this table it appears that the total diminution rate in the first half of the whole period is 289 per mille, or per thousand, and in the latter half it is 262 per mille, showing a difference of 27 per mille in favor of the first half. Slight as this difference seems to be, it is singular that pulmonary consumption should vanish more rapidly in the first half of that period, when hardly an effort was made or a thought was turned toward hastening that process directly, than it did in the second half of that period, when millions upon millions of money were spent, and a world-wide crusade was aroused to crush it, in which every possible physical and intellectual force was enlisted.

It is true that in New York City, and in Boston, where prevention laws have been vigorously enforced, in the former for seventeen, and in the latter eleven years, there is an increased diminution in the second half over the first half period of 4 per mille and 8 per mille, respectively; yet in Reading, Providence and San Antonio, where the preventive measures had only been applied for six years in the first two cities, and two years in the last, the decrease in the second over the first half period for these cities has been 18 per mille, 19 per mille and 18 per mille, respectively. This increased reduction rate in the five cities of this table may be ascribed, perhaps, to the salutary influence of the prevention measures which were applied. If this contention is true, it is plain that their action is extremely erratic and unreliable. For, under such an assumption, a reasonable explanation would have to be given why it requires a given force seventeen years to perform a certain amount of work in one locality, while it shows its capability of performing three times that amount of work in two years in another locality. This clearly expresses the relative proportion between the length of time and the effects which the prevention measures wrought in New York City and San Antonio, if they had any effects at all, and that which is true of these cities is also relatively true of Boston, Reading and Providence. To show the probable helplessness of these preventive measures still further, it may be pointed out that in Chicago, where the same measures were applied for nine years with the same vigor and supervision as were given to them in New York and Boston, and other cities, there was not only no decrease, but an increase of 2 per mille in the second over the first half of the period.

In summing up the two columns of this table it is shown that the total net increase of the second half is 27 per mille in excess of that in the first half, an indication which is confirmed by an analysis of Table II, and which is of additional importance in estimating the value of these protective measures.

Before going any further, Table No. II will be given, which will, in a great measure, accentuate the comments just made in relation to the factors which make for the reduction of the consumption rate. This table comprises the statistics of fourteen cities, which cover periods varying from eighteen to thirty years before 1912, and its general arrangement, with a few exceptions, is the same as that of No. 1.

TABLE II.—STATISTICS OF CITIES WHICH EMBRACE PERIODS VARYING FROM EIGHTEEN TO THIRTY YEARS PREVIOUS TO 1912.

Names of Cities	Number of Years Covered in Each City, Inclusive	Years in Which Prevention Measures Were Begun to be Enforced	Normal Diminution Rate per Thousand in First Half Period of Each City	Death Rate per Thousand in Second Half Period of Each City When Preventive Measures Were in Active Operation
1. Worcester	1886-1911	1902	0.90—	22—
2. Hartford	1889-1911	1909	19—	6—
3. Lowell	1890-1911	1903	29—	16—
4. Cleveland	1885-1911	1910	20—	2—
5. Louisville	1892-1911	1909	23	5+
6. Haverhill	1880-1911	1906	25—	31—

Total			220.90	146 Net increase of 74.9 per mille

That which is true of Table I is also true of the cities of Table II. While Worcester, Haverhill, Springfield, Nashville, and St. Paul show an increased diminution in the second half over the first half of the period, it still remains that the total net decrease in the first half of the period is 220 per mille, while in the second half, or the preven-

tion period, it is only 146 per mille, which leaves a balance of 74 per mille in favor of the first half, or what may be called the normal diminution rate period. By adding this balance of 74 per mille to the 27 per mille total net increase of Table I, it shows a total net increase of 101 per mille in excess of the second over the first half of the period in the twenty-seven cities which are under consideration in this paper.

Whatever distrust one may have in regard to the value of statistics, and whatever the shortcomings of those which are presented here may be, it is obvious that the trend of the evidence is strong enough to force the conviction that the decrease of the death rate of consumption has not been accelerated one whit by the preventive measures which have been evoked during the last ten or fifteen years; on the other hand, there are positive indications that, on the whole, the number of deaths from this disease have, for some unaccountable reason, increased during the years when these measures were in full sway. In other words, the modern prevention idea of stamping out consumption by fumigation, disinfection and isolation, is evidently proceeding on a blind trail, and it is high time that we strive to recall our mental equilibrium and to realize that experience, which is, after all, our best practical master, teaches that the only remedy which has so far been found effective in reducing the number of deaths from this disease, consists in the improvement of our physical and mental environment, and in the moral betterment of the human race. Additional proof of this will be furnished in that which follows.

History of Consumption in the Colored Race of This Country.—Before the Civil War the colored race was practically free from consumption—at least, its death rate in the South was not higher than that of the white population, in spite of the fact that they were probably more exposed to the disease then than they have been since. From reliable sources it is learned that the negroes "nursed the white consumptives, washed their spittoons, bedding and clothing, swept and dusted their rooms, and in many instances slept in the rooms with them—literally being with them night and day, and were more exposed to the tubercle bacillus than now as a general thing; still they resisted the disease." (Powell.) Notwithstanding their immunity before the war, it is well established that at the present time the death rate of consumption among the negroes of this country is from two to four hundred per cent. higher than it is among the whites. Why should the negro race, in less than half a century, be transformed from the least to the most consumptive race? Why should this come to them without the change of climate, or without the influence of migration, but in the land of their involuntary adoption, in which they had continually lived for more than two hundred years? The principal reason for this change was that since they obtained their freedom their entire social, economic and political existence became revolutionized. Instead of being dependent on their owners for food, clothing, shelter, medical care, and general supervision, as was their wont in the days of slavery, they were thrown on their own resources and were forced into a struggle for a living that was as unequal as it was tragic. And it is not at all surprising that in the severe stress and strain which they were compelled to undergo to readjust themselves to their new environment—to a civilization which was thousands of years ahead of their own social status—their constitution, and especially their brain and nervous system, became undermined and exhausted, and they fell an easy prey, not only to pulmonary consumption, but to insanity in excessive proportion, and from which they were also free before the war—showing that both diseases originate from common causes.

On the other hand, it does not require a very severe stretch of the imagination to perceive that if, through some magic spell, the negroes were translated into that state in which they could enjoy the advantages of care, food, shelter, clothing and general oversight, such as they received during slavery days, without being subject to the institution of slavery, they would in time revert to their former freedom from consumption and other diseases which now threaten to decimate them. To show the possibility of this, it may be incidentally stated on reliable authority that from 1860 to 1870 Spain brought 250,000 coolies under contract to the island of Cuba. They were drawn from the scum and offscouring, principally of the cities of Canton and Macao, and, in spite of the most careful selection, they brought with them consumption and other diseases for which China is noted. The vast majority of them were placed on plantations, and, being under contract and under the supervision of overseers, who ministered to all their physical necessities, so far as food, shelter and care were concerned, their condition being practically like those which obtained during negro slavery in the South, within the first few years consumption was eliminated, either through death or cure, and never reappeared in them or in their offspring.

Perhaps one of the most convincing examples of the influence of well applied sanitary regulations as a means of stamping out pulmonary consumption, so far as we have the figures, is given in connection with the history of exterminating yellow fever in Santiago de Cuba, immediately after the American occupation of that city in 1898, and which then had the reputation of being the filthiest city in the world. Major L. C. Carr, surgeon of the United States Army, was in charge of the work, and he states that a fairly reliable report of the deaths from yellow fever and consumption had been kept for some years before the occupation. The sanitary work, which was done for the chief purpose of clearing out yellow fever, began in 1898, and consisted of disinfection and re-disinfection of the foci of the fever, use of force-pumps to clean out cesspools, latrines, manholes, and wells; drenching and scrubbing of floors, ceilings, and walls; prohibiting the promiscuous throwing of filth, urine and excretions into the streets, and a general process of cleaning up the city and keeping it as sanitary as possible. No efforts were made to exterminate mosquitos, and no attention was paid to the expectoration of consumptives. In 1897 there were 325 deaths from yellow fever and 410 deaths from consumption; in 1898, 20 from yellow fever and 415 from consumption; in 1899, 53 from yellow fever and 173 from consumption; in 1900, no deaths from yellow fever from January to October, and 135 from consumption. From 1898 to 1900 the general death rate also fell from 133.71 to 6.00 per thousand inhabitants, while the death rate of yellow fever sunk to zero, and that of consumption diminished 67 per cent. during the last three years.

History of Former Crusades Against the Spread

of Consumption.—The facts which have been brought out in this investigation, concerning the inadequacy of the present preventive measures against the spread of consumption, are in entire accord with the results of similar crusades in the past, as the following historical facts plainly show. In 1754 the Grand Duke of Tuscany, in Italy, made it compulsory on all physicians to report every case of consumption to the health authorities of that country, under the penalty of a heavy fine, and even imprisonment, for failing to do so. In every case of death from consumption all articles used by the deceased had to be thoroughly disinfected, and nothing that was used in their illness could be sold for a month after death. Consumptives were compelled to spit only in special vessels of glass or glazed earthenware, which were to be disinfected, emptied, and cleaned frequently. These laws were rigidly enforced for thirty-nine years, when, on account of a want of support by the medical profession, they were repealed as being "a cause of bitterness, dissatisfaction, and vexation."

Laws of a like character were enacted in the Kingdom of Naples in 1782, and probably carried out with greater severity. In addition to the penalty imposed for not reporting cases of consumption and for failing to disinfect the expectoration, the rooms in which consumptives died had their ceilings, walls, floors, doors and windows torn out and burned. The bedding and furniture shared the same fate, and the houses were not inhabitable for a year. The sick were neglected, the families in which consumption occurred were shunned, and the owners of such houses were often turned into beggars on account of depreciation of their property. These laws were enforced about fifty years, and, as in the case of Tuscany, were abandoned on account of their absolute uselessness. Dr. de Renzi, the medical historian of Italy in that day, asserts that the injury which these laws inflicted were indescribable, and denounces the medical faculty in the severest terms for participating in their introduction and maintenance.

It may be urged here that medicine has made many advances since then, and that we are able to do more in the way of preventing consumption by disinfection and isolation than could be done a hundred years ago. It is true, they knew nothing of the tubercle bacillus, but is there any evidence to show that this germ was absent then, or did not possess the same virulent activity that is ascribed to it now? There is no evidence that the disease assumed a different character from that by which we know it now. The general description is the same as that given at present. It arose under the same influences, sprang from the same causes, had the same signs and symptoms, and was subject to the same laws of prevention and cure. In fact, the people at that time practically anticipated, by a whole century, the baneful effects which the then unknown bacillus is supposed to exert at present in the production of this disease, and under the ruthless isolation of consumptives which then prevailed, and which could not be enforced now to the same extent, neither the sick, their bacilli, their expectoration, nor any of their belongings had the remotest chance of ever reaching or infecting any one.

Rational Means of Preventing Pulmonary Consumption.—In looking for rational principles to solve the prevention problem of consumption, there is not a more positive guide in existence than that of experience. This teaches us to steer clear of the shoals and pitfalls that have wrecked ventures of this kind, and seek methods that insure safe sailing to the goal in view. No safer and more forcible indication can be found for such a course than a study of the factors which were active in reducing the death rate in our American cities from 1875 to 1893—the time which may be termed the ante-prevention period—or of the underlying elements which practically maintained the freedom of the negro slaves from this disease, as well as those which worked out immunity for the Chinese coolies in Cuba; and, lastly, an investigation of the most important example of Santiago, which demonstrates how profound an impression may be made on the march of this disease in the course of a few years by preventive means that prevent.

All of these exemplifications in their last analysis resolve themselves into the inculcation of sound fundamental principles of hygiene, which call for the expenditure of large sums of money and assiduous labor. Carried out in detail, this implies: (1) Eating wholesome and properly prepared food, (2) avoidance of living in damp, ill-ventilated and overcrowded dwellings, (3) wearing of suitable and comfortable clothing, (4) personal and domestic cleanliness, (5) avoidance of overwork and physical mental strain, (6) encouragement of learning trades, agricultural and mechanical pursuits, or any useful labor for boys, (7) importance of teaching girls the art of domestic economy, cooking, sewing, and taking care of a home, (8) the great value of education, (9) hygiene of the workshop and factory, good ventilation and temperature, and avoidance of dust as much as possible, (10) supervision of convalescence from what often seems a trivial cold or cough, or from illness or accident, (11) the procurement of efficient medical service and nursing in sickness or accident, (12) insurance against death, sickness and accident at the cheapest rate possible with safety, (13) erection of modern tenement houses, to be rented to working people at a rate sufficient to pay 4 per cent. interest on the cost, which amount, when sufficiently accumulated, to be applied for the erection of other tenements.

1829 Spruce Street.

CLAUDIUS GALEN.*

131 A. D. TO 200 A. D.

By THOMAS W. HARVEY, M.D.,

ORANGE, N. J.

"There is no pen, nor ever was, nor will be, that could do justice or a tithe of justice to the meaning of that historic moment in the history of mankind when the slowly but surely seminal labors of the appointed in many past generations, hitherto unavailing, jeered at by fools, unknown by the crowd, trivial in the eyes of kings, culminated for the saving of fools and crowds and kings alike in Listerian surgery."—(Saleeby "Surgery and Society.")

As we look back over the past of medicine, illumined by the wonderful light of the Twentieth Century, we may recognize these "appointed" ones, their work clearly showing up above the level of the great mass of error, of dogmatism, of sacerdotalism, of charlatanism, of mystery and magic, like distant peaks of snow-capped mountains in the Alpine after-glow when all else is shrouded in dark-

*Read before the Orange Mountain Medical Society, May, 1912.

ness and gloom. Such "appointed" ones, Vesalius and Boerhaave and Leuwenhoeck, Ambrose Paré and Pasteur, Harvey, Laënnec, Jenner, Priestley, Sydenham, Servetus, Paracelsus, Avicenna mark with their beacons the pathway across the ocean of obscurity and forgotten knowledge until we come to one great searchlight whose brilliance was so penetrating that it illuminated the path of medicine and obscured all other sources of illumination for fourten hundred years. Such an "appointed" one was Claudius Galen.

Changing the metaphor, if we look over a railroad map of a great country like our own we will see here and there centers toward which all lines concentrate and from which all radiate. So it is looking at the map of the history of medicine. We find here and there great minds to which converge all the lines of thought and knowledge that preceded them and from whom radiate similar lines of thought and knowledge to their followers, to be dissipated and lost in the ignorance and half knowledge of their disciples, or to be misinterpreted and denied by false prophets, ambitious to pose as new centers of knowledge.

After much winnowing of the chaff the lines of the old truths and the lines of new discoveries concentrate again in the new center; some great mentality with powers of analysis and of generalization so much greater than those of his contemporaries that the principles that he promulgates seem to have originated with him, and we call him a great discoverer.

Such a man was Galen, the great Eclectic. From all the widely differing schools of medicine that had flourished with more or less virility since the days of Hippocrates he took whatever theories seemed to him to be true, and in the great alembic of his mind he digested them and distilled a theory of medicine that might well have been called the Galenical school, so filled was it with his own personality and so persuasive was it to the loyalty of the physicians of the succeeding centuries.

His ideas of anatomy prevailed, founded though they were almost entirely upon studies of animals, until the dissections of Vesalius, and his physiology was accepted until William Harvey published the results of his studies on the circulation.

Particularly happy was he in his birth. His father lived at Pergamus, second only to Alexandria as a seat of learning. He was a learned man, and laid a broad foundation in his son's youthful mind so that when he was sent to study philosophy he easily became an adept and developed those powers of observation, analysis, and reasoning that enabled him to enter upon the study of medicine well equipped to differentiate truth from error, and to lead men back to the pure medical truths as laid down by Hippocrates, and which had been covered up and lost in the great mass of superstition and theoretical insanity that prevailed among the teachers of medicine and philosophy during the years that intervened between the lifetime of the Father of Medicine and that of his greatest disciple. That it is no exaggeration to apply the term pure medical truths to the theories of Hippocrates is readily appreciated if we consider his basic principle. There is a certain force that he calls "nature," a force later recognized under the title of Vis Medicatrix Naturæ, upon which we can rely when we cannot cure our patients by incantations, sacrifices, prayers, or drugs, which, if not prevented by our own malpractice, can generally be trusted to correct the aberration from health. To quote his own words from Smythe's Medical Heresies: "Nature is sufficient of itself for every animal. She performs everything that is necessary to them without any instructions how to do it. She distributes blood, spirits, and heat through all parts of the body by which means it receives life and sensations, nourishment, preservation, and growth."

Now this is good medical doctrine to-day and is about as near being exactly true as it was four hundred years before Christ. In his writings we find that he teaches that this force is a form of heat and that it is immortal, and this is a doctrine which under the title of the "Conservation of Energy" underlies all our modern theories regarding physical phenomena. These doctrines prevailed very generally until the time of Galen. However, rival schools and perversions of the original Hippocratic teachings had risen so that it was a difficult task that Galen set for himself, viz., to reform the practice of medicine. As he pursued his task his Eclecticism evaporated and he became a strong supporter of dogmatism in medicine, and so entrenched his principles that it took many centuries and the attacks of many such as Paracelsus to deprive him of his position as arbiter of the proper beliefs to be held about disease and its cure.

Besides nature, this force to which is ascribed so much by Hippocrates, he believed the four humors, blood, phlegm, yellow bile, and black bile, and their derangements to be the basis of all disease, and that these humors were subject to the malevolent or beneficent influence of the four elements, earth, fire, air, and water.

The one great principle that has come down to us from Hippocrates and his immediate disciples is the value of observation of the phenomena of disease, and the effect of outside influences such as diet, regimen, and climate. They attributed much to the influence of the stars, the solstices, and the equinoxes, and consequently easily yielded to the tendency to attribute disease to occult causes; and the pure speculations as to the effect of meteorological conditions became lost in the maze of astrology.

One of the Hippocratic precepts, to-wit, "Life is short, opportunity fleeting, judgment difficult, treatment easy, thought hard, but treatment after thought is proper and profitable," may well be accepted as a cornerstone for medical practice to-day.

After the days of Hippocrates numerous schools arose, all of them antagonizing more or less his teachings. The dogmatists, who were the earliest to be differentiated from the older physicians, were more given to speculation than to observation, and the more they theorized about the nature of disease and its causes, the less attention they gave to the study of its phenomena.

At Alexandria some two hundred years after the passing of Hippocrates there developed a great medical school, a school that inherited much from the ancient Egyptian civilization, which indeed had been the storehouse from which the Greeks had drawn the knowledge upon which, as a foundation, Æsculapius had developed the medical science that had culminated in the Hippocratic period.

All the world went to Alexandria to finish their medical studies, and even two hundred years later we find Claudius Galen studying anatomy at the feet of one of its noted professors. Alexandria in the earliest times had allowed its medical professors to dissect the human body, and here in 335-220 B.C. flourished Herophilus, who might be called

the father of anatomy, and so strenuously did he pursue its study that he is said to have dissected seven hundred bodies. He had a contemporary, one Erasistratus, who seems to have been equally skilled in anatomy, but differed from his colleague in many essentials. He might have been called the Hahnemann of the Ancients so persistent was he in opposing the use of venesection, and of active and unpleasant remedies of any kind, even to the extent of using infinitesimal dosage.

Erasistratus was the man who made his medical reputation by diagnosing love sickness in the case of the young prince who was pining for his stepmother, and had fallen into such a grievous state of illness that none of the local faculty could cure him, not being able to determine the cause. Erasistratus, however, perceiving that the young man's symptoms were always aggravated by the approach of the lady, recognized the disease. The diagnosis having been made, a speedy cure was accomplished, but history is silent as to the method. Not to be outdone, Galen made a similar brilliant diagnosis in another case of love sickness. Galen, like many of us to-day, took delight in telling of his successes in diagnosis, and he gives descriptions of consultations, narrating with much pride his clever use of his powers of observation, and unctuously expressing his belief that these patients had probably never before been in the hands of a competent physician. The fact is Galen had very little use for the average doctor, and was arrogant and supercilious enough to have acceptably filled a consulting chair in a metropolitan school of to-day.

During the five hundred years that preceded the advent of Galen many sects had arisen in medicine. The Empirics rejected as useless all search for the causes of disease, rejected the value of anatomy, and claimed that the true object of medicine is to cure the patient, and that the study of the clinical histories of similar cases should be a sufficient guide to the proper treatment. The Methodists attempted to pursue a path midway between the Empirics and the Dogmatists, who claimed to be the true followers of the Father of Medicine. The Pneumatic school devised a fifth principle called "Pneuma," this principle is breathed in and the effects of its proper or improper mixture with the well-known four elements of Hippocrates cause health or disease. Following these sects arose a powerful school called Eclectics, and it was from prominent teachers of this school that Galen received his early medical training.

According to Baas the world of that day seemed to be well supplied with medical men of all kinds and varieties, with all degrees of training, formulating many opposing and fantastical theories as to the cause, natural history, and termination of the phenomena of disease.

There were many specialties and there were many castes among physicians. Among the Romans in the early days of the emperors, most of the physicians were Greek or Egyptian slaves; the high and well-born Roman scorned to lower himself to either bodily or mental labor and employed slaves for such purposes, his best medically trained slaves being worth about three hundred and fifty dollars. In those days medical men were certainly of low degree, but as time went on and slaves became freedmen, or learned physicians from other countries came to Rome to practise their art, or were summoned thither to attend some great man, the social status of the medical man became very much better, so that in Galen's time it was considered an honorable calling even by the knightly and aristocratic native of the Imperial City. There were court physicians, city and district physicians, and ordinary practitioners, besides the military surgeons; there were apothecaries and barbers and bathers; there were dispensaries and even hospitals of a kind. The poor were treated for nothing and the well-to-do were charged according to their means. Later the doctors had many privileges such as freedom from certain forms of taxations, and many were salaried by the city or State. Their fees, as has been said, varied. Thirty cents was a common fee for a visit, but many very large fees are recorded. Baas mentions that the oculist Charmis received a fee of $10,000, while Galen received a fee of $2,100. Ancient Rome also had its midwives and sages femmes, also abortionists and poisoners, and in all things medical seemed to have attained a high degree of civilization.

And to this Rome came Galen in his young manhood, and here he spent most of his life, here he made his medical reputation, and here he wrote his books. Pergamus, his birthplace, was situated in Mysia and was one of the renowned centers of education of the ancient world. It had a large and important temple of Æsculapius, ornamented above its portal with the great carved serpent, and with its majestic columns covered with inscriptions written by those who had recovered from their diseases under the beneficent care of the temple physicians, carefully detailing the symptoms of their diseases and the methods of treatment, such clinical records being of use in training the young medical men, and also of assistance to those sick with similar diseases.

Galen, led by a vision of good old Æsculapius, who appeared to him in a dream, took up the study of medicine in his native city, and visited and studied in all the important centers of Grecian medical teaching. Whenever he heard of some interesting medical discovery he immediately journeyed to the spot so as to have a personal knowledge. In one of his travels he describes the finding of a human skeleton. A criminal had been left unburied and the carrion birds had cleaned the bones, and he devoted much time to the improvement of this unusual opportunity, and in his lectures on anatomy he urged his students to be on the lookout for such chances. He must have increased his acquaintance with anatomy while studying in Alexandria, where was still preserved a knowledge of that subject handed down from the days of Herophilus when dissection of the human body had been common. He pursued other studies in addition to medicine, and we find among his productions books on grammar, mathematics, logic, and ethics. He was also a great linguist and wrote his treatises in several languages and dialects. He is said to have written over three hundred treatises, more than half of them being still extant. Dr. George J. Fisher has calculated that Galen's extant works are nearly five and a half times as voluminous as the entire Bible. "These treatises were the great and exhaustless repositories of medical observations and opinions to which the whole medical world turned for fourteen hundred years."—(Fisher).

Certain of his more important treatises, viz., "De usu partium corporis humani," "De pulsibus," "Ars parvi," "Methodus medendi," "De crisibus," and "De differentia febrium," composed the standard "Canonical writings of Galen," and were the text-

books of the middle ages. These are the books that Paracelsus burned.

The anatomy that Galen taught was largely founded on the study of animals, yet his treatises were accepted as authority down to the time when the valiant Vesalius defied the arrogance of the monks, and despite the fulminations of the church published his wonderful works founded on his own dissections. Vesalius never could say severe enough things about Galen's anatomy and devoted much time to pointing out his errors, and yet many of Galen's anatomical writings were corrections of the teachings of his predecessors, as for instance when he pointed out that the nerves originated in the brain and not in the heart, as taught by Aristotle. He accurately described the larynx and compared it to a reed pipe. His osteology naturally was better known to him than the anatomy of the viscera or the muscles. He described accurately many muscles previously misunderstood.

In physiology he experimented as a vivisectionist and demonstrated to his pupils. He described the heart and its valves, and came very near to the discovery of the circulation of the blood. He opened a living animal, tied the aorta in two places and showed to his students the blood in the living artery. His predecessors had taught that the arteries in life contained air and that the phenomenon of bleeding from wounded arteries was due to the blood flowing into them after the air had escaped. He recognized the heart as the center of the circulatory system and its contractions to be the cause of the pulse of which he described many varieties and about which he wrote a book.

His explanation of the two sets of vessels was, that for different purposes the system required two kinds of blood, one bright and thin, the other dark and thick.

His physiological experiments taught him the value of the ligature, a fact that was forgotten after his death until Ambrose Paré reintroduced the ligature into surgery over one thousand years later. He explained the phenomenon of blood clotting by the presence of certain fibrous particles.

He taught that respiration was for the purpose of cooling off the excess of heat produced in the blood by the vital processes, and claimed that if we knew why the flame is extinguished by the absence of air, we could understand the influence of the respiration upon the blood.

His knowledge of the nervous system was fairly accurate, he recognized the two varieties of nerves, and described accurately the effects of cutting the nerves and of cutting the spinal cord. He also understood the crossed action of the cord in the transmission of impulses of sensation.

He was a careful observer of the phenomena of disease, but also was watchful for any evidence that would help him to a diagnosis. He describes with much evident pleasure the surprise of a medical patient at his diagnostic acumen and the graphic manner with which he described the patient's symptoms before he had commenced his examination, and explains his apparent mysterious skill by the fact that on his way to the patient's room he had inspected a stool that a servant was carrying from the room at the moment of his entrance. The peculiar bloody sanious appearance of this discharge he recognized as common to certain diseases of the liver, and the further observation of some medicine that the physician had been taking on his own account enabled him to understand the patient's own idea of his case, and it was a very easy riddle to solve as to the location and character of his symptoms.

It was such cleverness that led to his being called the Paradoxopoius, the wonder worker, and it was also the cause of his leaving Rome and returning to Pergamus for a short time, only to be called back by the Emperor, Marcus Aurelius. It is interesting to note that he was so well thought of in his home town that he was made physician to the school of gladiators. In these days he would probably have been made a football surgeon.

He seems to have made himself quite popular with the various emperors who reigned at Rome during his lifetime. He made a great reputation and earned a good fee by telling one of them that he was eating too much, and that he did not have malaria as diagnosed by his other advisors. He also took care of two of the sons of Emperor Commodus successfully through several illnesses.

Galen's therapeutics was of a very active character, blood-letting even to fifty ounces was used in all forms of diseases, and among those sensuous and high living old Romans was undoubtedly of great benefit. He, however, described accurately in his works the limitations that he would put on its use, as also for the use of purgatives and emetics. Emetics were used very commonly, and probably it would be better if more were used to-day.

The universally popular remedy of the day was the "theriaca," which was composed of several hundred ingredients, of which opium and ground-up vipers were the next important. It seems to have been used as a general tonic and also as an antidote to snake bite. The formula was retained in the British Pharmacopœia until within the last two hundred years. Galen was an expert in the compounding of this medicine and prepared it especially for the Emperor Aurelius.

He taught his students that the physician is a spectator at the bedside of his patient, of a life and death struggle between disease and the patient, and that it is his duty to discover the end for which nature is striving and give aid with that end in view.

Galen has been described as a man of great natural ability, versed in philosophy, an expert anatomist, an experimenter in physiology, and a physician of great experience. He taught that the end and object of medical science is to preserve the parts of which the body is composed in a natural state and to endeavor to establish their functions when disordered, hence he deduces the necessity for the study of anatomy and physiology.

Health, he taught, consists in the fair proportion of the four elements, fire, water, air, and earth of which the attributes are heat, cold, moisture, and dryness.

As a student and teacher of medicine he governed his methods of thought by that rule formulated many centuries later by Lord Bacon, and paraphrased as follows by Sir Thomas Watson: "Be not like the empiric ant, who collects from every side indiscriminately for present wants; nor speculative like the spider, who, seeking no material abroad, spins his web of sophistry from the recesses of his inner being; but imitate rather the praiseworthy bee, who, gathering crude honey from various flowers, stores it up within, and by his own operation matures and perfects it for future use."

We must recall that Galen lived in the second century after Christ, and that the great mass of

the world was still pagan. He knew the sect of the Christians, and in his writings speaks of their virtues and of their chaste abstemious lives, but takes exception to their mysticism and their dependence upon the supernatural rather than the rational philosophy which was the basis upon which he had built up his school of medicine and to which he referred the results of his observations of nature.

In a treatise entitled "De usu partium corporis humani," which is a dissertation on final causes, he argues for the existence of a supervising Providence, deducing from his studies of anatomy and physiology, and the adaptation of the body to its needs, proof of the presence of design in creation, anticipating Paley by many centuries.

I can close this sketch of this great man in no more fitting manner than by quoting from this treatise his "Hymn to the Deity," as it has been called, words that might well have been uttered by a Christian father, though they were written by the pagan, Claudius Galen:

"In writing these books, I compose a true and real hymn to that awful Being who made us all; and in my opinion true religion consists not so much in costly sacrifices and fragrant perfumes as in a thorough conviction impressed upon our own minds and an endeavor to produce a similar impression upon the minds of others of his unerring wisdom, resistless power, and his all diffusive goodness. For his having arranged everything in that order and disposition which are best calculated for its preservation and continuation, and his having condescended to distribute his favors to all his works, is a manifest proof of his goodness which calls loudly for our hymns and praises. His having found the means necessary for the establishment and preservation of this beautiful order and disposition is as incontestable a proof of his wisdom as his having done whatever he pleased is of his omnipotence."

THE IMPORTANCE OF THE LOCAL LABORATORY IN MEDICAL PRACTICE—THE COUNTY LABORATORY.*

By WILLIAM S. MAGILL, A.M., M.D.,

ALBANY, N. Y.

FIRST LIEUTENANT, M. R. C. U. S. ARMY; DIRECTOR OF LABORATORIES, N. Y. STATE DEPARTMENT OF HEALTH.

In appearing before this society upon your invitation to help the beginnings of the Genesee County Laboratory, the speaker occupies a rather anomalous position. You are, of course, aware that the legal authority which permits the establishment of such a laboratory vests the power of creation of a county laboratory and of all provision of its funds and its direction, management, and appointment of officers, in the hands of the Board of Supervisors of the County.

The State Department of Health apparently has no part or power in any of these initial steps and has no control in the operation of the laboratory, nor determinations of its functions nor the qualifications of its staff nor of their emoluments: and, unless by courtesy of the Board of Supervisors or their delegated authority, our State Laboratory would not be consulted in the matter at all. There is a provision in this enabling act for county laboratories which I believe states somewhat as follows: that the State Department of Health shall furnish supplies, etc., to such county laboratory when established.

I understand that no appropriation to enable the State Department to furnish these supplies has been specifically made, and without such appropriation the directions of the Commissioner of health to the laboratory are to help in so far as we are able in such effort to make a county laboratory successful and to furnish to such laboratory the supplies that it is possible within the limitations of our appropriations to furnish.

We are endeavoring, therefore, to help the successful operation of county laboratories by supplying to them as a loan various outfits for the transport of specimens through the mails; of sputum, diphtheria culture material, and the so-called Widal outfit for blood serum testing; and we endeavor to renew the culture supplies as they are utilized and we also furnish in assisting such a laboratory in special work, amounts of special media.

We are, of course, quite unable to undertake the supplying of a county laboratory with any extensive apparatus or materials of such nature, which would be quite beyond the possibilities of our present appropriations, besides involving other questions as to the amount of apparatus of such nature that we would probably be called upon to furnish a county laboratory.

As I have said, my position before your society now is somewhat anomalous for the reason that when my opinion has been asked in previous matters of establishing a county laboratory, I have constantly urged that at the first establishment of such a laboratory ample provision should be made to secure at the very beginning a competent staff, thoroughly sufficient equipment, proper quarters, and ample operating expenses to start a laboratory of the highest class.

I have frequently stated that in my opinion at least $3,000 per year should be appropriated as a minimum provision for the county laboratory to insure its ultimate success and I have pointed out the relative division of this amount for a necessary equipment and salaries for the start, urging that in making such a minimum appropriation it should be well established in the minds of the Supervisors that as the experiment progressed toward its success, they would be ready to increase this appropriation with necessary amounts to broaden the field of work and the quality of the workers in such a laboratory.

Recalling then my urgent insistence on an ample provision of means for the county laboratory, my previous statements that a minimum of $3,000 should be contemplated before making a beginning, also my strong preference that a county laboratory begin with ample means for equipment and for securing a staff of unquestionable qualifications that should devote its entire time to the laboratory work, for reasons that need not be dilated upon here it is a little difficult to urge upon you the advantages of your newly established county laboratory, which is far from realizing the minimum of appropriation and scope desired.

There can be no doubt, however, that deficiencies of money can be later recompensed and the important thing then in starting a laboratory is to secure efficiency of work.

At the present stage of medical practice in this State, as observed by me, there is no particular in which the practitioner can be more benefited than

*Address delivered by invitation before the Genesee County Medical Society, September 4, 1912.

by the improvement of quality and accessibility of laboratory facilities for his daily work. The rapid progress of modern medicine, the immense development of bacteriology, which has occurred since the graduation from their medical colleges of most of our present active practitioners, have developed possibilities of early, accurate, and control diagnoses in the laboratory, quite unthought of by the most skilful clinicians of twenty years ago.

Speaking in a very general sense, one can say that every case of disease occurring in a general practice now presents problems of very difficult solution by the clinician, but of simple and rapid determination with proper laboratory facilities. I do not need to enumerate to you all of the cases of medicine in which a laboratory can render assistance and the many of them in which the laboratory assistance is imperative.

You know, of course, the relative precision and ease of the precocious diagnosis of tuberculosis in the human being by laboratory method and test alone, before there are any marked clinical symptoms. You know the very recent but remarkable precision and extensive application of the laboratory diagnosis and control of disease progress in the matter of syphilis, in which a dependence upon clinical symptom alone has for years been considered quite impossible. It may be well, in view of our subject to-day, to dilate upon the certainty and utility of laboratory methods in the diagnosis and control of infectious diseases.

In our State Laboratory these efforts are confined rather closely to the examination of cultures to determine the presence of the germ of diphtheria in a suspected throat; to determine the presence of the tubercle bacilli in sputa, and the well-known blood serum test—the Widal reaction—in the diagnosis of typhoid fever. In undertaking these tests the laboratory is doing its utmost to carry out the motto of the state department to "Do for others what they cannot do for themselves."

The State Laboratory undertakes work of the above nature at a considerable disadvantage, particularly hampered by its long distance effort and the consequent loss of time. In doing work of this nature for a locality, such as this city for instance, it may be possible that at least three days elapse between the time of taking a specimen to the time of receipt of the laboratory report on the examination of such specimen. Operating at such a distance it is, of course, impossible for the laboratory worker to maintain any personal touch with the clinician engaged in the case of disease of which the laboratory diagnosis is requisite.

Because of long distance and loss of time in many operations susceptible to laboratory diagnosis, our State Laboratory can render very doubtful utility, if any, because of the difficulty of transporting specimens and their receipt at the laboratory with sufficient promptness to secure a sufficient freshness to permit a successful laboratory operation and diagnosis.

As an illustration of this difficulty, I would point out to you the very great work that has been accomplished in recent years and is still being carried on by the operation of local laboratories for the investigation and control of typhoid fever in the Rhine Valley of the German Empire. By reason of operation of such laboratories *in the locality*, it has been possible to develop methods of laboratory diagnosis and control, operating often with fresh stools of patients, convalescents, and suspects, to control the absence or presence of typhoid bacilli and consequent measures of precaution and quarantine to eliminate the dangers of infection with the germs of this disease by contact in direct transmission or carrier. There is undoubtedly a large field for work of this nature in this State.

After the first steps of ridding public water supplies of dangerous fecal pollution and other, so to speak, gross sanitary measures for protection of the public from generalized typhoid epidemics, comes, and will come with greater intensification, the necessity of further diminishing the typhoid death rate here of 12 to 16 per 100,000, whereas there are very populous European cities and countries with a typhoid death rate perhaps as low as three.

It is encouraging to feel that the typhoid death rate of this State has fallen so tremendously as our vital statistics show in the last 15 or 20 years, but it must descend far lower to reach anything that might be called a permissible typhoid mortality in a highly civilized and sanitarily developed country. As the typhoid mortality approaches a permissible minimum, each step in its further reduction requires more and more concentrated effort to discover and eradicate the more and more seldom occurring and, therefore, more difficultly found sources of infection. In such intensification of sanitary control, a system of local laboratories, such as those now operating in Germany, is absolutely necessary.

The problem of better laboratory work to help in the eradication of typhoid fever sources is constantly coming to our State Laboratory and, of course, it is our desire to perform every possible service and undertake every possible means to accomplish this important laboratory control. We find, however, an immediate difficulty when contemplating any measure of laboratory examination of stools for the discovery of the typhoid bacillus and consequent laboratory control, diagnosis and assistance in quarantine measures. The difficulty is that of the long distance for the transport of specimens and the consequent loss of time, whereby such specimens of stool do not reach the laboratory promptly enough nor in a condition fresh enough to permit any efficient examination or effort to determine the presence of typhoid bacilli in these specimens.

It is a very simple procedure for the laboratory to make such examinations with fresh specimens. A local laboratory could render great assistance in all such cases where specimens could be delivered in a fresh condition and immediately examined. Similar conditions exist and determine the advantage of a local laboratory for undertaking work with blood specimens and in particular such reaction tests as the Wassermann in diagnosis of syphilis.

But the particular field of attack for a beginning county laboratory is in my opinion, a campaign to make known to all of the local physicians exactly the way and extent in which laboratory facilities can be utilized in their work. It has been pointed out why the State Laboratory is seriously hampered by long distance, among other things, because there can be no personal relation of the laboratory worker with the clinician. Without this close association of the two parties engaged in the care and control of disease, a serious loss of opportunity is caused to each party.

Without the personal association and consequent

conversation and verbal information on each case, the laboratory worker is confined absolutely to the examination of a specimen of which he has very limited data and to that extent possibilities, of his diagnosis, of his suggestions of further work, examination or action in relief, must of necessity be eliminated. For this reason the clinician realizing the limitations of the results reported to him, fails to realize the great advantage and multiplicity of opportunities in which a laboratory should be utilized by him.

I believe that the clinician far removed from an active laboratory assistance, and by the limits of time and other occupation unable to keep up his own laboratory technique, gradually drifts away from the best utilization of laboratory resources. It must of necessity be so, because even the laboratory worker finds the utmost difficulty in addition to the time of his laboratory work to maintain the amount of reading to keep himself informed of each progressive step in laboratory utility to clinicians. If then the laboratory worker himself finds it difficult to keep up such information, how could it be considered possible for the clinician to know to what extent modern laboratory developments bring new assistance and precision to his work.

It is, therefore, in my opinion the most important function of the members of the laboratory staff of a county laboratory to undertake this active missionary work to see that all of the practitioners of that community are kept informed of what the local laboratory can do for them in all of their cases.

It seems to me most important that particular effort and particular time be given by such a laboratory man or men, to maintain a constant and personal relation with every practitioner in the county, to keep him reminded of the ever present and ready assistance of the county laboratory and to point out to him in each occurring case to what extent the laboratory could be utilized and to secure such utilization of the technical staff and ability.

With a conception of such a broad field of endeavor and utility for a local laboratory, you will, I think, realize the speaker's feeling of the necessity of employing for laboratory staff the most competent bacteriologist and securing all of the time of such competent people for this work, which has no limitations.

If the opportunity to a county laboratory and its director is unlimited in such a field, the ultimate success of a local laboratory must depend upon ample financial provision, ample qualification of the technical staff, the thorough conception of the field and opportunity to be developed by the laboratory and its staff and then, and perhaps most important of all, upon the thorough interest and cooperation of all of the medical practitioners in the county.

In appearing before this society to-day, my object is to call particular attention of every member present to his particular responsibility for the success of this new undertaking. If each one of you realizes the advantage in your own clinical work of immediate, ever present laboratory assistance; if you intend to utilize these provisions and special opportunities for better grade of clinical work, you must ever remember that it is the duty of every practitioner to secure for each of his patients every possible aid to the maintenance or re-establishment of health. Realizing then to what an extent in modern medicine the laboratory aids the clinician, it is the duty of each practitioner to see that he utilizes every possible laboratory aid in every one of his cases.

If your laboratory direction realizes its opportunity, it stands ready to assist with its laboratory technique, with its skilled expert bacteriological or other laboratory scientific advice, every practitioner in the community. There should be no personalities or feeling; no local jealousies that should limit the reciprocity of the clinician to his laboratory, nor of the laboratory to each practitioner.

If the members of this society admit the necessity of a laboratory in their work, they should remember that the initial step to provide such a laboratory, experimental as it may be, has been made and, therefore, in so far as the present provision has their confidence and endorsement, that it is incumbent upon each one of them to utilize this laboratory in every possible way for the benefit of their own work and the immediate benefit of their patients.

If the practitioners of this county meet the establishment of a county laboratory in this spirit; if the direction of the county laboratory is endeavoring to render its utmost for each of the practitioners, insufficient as in my own opinion the present financial establishment of the laboratory may be, I can yet see that it is but the first step toward an ultimate success.

It would seem to me unquestionable that, if the laboratory as now established has the essential qualifications for a beginning, if the practitioners now assembled endorse this laboratory and undertake ful-heartedly its utilization, a component future financial provision may be obtained.

It seems to me that the responsibility for the success of this county laboratory rests with the members of this County Medical Society or the other practitioners in the district. If all unite to utilize such laboratory facilities to their utmost, to act in the heartiest cooperation of the technical staff and in appreciation of the efforts of the Board of Supervisors to provide further facilities for them, it seems to me that this evidence of the appreciation of the local practitioners, the constant results that will be evidenced to their patients, and the improved medical work of this whole community, will be of such satisfactory demonstration as to insure the best interests and endorsement of the Board of Supervisors of this county and a consequent future provision, that shall amply meet the needs of this institution.

DISINFECTION OF THE INTESTINE BY INSUFFLATION OF OXYGEN.

By M. GROSS, M.D.,

NEW YORK.

Man is born without bacteria; immediately after birth the meconium is still sterile. The first bacteria are found 10 to 17 hours after birth, consisting of cocci, yeast cells, and short rods (*Bacillus bifidus*, Tissier).

The intestinal flora assumes a more characteristic appearance after the infant has been fed, and the findings are totally different according to whether the food has consisted of breast milk or cow's milk.

In breast milk stools there are usually to be found *Bacillus bifidus* and *B. acidophilus* (Moro). Much fewer in number are *Bacterium coli commune* and *Bacterium lactis aerogenes*. Moro designates the infection with the last two as "specific," and it is

these bacteria which represent the parent stock of the "physiological" intestinal flora.

After cow's milk, the coli group is particularly prominent, as a rule, while bifidus and the other bacteria are less numerous.

In the normal stool of adults the intestinal flora presents an exceedingly prolific picture, the most striking phase of which consists in the ever-occurring flora of the coli group: *Bact. coli commune* and *Bact. lactis aerogenes*—the "friendly," "individual," "personal" flora.

Between this friendly flora and the individual being, a lifelong symbiosis is slowly developed; they are on terms of good companionship. These bacteria normally form metabolic products of an antiseptic nature (autotoxins), which display an elective, antiseptic action not only against "foreign," invading bacteria, but also against an overproduction of their own kind.

Schottelius was the first to demonstrate the usefulness of bacteria in an unmistakable manner: useful for the maintenance of life and growth of the individual. They assist in the process of digestion; the amylaceæ in the small intestine; cellulose in the cecum and ascending colon; fat in the lower intestinal section; protein chiefly in the large intestine. Some bacteria produce ferments, resembling the enzymes of the human organism, which aid digestion.

Ninety-nine per cent. of the germs introduced into the intestine from without are destroyed in the stools (Strassburger), destroyed by the friendly bacteria, by a normally functioning stomach, by a normally acting small intestine. In the latter organ particularly their development is arrested by the great bactericidal power with which the epithelium is endowed.

Thus it follows that the conditions of existence and development for "wild" pathogenic germs are not particularly favorable. But these conditions assume a different aspect when the "wild" germs by dint of numbers overpower the useful coli group, arresting its antiseptic work; conditions become worse if, in addition, there occurs irritation of the intestinal mucosa, or if irritation has already formerly been present from an unsuitable diet, laxatives, worms, motor disturbances, circulatory disturbances, etc. It is the irritation of the mucous membrane through which transudations develop that easily undergo putrefaction and thus form a still more favorable culture ground for the proliferation of pathogenic germs.

It is not yet definitely decided whether the bacteria of the coli group may themselves display a pathogenic effect either by increasing in number or by increased virulence. At any rate, certain bacteria of this group seem to form the transition stage between the friendly and the directly pathogenic bacteria (paratyphoid, typhoid, etc.).

Another non-settled point is whether the individual, friendly, intestinal flora as such is capable of perforating a normal intestinal wall or whether it must undergo a metamorphosis, by which the friendly relations are disturbed. It would certainly seem that a healthy intestinal wall is an almost insurpassable barrier to the invasion of friendly bacteria, unless they have undergone some hostile change. The invasion accomplished, they inundate the organism from the intestine with their toxins (autointoxication), or penetrate into the tissues (autoinfection).

Infections and anatomical disturbances often assist each other in pathological processes, forming a *circulus vitiosus* which may render it difficult to establish the primary causative factor.

The pathological conditions we have mainly to deal with are fermentation and putrefaction.

Normally, fermentation (carbohydrate fermentation) occurs chiefly in the small intestine, and putrefaction is more prevalent in the large intestine; but the extent to which both are present is not large enough to interfere with the healthy condition of the individual. Increased infection establishes fermentative and putrefactive dyspepsias which often, by the additional manifestations of inflammatory processes, develop into fermentative and putrefactive catarrhs.

The primary focus of these affections is often found in the stomach (atony, achylia, etc.), while in other cases they appear under the picture of a more localized intestinal affection. Examination of the stool after Ad. Schmidt's test meal will often enable us to demonstrate the disturbance of function and its localization.

We may here briefly summarize the most salient points:—

(1) Disturbed *motility* (increased peristalsis) never occurs singly and primarily; it always occurs as a secondary factor and following irritation of the mucous membrane.

(2) *Resorption* of carbohydrates and albumin is not disturbed even in serious affections; but the presence of fats in the stools points to disturbed resorption, provided affections of the pancreas and gall-bladder can be ruled out.

(3) Large quantities of undigested food remnants point to disturbed *secretion*. Such remnants are: Connective tissue in disturbances of gastric secretion. Muscular tissue in disturbances of pancreatic secretion. Fats in disturbances of the pancreatic and biliary secretion, and in disturbances of intestinal resorption. The presence of carbohydrates in the stools points to disturbed secretion of the pancreas and intestinal ferments.

In *fermentative* dyspepsia there is in the first place insufficient cellulose digestion; proteins and fats are here often found well digested. Here the acids formed in the decomposition of starch may irritate the intestine, cause transudation, fermentative catarrh, and decomposition, so that a putrefactive catarrh is added to the fermentative catarrh. These patients complain of lassitude and depression. There is no actual diarrhea, but the defecations occur more frequently.

In pure, non-complicated fermentative dyspepsia the feces are light yellow, frothy, of acid odor and reaction. Microscopically, large quantities of granulose bacilli, which stain blue upon addition of iodine, are found, especially in soft, pasty stools. We find mucus in fermentative catarrh only.

In *putrefaction* there is a mixed infection of aerobic and anaerobic bacteria. While *B. proteus* is held responsible for normal putrefaction (Escherich), pathological putrefaction is probably due to the anaerobic *B. putrificus* (Bienstock).

The feces are dark, of putrid odor, and alkaline reaction; they contain mucus and undigested food remnants.

The ileocecal valve serves normally as a barrier against putrefaction spreading toward the ileum. But should inflammation localize here, the valve will lose this power, and the putrefactive bacteria, which are otherwise confined to the large intestine, will now spread to the small intestine (Schmidt). Clin-

ically, these cases run under the picture of chronic appendicitis, but they will usually undergo no improvement, even after operation.

Therapy.—Dietetic and hygienic measures in the eminently chronic affections just named, which often require a stay in a sanatorium, may lead to satisfactory results; in many cases, however, relapses will occur, leading to invalidism.

A general dietetic law is the following: The food should be of the right temperature, in a properly dissolved state, of correct mechanical morselation, and chemically non-irritating. All articles should be fresh and predigested by appropriate preparation. Cellulose is badly borne; so is milk in many cases. Carbohydrates are allowed only as finely ground flour. Rice and potatoes are not borne well.

Patients may get slowly accustomed to "salicyl milk" (Schmidt), 0.2 salicylic acid being added to a quart of boiled milk. Abstention from carbohydrates and meat, or limitation of these articles will often be indicated. The use of *Bacillus bulgaricus* cultures is varying in effect and often negative.

Secondary processes, pointing to the stomach as the primary cause, will direct our attention to that organ.

Drugs, as a rule, are followed by much less satisfactory results than dietetic measures. Intestinal antiseptics are rightly held in disrepute; laxatives, especially saline waters, and often calomel, should be directly interdicted, as they interfere with the work of the friendly flora by the irritation of the protective mucous membrane and by the profuse diarrhea they occasion.

The idea of using oxygen as an intestinal antiseptic was taken up after Berger, Hirata, and others had shown that excessive bacterial proliferation could be restricted by introducing nascent oxygen into the small intestine. But the O_2 combination or peroxyde per os has not achieved any favorable results.

Ad. Schmidt, however, introduced oxygen directly into the small intestine by means of the "duodenal tube," and the results he reported were very favorable. (*Zentralblatt f. innere Medizin*, 1912, No. 1). We have since had occasion to repeat this treatment with our "duodenal tube" on a small number of patients and can fully confirm those favorable results not only in cases of pathological fermentation, but also in putrefactive processes.

The change occurring in the pathological intestinal flora after insufflation of oxygen can best be followed with the aid of the Weigert-Escherich method (Gram). This method supplies information on the intestinal flora and the relation of the putrefactive and fermentative germs to each other. There is no other method, aside from clinical measures, which so clearly indicates an improvement or an exacerbation. The technique, according to Alexander Schmidt, is the following:

(1) Boil 2 gm. of gentian violet with 10.0 c.c. of distilled water for half and hour and filter (stable); (2) 11 c.c. of absolute alcohol are mixed with 3 c.c. of aniline oil (stable); (3) 1 gm. of potassium iodide, 60 c.c. of distilled water (Lugol); (4) Aniline oil and xylol, in equal parts; (5) Xylol.

The feces are finally rubbed up with water and centrifuged, in order to separate the bacilli from the feces. Before staining, they are again centrifuged with alcohol.

The Stain.—Mix (1) and (2) in the proportion of $8\frac{1}{2}$ to $1\frac{1}{2}$ (stable for 2 or 3 weeks). The stain is applied on the slide for one-half minute and carefully tipped off with blotting paper. Then apply Lugol on the slide and immediately tip off again. Apply a few drops of aniline oil-xylol and let flow off; repeat until no more blue color is given off. Finally rinse with pure alcohol and let dry. Weak fuchsin solution (aqueous) is used for the after-stain.

We have adopted the following procedure for the oxygen insufflation: Our duodenal tube is introduced in the morning on an empty stomach down to mark 90 cm., which means about 30 cm. beyond the pylorus. This so-called "deep exploration" is particularly desirable for the present purpose, as it prevents the return-escape into the stomach of too large quantities of oxygen. The outer end of the duodenal tube is now connected direct, with the regulator of an ordinary oxygen jar, and the gas is slowly allowed to flow in. From time to time, when the patient complains of distention, the influx is interrupted. In this way we were able to administer any desired quantity of oxygen. We endeavored to apply a kind of "continuous gas bath" which may last from $1\frac{1}{2}$ to 2 hours.

Instead of making two insufflations a day, as advised by Ad. Schmidt, we allowed in one case the tube to remain in situ from morning till evening and administered the second insufflation in the evening. In the meantime the patient received liquid food per os, not through the tube.

Expulsion of odorless flatus could often be observed during the administration, showing that the gas had passed the ileocecal valve.

As a rule we carried out the following program:

In the first week 1 insufflation daily;

In the second week 1 insufflation every two days;

In the third week 1 insufflation every two days;

In the fourth week 1 insufflation every three days.

Disturbances which point to serious anatomical changes localized more in the large intestines (colitis, typhlitis, etc.) may require the applications of O_2 insufflation per anum in addition to the jejunal insufflation or alone. Ad. Schmidt also reports favorable results with O_2 insufflation of the colon, notably in intestinal catarrhs of children.

Both objective and subjective results after O_2 insufflation are often so striking that the patient as well as the physician willingly undergoes this test of patience. Fermentative and putrefactive dyspepsia as well as catarrhs are favorably influenced by insufflation of oxygen, and above all the annoying symptoms and pain are arrested. Admixture of mucus to the stool is only gradually overcome and is the last symptom to yield to the treatment.

Although we have so far treated only 9 cases, we feel that our method serves its purpose exceptionally well and is worthy of being tested by others.

The diet is most carefully regulated as before.

It is, of course, impossible, and a positive mistake, to try to clear the intestine completely of bacteria; our endeavors should be confined mainly to preventing overproliferation of bacteria.

The object of the dietary measures is above all to obtain a normal intestinal wall. An efficient intestinal mucosa will furnish the friendly bacteria with improved conditions of living, while the pathogenic bacteria are deprived of a favorable culture ground.

The insufflation of oxygen will prove of incalculable value, as it will exert a directly inhibitive or paralyzing effect upon the highly pathogenic bacteria (anaerobes) by rendering their condition of life unfavorable.

Following is the description of cases treated with insufflation of oxygen:

Case I.—*Chronic Fermentative and Putrefactive Catarrh.*—Miss A. L., 22. Family history negative. Was never ill until about a year ago, when the present trouble commenced with cramps in the abdomen and increased fecal evacuations. Slight improvements were of short duration, the ailment persists almost unchanged to this day of our first examination. The first stool in the morning is sometimes formed; this is followed by 3 or 4 stools of soft consistency during the forenoon; smaller quantities are some days evacuated at rare intervals also in the afternoon. Really diarrheal, fluid stools are said never to have occurred. Large, macroscopically visible quantities of mucus were always present. A number of therapeutic measures, instituted by others, including a six weeks' stay in a hospital, were not attended with any very noticeable success. Patient is incapacitated from work and is mentally and physically depressed. Appetite varying. There never was vomiting, but often nausea. Menstruation regular. Patient is pale and, contrary to expectation, still rather well nourished. Pupils very large, teeth good, no fetor ex ore. The examination of the chest is negative. Urine is normal, indican is increased. The gastric functions have been found normal.

Proctoscopic.—Mucous membrane hyperemic, easily bleeding, granulated in places. Ulcers could not be found. No amebae could be found in the mucus adhering to the mucous membrane of the intestine. No parasitic eggs in the feces. The stool which the patient brought is of somewhat soft consistency and permeated with large mucous flakes. Color dark, dirty brown, interspersed with light parts. Reaction alkaline. Odor offensive.

Microscopical Examination.—There is neither fat nor connective tissue. A few muscle fibers and an enormous quantity of granulose bacteria. Mucus. No blood. The stool after Schmidt's test meal is somewhat better formed, enveloped by mucus, color light, reaction indistinct, odor offensive. Microscopical examination shows traces of fat in the shape of neutral fats and soap needles, many undigested muscle fibers, granulose bacteria in large quantities, mucous threads. The patient is put upon the oxygen insufflation treatment.

Third Day.—Stool somewhat better formed, uniformly dark brown, has a peculiar moldy odor, but not putrid. Mucus in large quantities. Granulose bacteria distinctly decreased.

Eighth Day.—No subjective pains. Stool formed, defecation once or twice daily; color nearly normal; still offensive; little mucus.

Fourteenth Day.—Subjective condition good. Stool.—Mucus only in traces, not offensive; bacteria few, nearly normal.

End of the Fourth Week.—Same findings; mucus only microscopically visible.

The diet consisted at the beginning of little meat of an easily digestible variety, meat jelly, little cream, butter, cream cheese, toast, biscuits; one or two eggs daily, fine cereals with sweet butter; no rice or potatoes; vegetables only after the condition improved, as finely minced spinach, also fruit jelly. Milk is better borne recently and is only given boiled with fine flour. It will still be necessary for the patient to adhere to this strict diet for another few months.

Case II.—Colitis.—Mrs. L. B., married, mother of one child. At the age of 5 she contracted a fever (typhoid?). About 18 months ago she had a severe attack of hemoptysis. Tubercle bacilli were found in the sputum. A stay in the mountains for eight months improved her condition to such an extent that she gained 30 lbs. in weight and there was no more coughing. Nor were there any more tubercle bacilli, as demonstrated by repeated examinations. During the last weeks of her stay in the country she acquired her present intestinal complaint which set in acutely with pains and violent diarrhea. The pains were abated, but diarrhea persisted to a certain degree; it occurred especially after partaking of badly digestible food. The stools were evacuated in the morning hours in rapid succession, and there were seldom complaints during the rest of the day. She lost considerably in weight.

Examination.—The old tuberculous attack which had been cured can still be demonstrated at the apex of the right lung. The spleen is not enlarged. The region of the gall bladder is not sensitive, but there is some slight sensitiveness in the region of the sigmoid. The stool is soft, dark, alkaline, of offensive odor, and contains distinct mucus. The microscopic findings reveal fat and fairly well digested meat. There are a large number of granulose bacilli which stain blue with iodine. There are no parasitic ova, especially no tubercle bacilli.

The proctoscopic examination discloses a hyperemic mucosa, easily bleeding, and dull in places. No amebae were found in the freshly obtained mucus. The urine contained hyaline casts, no sugar, indican in distinct traces. Urobilinogen negative.

After a dose of castor oil and a rigid diet, in which milk, fruit, vegetables, and certain starch products were excluded, the subjective complaints underwent rapid improvement, but with the slightest dietary error the old complaints reappear. The stool has never quite lost its pathological appearance, not even when the rigid diet was observed.

The patient then received insufflation of oxygen per anum for two weeks, which had the desired result. After as few as six insufflations the stool assumed normal appearance, which means that there was no mucus, no offensive odor, and that it was normal in consistency and color; the granulose bacilli were reduced in quantity. Two weeks after the cessation of treatment the stool was still firm, even after freely partaking of carbohydrates. There are only slight manifestations of fermentation, but no putrefaction. The patient's subjective condition is very good.

Case III.—*Typhlitis.*—Mrs. T. M., 32 years old, mother of one child. Does not remember ever having been seriously ill, but has suffered for years from constipation (hereditary). About six months ago disagreeable sensations commenced in the abdomen which were often so unpleasant as to become painful. They then assumed a more constant character and have been latterly chiefly localized in the right abdominal region. The pains radiate to the right, backward and upward, rarely to the right hip. Brisk movements sometimes aggravate the pain. The pains occur independently of meals, but the patient has a feeling of distention after eating. Advice by another physician to undergo an operation (appendicitis?) aggravates her mental depression. There is a systolic murmur at the apex of the heart the heart, however, is not enlarged. The liver is neither enlarged nor sensitive. The right kidney is not palpable. There is a distinct sensitiveness to pressure not only at the cecum, which is slightly displaced downward, but also along the ascending

colon up to the right costal arch. There is also cooing and slight movability of the parts. The function of the stomach is normal. The uterine appendages are likewise normal.

The urine contains no albumin, no sugar, traces of indican. Absence of urobilinogen according to Ehrlich's "aldehyd" test excludes an affection of the gall-bladder. Stool dark, rather firm, offensive, and covered with mucus in places.

Microscopical Findings.—Food well digested. Triple phophate crystals and fatty acid needless present, but no parasitic ova or amebæ.

Local application of ice for 10 days, semifluid but nourishing diet and warm soap enemas every evening effect rapid improvement subjectively, but not objectively, as there is still some, though reduced, sensitiveness in the cecal region and mucus in the stool. Oil injections which were now prescribed, entirely overcame the chronic constipation. After some time, however, the pains returned, showing that there had been improvement in the local conditions, but no cure.

From now on, the patient received daily insufflations of oxygen per rectum. The rectal tube, not very large, is directly connected with the oxygen cylinder, the gas is slowly introduced, and interrupted as soon as a feeling of tension occurs. In this way it is possible to keep the patient under insufflation for an hour. The colon was inflated up to the ileocecal valve and probably beyond, as the abdominal region below the umbilicus was distinctly distended. These "gas baths" were continued for 14 days, with the striking result that the conditions of the stool became normal (in color, odor, and absence of mucus). The result is equally satisfactory in reference to the ever-present local pressure pains, which have entirely disappeared. Insufflation was continued for another week. Up to the present, or four weeks after treatment, there has been no relapse. Correct diet and occasional enemas keep the stool in order.

The following additional remarks in regard to the technique of rectal insufflation of oxygen may be in place:

In some cases it may be necessary to employ a mechanical attachment in the form of a perforated trunkated cone of hard rubber, introduced with the pointed end toward the anus, to prevent the escape of gas. We have obtained the desired result in most cases by digital compression.

Part of the insufflated gas seems to be rapidly absorbed in this case, too, or else is distributed in the higher intestinal regions (ileum), because even a strong feeling of tension is rapidly relieved by a short interruption of the insufflation.

40 East Forty-first Street.

Circumscribed Lichenification (Névrodermite).—S. E. Dore reports the case of a patient, aged 40, who presented a patch of circumscribed lichenification in the right lumbar region which had existed for three years. The plaque showed the characteristic aggregation of glistening round papules, with a certain amount of thickening and slight pigmentation of the skin, but the three zones described by Brocq could not be differentiated. During the past four months the patient had had similar patches on the arms, thighs and legs, but these had recently disappeared. There was a generalized prominence of the follicles, especially on the legs, and the hairs were rubbed away by the constant scratching. According to the patient's statement, the pruritus preceded the formation of the skin lesions.—*Proceedings of the Royal Society of Medicine.*

Medicolegal Notes.

Diagrams in Supplement of Evidence.—In a prosecution for assault with intent to kill a physician and surgeon testified concerning the wounds upon the victim's body when he was called to give medical attendance immediately after the shooting. He illustrated his testimony with a diagram which he had made of the man's body and the location of the wounds, and at the end of the testimony the diagram was introduced in evidence over the defendant's objection. It was held that the diagram was admissible, not being introduced as independent testimony, but merely as a part of the witness' testimony.—Hankins v. State. Arkansas Supreme Court, 145 S. W. 524.

Malpractice—Degree of Skill in Osteopathic Treatment—Hearsay Evidence.—Suit was brought against a school of osteopathy and its vice-president for malpractice in treating the plaintiff for disease by osteopathy. The evidence showed that the plaintiff had been a trained nurse who matriculated in the school, paying a fee which entitled her to free osteopathic treatment by members of its faculty who were doctors of osteopathy duly qualified for the practice. The vice-president treated her in 1902 for some ailment from which she was suffering. In 1905 she became unable to practise her profession of osteopathy and became a confirmed asthmatic. At the time of the trial she had a distinct deformity of the thorax, consisting of an abnormal position of the breastbone and the ribs. She introduced evidence tending to show that her condition was caused by the application of the "knee treatment" by the defendant physician. The defendants introduced evidence tending to show that the plaintiff suffered from asthma when she came to the school and that the disease had since gradually progressed until she had become a confirmed asthmatic. They also introduced expert testimony to show that the result of the injury the plaintiff claimed to have received would have been much more serious than that admitted by her to have followed it. The evidence was held to justify the submission to the jury of the issue of negligence in the treatment, against the objection of the defendants that the physical facts contradicted the evidence and showed the impossibility of negligence. The Missouri statute expressly recognizes osteopathy as "a system, method or science of treating disease of the human body," and also the defendant's school as the exponent of its method and practise. It also expressly authorizes persons having diplomas from that or any other legally chartered school of osteopathy to treat diseases of the human body according to such method. It was therefore held that an instruction that if the treatment was improper and not such as an ordinary skilled man would have given the plaintiff under the circumstances the verdict must be against the corporation and its agent was objectionable because it ignored the fact that the plaintiff had submitted to the treatment by osteopathy and gave the jury the right to find that osteopathic treatment was not a proper treatment, and that the person administering it was not ordinarily skillful. The error was, however, held not to be prejudicial where the undisputed evidence showed that the treatment as described by the plaintiff was improper according to osteopathic methods. Judgment for the plaintiff was reversed because the plaintiff was permitted, against the objection of the defendant properly made, to testify on the trial that the osteopath who, at the instance of the defendants, treated her after the date of the alleged injury for the ailments from which she was then suffering, told her that her second, third, and fourth ribs were broken, caused from the defendant physician's treatment. The cause of her condition being the real question in issue, such hearsay evidence was held to be inadmissible.—Atkinson v. American School of Osteopathy, Missouri Supreme Court, 144 S. W. 816.

Qualification as Expert on Insanity.—A lay witness who has handled a great many insane persons, and has observed and studied them in the course of their transfer by him from one point to another and who has "lately read medical works on the subject, and studied in that way" is not thereby qualified to testify as an expert on insanity. The general rule is that only medical men—persons licensed by law to practise the profession of medicine—can testify as experts on the question of insanity. An exception, it was said, may perhaps be recognized where the witness has made a protracted and systematic study of mental science and disease under approved conditions. But the rule is that the competency of an alleged expert is addressed to the sound discretion of the trial judge.—Odom v. State, Alabama Supreme Court, 56 So., 913.

THE SPIROCHETES.

THE question as to whether the spirochetes are protozoa or bacteria, that is animals or plants, is one about which there has been much controversy in recent years. The distinctions which decide such a question are purely arbitrary and such a controversy is only of academic interest. At the time of the earliest descriptions of spirochetes, some of those organisms which we know to-day as bacteria were also regarded as animals. That this is true is shown by turning to the beautifully colored illustrations published by Ehrenberg in 1838. There one finds accurate representations of a large spirochete which occurs in pond water as well as of some of the bacilli; both being regarded as animalculæ and so classified; in fact, the term bacilli of modern usage came from the former zoological group name, *Bacilli*. It was only after the introduction of methods of artificial cultivation by Pasteur and his followers that we came to have exact knowledge of the bacteria. Knowledge of a great many varieties of spirochetes was gained, however, simply by observing their differences in form and behavior; large varieties like those which commonly occur in the stomach of the oyster, and small varieties like those which occur in the mouth of man. The animal nature of the larger varieties with crista and elastic bodies can hardly be denied; it is the more minute spiral organisms that have been the subject of controversy. These small spirochetes, many of which are harmless, are of such widespread occurrence, that the mere finding of a spirochete associated with a disease process is not sufficient to prove the causal relationship. In fact, from 1837, when a spiral microorganism was believed by one observer to be the cause of syphilis, until as late as 1905, all observations, except those of relapsing fever, in regard to the pathogenicity of spirochetes were doubted. It was then that Schaudinn recognized the differences in form between the organism of syphilis, *Treponema pallidum*, and the common varieties of spirochetes. With these correct descriptions and definite names of the different species, the knowledge of spirochetes became greatly advanced and the scientific world became convinced that an organism of this nature is the cause of syphilis. We should remind ourselves that it was just such niceties as zoologists quibble about that finally resulted in the determination of the pathogenic spirochetes.

The next step was to cultivate these and make them satisfy the postulates of Koch. Little by little it was shown how spirochetes might be cultivated, and to-day Noguchi has successfully cultivated in artificial media all of the known pathogenic species, except possibly the variety associated with Vincent's angina. It was by virtue of an animal quality of the most elusive variety, the spirochete of syphilis, that he succeeded in capturing it free from all bacteria; for he obtained his pure culture from where the spirochete had moved out into the solid media. These pure cultures when reinoculated into animals produced the disease from which they were originally obtained and thus conformed to the postulates of Koch.

In his latest publication (*Journal of Experimental Medicine*, Vol. XVI, No. 5, November 1, 1912), Noguchi reports having successfully cultivated *Spirochæta gallinarum*, the cause of a febrile disease of chickens. In itself this is of no great importance to the practitioner of medicine, but some of his findings are of general interest. In the first place he has found that these spirochetes do not pass through the filter, through which they were at one time believed to be able to pass. This is interesting because it demonstrates that in the past the filter may have only hindered the progress of morphological research instead of aiding it. Statements in regard to filters, however, cannot be absolute, as one must consider their thickness and quality as well as the pressure and length of time used. In the second place he has shown that these spirochetes can be propagated indefinitely in artificial media, and thus disproves the idea that another phase of their life cycle, passed while contained in the bodies of ticks, is essential to their continued propagation.

This important work of Noguchi in obtaining pure cultures of the various pathogenic spirochetes makes it possible now for scientists to come closer to obtaining perfect remedies for the diseases caused by these organisms, and, let us hope, remedies unencumbered with proprietary rights. But to the question as to whether they are protozoa or bacteria there is no answer, for just at the time spirochetes were found to grow in solid media, the supposed exclusive manner of growth of bacteria. Anna Williams (*Journal of Medical Research*, Vol. XXV, 2) succeeded in cultivating on solid media, without symbiotic bacteria, amebas, the animal nature of which has never been questioned.

THE MAKING OF THE PHYSICIAN.

AT the one hundred and seventy-ninth session of the Edinburgh Royal Society, held on October 18 last, Dr. Robert Hutchison of London delivered an address (*Medical Press and Circular*, October 23, 1912), in which, taking as his text the saying of Bacon that "reading maketh a full man, conference a ready man, and writing an exact man," he developed it into an instructive address on the function of such a society in the medical curriculum. The use of a library was not

only to provide material for reading, but for reading in the proper way, to get up information concerning subjects in which one was really interested for the time being. Next to being really well read in a subject came the ability to find out in what books the best information could be obtained. If the student learned nothing else than how to use the Index Medicus, he had gained a great deal. He was of the opinion that the student ought to depend largely on text-books, and lesson journals in his work. Ephemeral literature was rather dangerous fare. The older writers of the last century ought never to be neglected. In reading them one misses, perhaps, the scientific treatment of the day, but one gains a more practical viewpoint than is induced by much of the present-day laboratory work. One comes to see that many so-called new discoveries are in reality but old truths; and lastly, one finds that a text-book need not be dry, but may have charm and literary style. Hutchison advised the medical student to endeavor to become versed in general literature, for it was essential that the doctor of to-day should be a well-read man; the time was past when it was necessary for him only to know of drugs and the symptoms of disease.

Debates supplied the readiness of mind begotten of what Bacon called conference. It was necessary that the physician should be a more or less ready speaker, for nowadays he was often called on to explain in clear and concise language medical and scientific matters, especially in the domain of preventive medicine, to the general public. The art of speaking could be acquired only by practice, and debates afforded such practice. Another most valuable qualification for a doctor which could be acquired at society meetings was the power of suspending judgment until all the facts were known; and, lastly, he would learn—at least some of the members would learn—to bear with fools gladly.

It certainly is becoming more evident that the physician should be a well-read man, and the time is rapidly passing when a man of little or no education could join the profession. A general education tends to widen the mind. The faculty of extracting the most valuable information from books is not common, but the advice may be given to read with this object in view only standard works. Promiscuous and ill-regulated reading is nothing less than mental dissipation, which is antagonistic to that concentration of mind at which all students should aim.

The medical student should not neglect general literature, both as a relief from technical subjects and as a means of widening his knowledge. As for speaking, there can be no doubt that the doctor should practise the art, for, as a rule, he does not shine as an orator. The doctor of the present time should be an all-round man, and with this end in view he should be thoroughly grounded in the humanities ere he commences the study of medicine, for it must be borne in mind that his medical curriculum is so full that he will have little time to spare for outside studies when he has entered upon his medical studentship.

EUGENICS AND EUTHENICS.

THERE appears to exist at the present time a marked tendency on the part of the advocates of eugenics and euthenics severally to magnify the influence of their especial pet theory. Those who hold that heredity is at the base of most human ills claim that environment counts for little, while per contra the supporters of euthenics insist that environment is at the root of all the trouble. It is difficult, indeed for the present impossible, to hold the scales evenly and to adjudge to each factor the amount of influence it exerts. Much ink is being spilled in this endeavor, but we appear to be as far away as ever from arriving at a just conclusion. When the greatest authorities on the matter express entirely divergent views, what are the humble rank and file to think?

In the *Popular Science Monthly* for November, 1912, Professor Leon I. Cole takes the ground that acquired characteristics are in no specific sense inherited, and argues, therefore, that the proper place of environment in a eugenic program is not a simple question. In the first place, it is very difficult to separate these characters which are the results of inborn determinants from those which are produced solely by reaction to environment. Or, it may be, as is probably usually the case, that both influences are at work in the expression of the same character. Cole expresses decided views as to the menace of immigration, stating that the scum of Europe is imported to supply the cheap labor by which the rich man may amass his millions. As to the decreasing birth rate of civilized countries, the writer says again what many authorities have been endeavoring to impress on the minds of statesmen, philanthropists, and social workers for years, that the dangers arising from this fact do not consist so much in the falling birth rate itself as in the fact that, because of it, the worst and not the best types are being reproduced.

There is really no cause for a conflict between eugenics and euthenics. Neither can accomplish the results that its enthusiastic followers claim, but that is no reason why each system should not effect much. The two methods should work together in harmony and there is no doubt that intelligent co-operation will tend to produce a better race mentally and physically. The eugenists, however, while laying much stress on the successful breeding of animals and plants, apparently forget that human beings are neither animals nor plants. If the sole aim were physical excellence then careful breeding would to some extent answer the purpose. But human beings are different from animals and plants, in so much as brain power is of equal if not of greater importance than physical perfection or even good health.

As a matter of fact, supreme powers of the body seldom accompany the agile brain, and perhaps more frequently than not a high order of brain is lodged in a creaky tenement of clay. There is much to be said for eugenics and euthenics, but the eugenists are somewhat too apt to be dim of sight with regard to the merits of any method other than their own.

RELAPSING FEVER AT PANAMA.

An interesting outbreak of relapsing or seven-day fever has been reported in the Canal Zone by Surgeon J. C. Perry of the U. S. Public Health Service (U. S. Public Health Reports, Nov. 1, 1912). This disease, it will be remembered, is caused by the spirochete of Obermeier and is characterized by a definite febrile course of about six days, followed by a remission of a similar duration, and this remission and relapse may be repeated several times. The disease has always been associated with the same conditions which favor the spread of typhus fever, overcrowding and filth apparently playing a more important part than sex, age, season, or other factors. Since the spirochete is found in the blood in the febrile stage, it would seem probable that bedbugs, ticks, and other biting and blood-sucking pests might be important agents in its transmission. The disease has been produced in man and monkeys by infected blood. The spirochete has not been found in the excretions or secretions. Relapsing fever has seldom been seen in the United States since the New York and Philadelphia epidemic of 1869.

Enough has been said to show the interest attaching to the outbreak reported by Perry. In all, 62 cases of the disease were found in the Canal Zone, of which 43 were treated in the Ancon hospital. Most of the cases developed in the Ancon post-office and the residence building for bachelors opposite to it. All were in adults and all but two were in men. It is a matter of interest that no cases were found in Spanish or Italian laborers, or in negroes.

The cases presented the usual clinical picture of the disease. Fifty per cent. showed a rash, confined to the legs, feet, forearms, and hands. In a few it was finely petechial. Curiously the fever consistently ran a single course after continuing with remissions for six days, declining by slow crisis in from twelve to fourteen hours.

This outbreak illustrates forcibly the need of a hospital in the Canal Zone so situated and conducted that it could utilize the wealth of new clinical material which will be found there for study and observation. Considering the great intercontinental traffic which will center at the isthmus upon the completion of the canal, and the large number of sailors who will congregate or pass through there from all parts of the world, it is evident that a marine hospital will be a prime necessity. The Public Health Service now operates 23 marine hospitals in the larger ports of the country, besides 120 other stations, for the medical relief of American merchant seamen. In addition to this there is the large tuberculosis sanatorium at Fort Stanton in New Mexico. This medical relief is free for American sailors and only a nominal sum is charged for the care of foreign sailors. A marine hospital will certainly be needed at Panama and its maintenance there will afford excellent opportunities for the study of epidemic and other diseases, not only those of the tropics but those peculiar to every nation and clime on the face of the earth.

International Standardization of Disinfectants.

The question of standardizing disinfectants was discussed at the recent International Congress on Hygiene and Demography held in Washington. Two resolutions bearing on the subject were passed. First, "that the disinfectants used in different countries should be controlled by a simple bacteria test, capable of being easily effected, and that a committee from this Congress confer with the Committee of the International Congress on Applied Chemistry to define such tests." Second, "that the Permanent International Commission of the Congress of Hygiene and Demography be requested to appoint a committee of not less than five members to represent the Congress for that purpose." These resolutions are decidedly steps in the right direction and should result in the establishment of a method for the standardization of disinfectants which shall be uniform and satisfactory. At the present time, however, opinions differ somewhat widely with regard to the means to be adopted whereby the germicidal value of disinfecting preparations may be fixed. In this country, even more than in Europe, adequate measures for standardizing disinfectants are needed, as practically any preparation may be manufactured and sold concerning which the public have no mode of discovering whether such are effective or otherwise. In Europe and in Great Britain, although it is acknowledged that the methods employed to protect the public are by no means wholly satisfactory, yet some restraint is placed on the manufacture and sale of manifestly useless disinfectants. As is pointed out in the *Lancet* of October 26, its commission which investigated the matter some few years ago found that different lines of experimentation produce different results, and therefore probably a considerable time will elapse before a perfect or entirely satisfactory method will be evolved. The sooner the resolutions passed at Washington are acted upon, the better it will be for the public. There would seem to be no valid reason why an international investigation of this nature should not be commenced at once and the question of disinfectants placed on a satisfactory basis for all time.

Citrate of Sodium in Gastric Pain.

Remedies for the gastric pain which so frequently occurs after eating have been and are legion. As is pointed out by the Paris correspondent of the *Medical Press and Circular*, it is generally attributed to hyperacidity and treated by alkalies, chalk, magnesia, and especially by bicarbonate of sodium. Almost, however, in the same measure as these alkalies relieve the pain, at the same time they stimulate the secretion of the hyperacid gastric juice. It has been stated on the authority of Hayem that certain patients who had prolonged the use of bicarbonate of sodium eventually found that it had no effect on their sufferings. Wright in England was the first to use citrate of sodium for gastric pain and recently it has been introduced into France and prescribed with great success in gastric intolerance of children. Lacheny, who has been writing on the matter recently, describes how sodium citrate relieves gastric suffering coming on three or four hours after meals. Not only, he says, does it relieve gastric pain, but it has also a remarkable curative effect on the morning vomiting of drunkards.

News of the Week.

Health of the Canal Zone.—The reports of the Chief Sanitary Officer of the Isthmian Canal Commission for the months of August and September, 1912, gives the total number of deaths from all causes among employees as 42 and 39 respectively, making an annual average rate per thousand of 10.01 and 9.19. The total death rate among the entire population was 25.69 and 22.42 for the two months, the calculations being made on the basis of the census last February which gave the population of the cities of Panama and Colon and of the Canal Zone as 62,810. The principal causes of death were: Tuberculosis, 16; lobar pneumonia, 11; malaria, 3; dysentery, 1. Twenty-two deaths were due to external violence. No cases of yellow fever, smallpox, or plague originated on or were brought to the Isthmus during the time covered by the reports.

Lloyd-George's Terms Again Rejected.—At a meeting of the British Medical Association on November 19, a resolution was adopted declaring that the proposals of the Chancellor of the Exchequer in regard to the compensations of doctors under the Insurance Act, are "unworkable and derogatory to the medical profession, and consequently the profession declines to undertake service under the act and the regulations as at present instituted." The members of the association, however, expressed their willingness to confer with the authorities with a view to settling the disputed points.

Hospital Permit Denied.—The application made by the Westchester County Board of Supervisors for permission to establish a hospital for tuberculosis patients at Yorktown,, N. Y., has been denied by State Commissioner of Health Porter. This decision is final, and is based upon the objections of the New York City authorities and civic organizations on the ground that the establishment of such an institution at Yorktown would be dangerous because of possible contamination of the water supply of New York.

Sanitary Science.—Three courses in sanitary science are being offered at the Tulane University of Louisiana, New Orleans, for medical, science, and engineering students specializing in sanitation. Instruction is given in the School of Tropical Medicine which is a part of the university.

National Housing Association.—The second National Conference on Housing in America will be held on December 4, 5, and 6 in Philadelphia, which has been selected because it has more to show in the way of constructive effort than any other American city..

Postal Raid.—By concerted action in seventy-two cities in twenty-two states, post office inspectors on November 20 arrested or prepared to arrest 175 men and women charged with having used the mails in the sale of illegal medical and surgical devices. The raids, which were ordered by the Postmaster-General after six months' preparatory work, embraced alleged quack doctors, druggists, and proprietors of so-called medical establishments. Two arrests were made in New York. The raid, which as a whole was the largest ever made in the history of the Post Office Department, furnished an excellent example of the power which can be exercised through the postal laws to wipe out illegal practices apparently beyond the control of the State authorities.

Pregnancy after Oophorectomy.—Dr. George W. Kosmak, of 23 East 93d street, New York, writes that, being interested in this subject, he would appreciate information from any of our readers who have had cases of this kind, and care to favor him with an account of the same. The facts desired involve the question of the relief of sterility following this operation, the character of the labor where pregnancy has occurred, the indications for removal of the ovary, the pathological condition of the same, an account of any other operations done at the same time, the character of the menstrual period subsequent to the operation, the date of birth of subsequent children, and their sex. A blank form has been prepared which embodies these questions and which will be forwarded in reply to a post-card request.

Public Clinics.—Commissioner Drummond has ordered that on and after October 1, 1912, all clinics held in the amphitheatres and operating rooms of the hospitals of the Department of Public Charities shall be open to duly licensed graduates in medicine and to the students in all regularly organized medical schools and colleges.

For the convenience of those desiring to attend the Clinics, the cards of admission have been placed at the Academy of Medicine, 17 West 43rd Street, Manhattan, and the Medical Society of the County of Kings, 1313 Bedford Avenue, Brooklyn, at which institutions they may be obtained on personal application by all regularly registered physicians. Commissioner Drummond has also issued an order to the Superintendents of the several hospitals, directing that each day before 9:30 A. M., an explicit list of Clinics, both medical and surgical, to be held on that day shall be telephoned to the Academy of Medicine and the Kings County Medical Society, in order that those physicians who wish to attend the Clinics may have timely information as to their precise nature, and select such as are deemed of special educational value to them. A calendar of the Clinics to be held during the month of December will be found on page 1015. A schedule of the Clinics to be held during the present season will shortly be issued in pamphlet form.

Associated Clinics.—Delegates representing twenty-nine dispensaries in the Borough of Manhattan, New York, met at the Academy of Medicine on November 20 and organized an association to be known as the Associated Out-Patient Clinics of the City of New York. The aims of the association are the co-ordination of the work of existing dispensaries and clinics, the elimination of unworthy applicants for treatment, and the promotion of proper standards of treatment and of economy and efficiency in dispensary management.

Medical School Needs.—In his annual report for the year ending June 30, 1912, President Nicholas Murray Butler of Columbia University, New York, places the amount of money required to meet the present needs of the university and the general schemes for its development at approximately $16,000,000. Of this $6,000,000 is the estimated cost of removing the College of Physicians and Surgeons from its present site, in accordance with the agreement with the Presbyterian Hospital. Concerning this agreement, President Butler, after pointing out that the affiliation so far accomplished has not been accompanied with any of the difficulties feared, says: "It is now clear to hospital managers that the mere cure of the ill and suffering is

only one-half of a hospital's business. The other half is to assist in the study of disease and in the better training of those upon whom is to devolve the responsibility for the prevention and cure of disease hereafter." President Butler asks also for $1,000,000 in order that the university may establish a fitting Institute of Hygiene and Preventive Medicine.

Gifts to Charities.—By the will of the late Dr. Frank J. Parker of New York, the Yale Medical School receives a trust fund of $1,000, the income to be awarded to the student who shows the best qualifications for succeeding in the practice of medicine, personality, habits, neatness of dress, common sense, and kindness and human feeling in the treatment of the poor and unfortunate, to be considered. To his native town of Branford, Conn., Dr. Parker gave thirteen acres of land for a public park in memory of his parents, and to the Manhattan Eye, Ear, and Throat Hospital, New York, of the staff of which he was a member, a half interest in his city property, the value of which is not stated.

The Presbyterian Hospital of Philadelphia receives $5,000 for the endowment of a free bed by the will of the late Miss Elizabeth Norris Brown; the Children's Hospital also receives the sum of $1,000.

The Boston Lying-In Hospital, as residuary legatee under the will of the late Mr. Francis Amory of Boston, will benefit to the extent, it is estimated, of $500,000. The sum of $25,000 is given to the American Academy of Arts and Sciences in memory of Thomas Amory, with the provision that the fund shall be allowed to accumulate for twenty-one years and that the income shall then be given as a septimal prize with a gold medal to the individual who shall discover any notable useful remedy or invent any cunning device or instrument for the treatment of certain diseases, or in the absence of such a discovery, to the individual who has written the best treatise on such diseases.

By the will of the late Mrs. Mary Huntington Cooke, the Cambridge, Mass., Hospital receives the sum of $5,000.

Convalescent Home.—The Sanitarium for Hebrew Children at Rockaway Park, N. Y., is planning to remain open during the entire year as a convalescent home for invalids from the general hospitals. During the past the institution has been open for only two months of the year.

Sir Thomas Crosby, the retiring Lord Mayor of London, although eighty-two years of age, is preparing to return to the practice of surgery after laying down his official duties.

Geheimrat Dr. Wilhelm Ebstein, professor of internal medicine at the University of Göttingen from 1877 until 1906, and previous professor and director of the medical clinic at the University of Breslau, the author of many books and treatises on medical subjects, died on October 22 at the age of seventy-six years. He was known more especially for his studies of obesity and for having devised a very efficient method of reduction.

Southern Medical Association.—The sixth annual convention of this association, which embraces the states of Mississippi, Tennessee, Georgia, Alabama, Louisiana, and Florida, was held in Jacksonville on November 12, 13, and 14, the following officers being elected for the ensuing year: *President,* Dr. Frank A. Jones, Memphis; *Vice-Presidents,* Dr. Stuart McGuire, Richmond, and Dr. James D. Love, Jacksonville; *Secretary-Treasurer,* Dr. Seale Harris, Mobile.

Tristate Medical Society.—With an attendance of about fifty members from the states of Arkansas, Louisiana, and Texas, the annual meeting of this society was held in Shreveport, La., on November 12 and 13. Officers for the ensuing year were elected, as follows: *President,* Dr. Thomas B. Younger, Fisher, La.; *Secretary-Treasurer,* Dr. J. M. Bodenheimer, Shreveport, La.; *State Vice-Presidents,* Louisiana, Dr. John L. Scales, Shreveport; Texas, Dr. W. G. Hartt, Marshall; Arkansas, Dr. T. V. Sauter, McNeil.

Southern Illinois Medical Association.—The following new officers have been elected: *President,* Dr. Harry E. Wilson, Centralia; *Vice-President,* Dr. W. E. Lingle, Cobden; *Treasurer,* Dr. James W. Armstrong, Centralia; *Secretary,* Dr. Charles W. Lillie, East St. Louis.

Obituary Notes.—Dr. Caesar A. Von Ramdohr of New York, a graduate of the New York University Medical College in 1877, a member of the New York State and County Medical Societies, the New York Obstetrical Society, the Society of Medical Jurisprudence, and the German and Yorkville Medical Associations, professor emeritus of obstetrics in the New York Post-Graduate Medical School, consulting obstetrician to the Post-Graduate and St. Mark's Hospitals, and consulting gynecologist to the People's Hospital and the German Poliklinik, died suddenly at his home of Bright's disease on November 17, aged 57 years.

Dr. Robert Ferguson Chapman of New York, a graduate of the University of Maryland, School of Medicine, Baltimore, in 1865, and a member of the Maryland Society of New York and the New York Southern Society, died at his home on November 11, aged 71 years.

Dr. Francis Duffy of New Bern, N. C., a graduate of the University of Virginia, Department of Medicine, in 1868, a member of the North Carolina State and Craven County Medical Societies, acting assistant surgeon of the Marine Hospital Service, and a member of the County Board of Health, died at his home of typhoid fever, on November 5.

Dr. James W. Abercrombie of Warwood, W. Va., a graduate of the Medical Department of Western Reserve University in 1888, a member of the American Medical Association and of the West Virginia State and Ohio County Medical Societies, and formerly Mayor of Warwood, died at his home after a long illness, on November 7, aged 53 years.

Dr. Lucius Wadsworth Clarke of Cambridge, Wisconsin, a graduate of the University of Vermont College of Medicine in 1863, and a surgeon in the United States Army during the Civil War, died on October 31, in the home in which he had lived for forty-five years, at the age of 81.

Dr. J. Denham Palmer of Jacksonville, Fla., a graduate of the University of Maryland School of Medicine, Baltimore, in 1872, and a member of the Florida State and Duval County Medical Societies, died in St. Luke's Hospital, Jacksonville, as the result of an accident, on November 3, aged 62 years.

Dr. Edgar DuBois Biddle of Patoka, Ind., a graduate of the Missouri Medical College, St. Louis, in 1880, died in the Presbyterian Hospital, Chicago, on November 7, aged 55 years.

Dr. Bradford S. Gallaway of Los Angeles, Cal., a graduate of the University of Michigan, Department of Medicine and Surgery, in 1880, formerly a prominent physician of Colorado and of Nevada

died suddenly, from embolism on November 2, aged 58 years.

Dr. GABRIEL G. BICKLEY of Waterloo, Iowa, a graduate of the Philadelphia College of Medicine and Surgery in 1863, died at his home of diabetes on November 1, aged 72 years.

Dr. ALDEN MARTIN of Norwalk, Ohio, a graduate of the Cleveland University of Medicine and Surgery in 1896, died suddenly on November 10, aged 44 years.

Dr. LYNN B. GRADDY of Nashville, Tenn., a graduate of the University of Nashville, Medical Department, in 1874, died at his home in Lexington, recently, aged 67 years.

Dr. THOMAS STANHOPE HENRY of Brookneal, Va., said to be the last surviving grandson of Patrick Henry, a graduate of the Medical College of Virginia, Richmond, in 1864, died at his home on November 11, after a long illness, aged 80 years.

Dr. RICHARD ALSOP CLEEMAN of Philadelphia, Pa., a graduate of the University of Pennsylvania, Department of Medicine, in 1862, a veteran of the Civil War, and a member of the American Medical Association, the Pennsylvania State and Philadelphia County Medical Societies, the Philadelphia Obstetrical Society, the Philadelphia Pediatric Society, and the Philadelphia Pathological Society, died at his home on November 19, aged 72 years.

Dr. W. ROSS BUSTARD of College Point, N. Y., a graduate of the College of Physicians and Surgeons of Cleveland, O., in 1901, died at his home on November 18.

Dr. EDWARD PAYSON SMALL of Philadelphia, Pa., a graduate of the Homeopathic Medical College of Pennsylvania, Philadelphia, in 1866, died at his home on November 16, aged 74 years.

Dr. JOHN C. SUNDBERG of Seattle, Wash., a graduate of the Northwestern University Medical School, Chicago, in 1874, a member of the American Medical Association and the Washington State and King County Medical Societies, and formerly United States Consul at Bagdad and physician to the Sultan of Turkey, died at his home on November 19, aged 67 years.

Dr. FRANCIS R. GERHARD of Douglassville, Pa., a graduate of the University of Pennsylvania, Department of Medicine, in 1869, died in Reading, Pa., on November 14, aged 69 years.

Dr. JOHN STEWART of Philadelphia, Pa., a graduate of the Jefferson Medical College, Philadelphia, in 1896, a member of the American Medical Association and the Pennsylvania State and Philadelphia County Medical Societies, died at his home on November 14, aged 40 years.

Dr. ISAIAH BEE of Princeton, W. Va., a graduate of the Cleveland Medical College in 1860, died at his home on November 15, aged 81 years.

Dr. PRESLEY B. OGDEN of Shinnston, W. Va., a graduate of the Jefferson Medical College, Philadelphia, in 1867, died at his home on November 17, aged 72 years.

Dr. HARTLEY SPINNEY JACQUES of Halifax, N. S., a graduate of the New York University Medical College in 1887, died at his home after a long illness on November 11, aged 54 years.

Dr. RICHARD M. FLETCHER of Birmingham, Ala., a graduate of the University of Alabama, Medical Department, Mobile, in 1894, died at his home on November 9, after a long illness.

Dr. ARTHUR MACCABE of Gloucester, Mass., a graduate of the Baltimore University School of Medicine in 1897, a member of the American Medical Association, and of the Massachusetts State and Essex County Medical Societies, and formerly city physician and chairman of the Board of Health of Gloucester, died at the Addison Gilbert Hospital on November 12, aged 44 years.

Dr. WILLIAM O. BEAM of Moline, Ill., in 1893, was burned to death on November 14, while attempting to save some valuables from a burning stable. He was 43 years old.

Dr. SAMUEL M. CLEVELAND of Philadelphia, Pa., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1875, died November 23 after a long illness, aged 75 years.

Obituary.

JAMES WOODS McLANE, M.D.

NEW YORK.

DR. JAMES W. MCLANE, formerly one of the most prominent obstetricians in New York, but for several years retired from active practice, died at his home in this city on Monday of this week. He was born in New York August 19, 1839; was graduated in arts from Yale in 1861, and in medicine from the College of Physicians and Surgeons in 1864. He was connected with this school for nearly forty years in various capacities: first lecturer, then professor of materia medica and therapeutics from 1867 to 1872; professor of obstetrics and gynecology from 1872 to 1898, and appointed emeritus professor in 1898. He was dean of the medical faculty of Columbia University from 1891 to 1903. He was at various times attending physician to the New York, St. Luke's, Roosevelt, Nursery and Child's, and Sloane Maternity Hospitals. It was through Dr. McLane's influence that the money was given for the erection of the Vanderbilt Clinic and the Sloane Maternity Hospital.

(From Our Regular Correspondent.)

BRADSHAW LECTURE—UNION OF MEDICAL SCHOOLS—HUXLEY LECTURE—HOUSING AND HEALTH—INSURANCE TROUBLES—MUSEUM OF HEALTH APPLIANCES—MEDICAL HISTORY—OBITUARY.

LONDON, November 8, 1912.

THE Bradshaw lecture at the Royal College of Physicians was delivered by Dr. D. B. Lees. He took for the subject of his discourse the "Diagnosis and Treatment of Incipient Pulmonary Tuberculosis," and, contrasting the mortality of this with other forms, he held that if one would eliminate this we could be assured of victory over the others. In the United Kingdom the annual deaths from phthisis numbered no less than 50,000, while other forms of tuberculosis accounted for less than half as many —20,000. To get rid of the disease the first thing to be done, said the lecturer, was to insure that every medical man should be able to detect it at the earliest moment it appeared, that was long before the bacillus was to be found in the sputum. To meet it at that stage, moreover, a simple, harmless, inexpensive but effectual method of home treatment must be devised. Waiting for a bacteriological report was dangerous, and such delay must be held responsible for many deaths from tubercle. In percussion they had a means of early diagnosis. The use of *x*-rays had now become available, but the

practitioner who had learned to trust his own percussion could dispense with the radiograph, for he held in his own hands the possibility of a correct early diagnosis. I am glad to report so distinct a testimony to the value of percussion, although I cannot call it new, for it reminds me of equal reliance on the method by some who passed away before the bacillus or the *x*-rays were discovered, but who taught so confidently the supreme importance of early diagnosis, and that this could be attained by careful proper percussion. But ears and fingers must both be trained for the purpose. As regarded treatment, Dr. Lees said a great deal had been heard about sanatoria and tuberculin, but there was no little skepticism in the profession as to these methods. The value of sanatorium treatment was doubted by many observers. It was undecided whether tuberculin should be used in large or small doses and whether the patient under it should rest or continue to work. Was it certain, he asked, that the administration of ordinary antiseptics was of no use? Why should they not employ them by inhalation? Here again I seem to be listening to older teaching, the use of which I saw before recent discoveries put them aside with brighter promises which have not been fulfilled. Dr. Lees gave an account of 70 cases treated in this manner, a mixture of creosote, iodine, alcohol, ether, and chloroform being employed. Of the 70 patients, 48 completely recovered, 10 were incompletely cured, 3 probably recovered, 7 died (some from other diseases), 3 cases were not traced. This seemed to the lecturer effective home treatment, and with the earliest possible diagnosis so many cases might be saved that they could hope for the day when pulmonary phthisis would be a disease of the past.

It has long been recognized that there are too many medical schools in London, and from time to time there have been suggestions for amalgamation. This week a step in that direction has been taken by the transference of the new bacteriological and public health laboratories of Charing Cross Hospital to King's College department of the University of London. This is but the natural result of the arrangement made last year when the teaching of the preliminary subjects was handed over to King's College. The ceremonial transfer was performed by Prof. S. Flexner on behalf of the school committee. In doing so he remarked that the bringing together such large populations as those of London and New York was a fact which rendered proper quarantine impracticable. It was a duty of universities and medical schools to instruct the public how to meet the dangers which threatened. The object of the school was to teach what was known and to find out what was still wanted to be known..

The Chairman of King's College (the Hon. W. F. D. Smith) spoke of the monumental skill and labor of Dr. Hunter, which had made it possible to open the laboratories, and said they would be used for research and post-graduate teaching. Dr. Headlam (Principal of King's College) emphasized the advantages of concentration and hoped other hospitals would join in the scheme, but not to squander money on great buildings. Their hope was to gradually develop a complete institute of public health. Sir H. A. Miers (Principal of the University) said the problem of university education in London rested with the teachers and required the cooperation of all. A real example of what ought to be done was that before them.

Afterward the Huxley lecture was delivered at the hospital by Professor Flexner, who took as his subject "Recent Advances in Science in Relation to Practical Medicine." He recognized perhaps too briefly the work of Huxley in biology and his early recognition of the discoveries being made in his time as to fermentation, putrefaction, and their relation to disease. In fact, Huxley saw, said the lecturer, that bacteriology was about to throw a protecting mantle, not only over men, but over all the higher animals, and even, perhaps, over plant life. Up to now, he continued, bacteriology had distributed its favors unequally. In some instances the knowledge of diseases it had given us was of slight value, but in others it was of great importance. Professor Flexner then took up the subject of poliomyelitis, which he examined in great detail, and relating the story of the working out of its natural history—a disease which has claimed his attention for several years, and illustrated the advances in science in relation to practical medicine, to which he desired to draw attention.

The Chairman of the London Insurance Committee (Mr. J. A. Dawes, M.P.) on Wednesday addressed the Mansion House Council on health and housing, respecting the sanatorium benefit which he said was now in force, and by no means meant, necessarily, residence in a sanatorium. The idea of his committee was to take a number of hospital beds for observation of cases. They had formed subcommittees in the different boroughs and he expressed gratitude for the assistance received from the Medical Officers of Health. There would be needed a dispensary in each, and he hoped that they could think of all forms of treatment. They had had 460 applications and all were under treatment or being arranged for in some way or other. The Asylums Board could provide 1,000 beds, but as it was a Poor Law institution it was said it could not be used, the act not permitting. But they were negotiating with the County Council, which, it was said, could act as an intermediary. This difficulty is being spoken of generally as an illustration of the evils of hasty legislation.

All the week we have been troubled with the insurance dispute. Meetings, circulars, correspondence, and discussions have intruded at every turn. Even the Parliament has been talking of the doctors and the act. The National Medical Union has sent a circular to every practitioner saying it is not prepared to compromise on any of the six points on which it supported from the first the British Medical Association. At a meeting in Westminster, attended by men from all districts of the metropolis it was resolved that the provisional rules, combined with the fresh statement of the Chancellor, though not securing all the reasonable demands, afford a basis for negotiation. The British Medical Association has written to the Chancellor on some of the points at issue, and has received a lengthy reply in which Mr. Lloyd George explains or explains away previous remarks. Thus, the inspection to which objection was made he holds necessary, but will be made by medical inspectors. The keeping of records of cases is to be in books provided by Government, and not much more than the common visiting lists in use by many, and will not be open to others than inspectors and so far "secret." This will concern the patients as well as the doctors, who will scarcely like to have their practice overhauled even by other medical men. Mileage is to be provided, but out of the amount set apart for remuneration, which still appears to be liable to uncertainty,

although Mr. Lloyd George estimates it at 7 shillings. If he had offered that as a firm, flat rate I believe it would have been accepted, but he has mixed it up with such a mass of verbiage that many doubt what he really means and others reflect that his financial estimates usually turn out erroneous. The Council of the British Medical Association met and considered his letter, and determined to leave the matter entirely to the representative meeting which is fixed for the 19th and 20th inst. The Council thus declines to give any lead to the profession, and though it fought well and secured wide support, it seems now afraid to push home its advantage. Probably this hesitation will be reflected among the representatives.

A museum of safety and health appliances is to be established in Westminster, where the Government has secured a central site and will erect a building for the purpose.

Another section of the Royal Society of Medicine has been practically established, more than 100 members having joined it and the first meeting being fixed for the 20th inst. The subject to which it is devoted is medical history. At the opening there is to be a paper on epidemic diseases and an account of some early medical portraits, of which a number will be exhibited together with early manuscripts. Such a society has many times been proposed, but hitherto we have not had one here, though you have in the United States, I think, and there is one in France and another in Germany.

Dr. Fred. Bagshawe, Justice of the Peace of St. Leonard's, died on November 2. Always an active man, he continued work almost to the last, and reached the age of 80. He graduated at Cambridge, A.M. and M.D., 1861-65, joined the College of Physicians, 1865, and was elected Fellow in 1879. He took an interest in public affairs, was six years Alderman of Hastings, and was Mayor in 1897-8. He was also Justice of the Peace for County Sussex and consulting physician to the hospital. Also held office in a number of other medical institutions. He delivered the presidential address at the Health Congress in Hastings.

Dr. Ludovic William D. Mair died November 4, aged 46. He was a medical inspector of the Local Government Board, served on the Belfast Health Commission, 1907; was Medical Officer of Health for Croydon. He took M.D., London, 1890; D.P.H. of the Royal College of Physicians, 1893. He made several reports on hypnotic diseases and other subjects for the Local Government Board, and wrote in the journals on cholera, diphtheria, and preventive medicine.

Lieut.-Col. Fred A. Rogers, D.S.O., late of the Indian Medical Service, has died at the age of 51. He was in the Burmese expedition, 1885-89; was twice mentioned in despatches, and received the medal with two clasps. For services in the Chin-Lushai expedition, 1889-90, he was awarded the D.S.O. He retired in 1905.

Mr. Frank Godfrey, late surgeon to the convict prison at Gibraltar and later to Northwest London Hospital and the City Lying-in Hospital, has died at the age of 70. He held the double qualification of the Edinburgh College (1885) and went with the British Legion to serve under Garibaldi.

The Protein Needs of the Child.—J. Stargardter states that his experiments confirm the conclusion based on Schlossmann's calculations, namely, the protein needs of the child beyond the infantile period may be satisfied with from 1.5 to 2.5 grams of protein per kilo of body weight.—*Archiv für Kinderheilkunde.*

OUR LETTER FROM THE PHILIPPINES.

(From Our Regular Correspondent.)

MEETING OF THE MANILA MEDICAL SOCIETY—FLY PEST IN BAGUIO—THE PLAGUE—CHOLERA IN JAPAN.

MANILA, P. I., October 21, 1912.

THE regular monthly meeting of the Manila Medical Society took place in the amphitheater of the College of Medicine and Surgery, at 8.30 P.M., October 7, 1912. Drs. Sison and Gutierrez presented a woman who had a wandering spleen. Dr. C. S. Butler, Commander, United States Navy, in charge of the Cañacao Hospital, Cavite, read a paper entitled "Some Laboratory Notes on Dysentery Bacilli." Charles S. Banks, Entomologist of the Bureau of Science, read a paper called "The Baguio Fly Campaign of 1912." It will perhaps be remembered that Baguio is to the Philippines what Simla is to India, and that during the hot season the seat of Government is transferred there. Owing to improper disposal of horse-manure and human excrement, enormous numbers of flies bred there, and during the height of the season they were so numerous as seriously to interfere with the comfort of the people who lived there. In the opinion of Mr. Banks, the flies were also responsible, to a considerable extent, for the transmission of the bacillary dysentery which was present.

During the past ten days there has been a considerable increase in the prevalence of plague in Manila, no less than six human cases having been reported. The situation is also made more serious by the fact that one case came from Calle Principe, near the river water front, which establishes a new center of infection. This address is in the San Nicolas district and is fully half a mile from where previous cases have occurred in man or in rats. This last case was in the person of a barber who occupied the first floor of a large tenement house which was practically unoccupied with the exception of the part which he used. The building gave evidence of being badly rat-infested, and skeletons of rats, and dead rats in varying stages of decomposition, were found. Some of these were encountered in the hollow walls of the building. Laboratory examination, however, failed to reveal any plague in the rats which were found dead. Since then a thousand rats have been caught in this vicinity, and a number that were plague-infected have been found in the same block or adjacent blocks. This section of the city is largely occupied by grain warehouses and other large stores of food supplies, and considerable difficulty will no doubt be encountered in the rat campaign which has been started.

The first case of plague in a white person occurred to-day in an American child aged six years. The child gives a history of having been ill for a period of six days, but did not develop a bubo until to-day. Fluid drawn from the bubo showed characteristic bipolar staining organisms which can be stated, with reasonable certainty, to be plague bacilli. Culture and inoculation experiments will, of course, be carried out. The child lived on the south side of the Pasig River, which, up to this time, has not had any cases of plague, but is said to have been in the plague-infected area, and it is possible that it might have become infected at such a time.

Up to the present time there have been sixteen cases of plague, of which fifteen were fatal. At Iloilo the number of cases and deaths still remains at nine, no cases having been reported there since September 17.

At the present time there is a severe outbreak of cholera in Japan, over 2,000 cases having already occurred. It is reported that the disease was transmitted from Shanghai to the vicinity of Moji by a vessel which had cases of cholera on board. Soon after some of the sick were taken ashore the disease appeared among residents, and has now spread rapidly throughout Japan, having appeared in many towns along the Shimonoseki Straits, in Nagasaki, and in Tokio. In the Philippines, stool examinations are being made of all arrivals from Japan, with the exception of first-cabin passengers.

The annual meeting of the Philippine Islands Medical Association will be held in Manila on November 4, 5, 6, and 7. A number of papers on original research and other pertinent subjects will be read.

Progress of Medical Science.

Taylor; (*b*) The Surgical Treatment of Head Injuries Affecting the Brain, John Homans; (*c*) The Surgical Treatment of Injuries of the Spinal Column Affecting the Cord, John T. Bottomley.
2. A New Device for the Safe and Certain Administration of Salvarsan. William McGurn.

1 (a). Neurological Aspects of Injuries to the Cranium and Spinal Column.—E. W. Taylor concludes from a study of the clinical disturbances and pathological findings in traumatic injuries of the cord that hemorrhage external to the cord is unusual and need not be seriously considered in deciding upon operation. Concussion of the cord without definite microscopic lesions is a possibility. The damage to the cord is immediate following the injury, but it is not immediately possible to determine the amount of damage done the cord. This being the case it is essential to wait at least twenty-four to forty-eight hours before a decision is reached. Immediate operation may at times so far increase the shock already sustained as to hasten a fatal outcome. The operation is unavailing when signs of complete transverse lesion persist. If signs of improvement begin to show themselves and the patient's condition justifies the operation, a laminectomy may be indicated and may help toward restoration of the functions of a partially damaged cord. Lesions in the thoracic cord do not threaten life except through complications.

3. Heliotherapy.—A. Mackenzie Forbes and G. C. Copeland report three instances of children suffering from open wound, which, though apparently unhealing, have been submitted to the local action of the sun's rays with marked improvement. The first patient was suffering from Pott's disease and an attempt had been made to immobilize the spine by operative procedure, when a cold abscess broke through the incision to the spine laying the unhealed wound open and making it evident that it would only heal by granulation. The second patient had been operated on for tuberculosis of the great trochanter. A few days after the operation the wound became infected with staphylococcus and broke down. Tubercles were continually being formed on its gaping surface. Treatment by exposure to the sun's rays caused a disappearance of the tubercles and the formation of granulations over the deeper parts of the wound, and an improvement of the general condition of the child who was also suffering from a serious lung lesion. The third patient was a boy who was suffering from tuberculosis of the hip with several sinuses leading to the hip joint. Under heliotherapy both his local and general condition have improved. The report of the improvement of only three patients at the Montreal General Hospital is not sufficient to prove the efficacy of this form of treatment but should draw attention to the curative value of the sun's rays.

7. The Rational Therapy of Syphilis in the Light of Recent Investigations.—J. S. Eisenstaedt construes the following conditions as being possible reasons for the intravenous salvarsan injections: Impending perforation of the palate; certain luetic lesions of the central nervous system, such as meningitis and gumma; extreme involvement of the mucous membranes; early cases of syphilis in which secondary symptoms have not yet appeared; intense specific bone conditions, periostitis, and gumma; and especially cases of syphilis refractive to thorough mercurial treatment. The treatment of election is the combined salvarsan-mercury treatment carried out as follows, unless there are distinct contraindications, such as cardiovascular disease or lesions of the optic nerve. An intravenous salvarsan injection in full dose is administered to be immediately followed by twelve to fifteen intramuscular injections of mercury salicylate given at intervals of five or six days. Hoffman recommends four complete courses given within the first year of the disease. The writer has not been so energetic but has used intravenous salvarsan injections in the instances above enumerated. This was immediately followed by a series of mercury salicylate injections, followed later by four to six injections intramuscularly of small doses of salvarsan, from one to decigrammes, in sesame oil, after which new series of mercury salicylate injections are inaugurated and continued at increasing intervals during the first year of the disease. Treated in this way a fair number of cases seemed to be cured, though the time was too short to be certain. The patient should be treated until clinically cured and then observed for eighteen months longer, during which time the blood should be examined repeatedly. Pills of mercury biniodide or protiodide may be used as adjuvants to energetic therapy, being given between "cures."

3. Blood Changes Caused by the Hypodermic Administration of the Cancer Proteid.—J. Walter Vaughn reports that during the past six years over 200 cases of recurrent or inoperable cancer which have come under his observation have been treated by some method of vaccine therapy. Two forms of vaccine have been used in his work, namely, cancer residue and a vaccine made

of the cancer cell in its entirety. The methods are described and the results tabulated. In about 20 per cent. of these cases all visible signs of malignant tissue disappeared, but this was not always permanent, and the percentage was reduced to 10 on longer observation. The work was begun in the belief that it was possible to compel the body to form specific ferments for the splitting up of given proteins introduced into the body in dead form. These were looked for in the white blood cells and daily differential leucocyte counts were made to the number of more than twenty thousand. It was found that in cases with marked decrease of the polymorphonuclears and a corresponding increase of large or small mononuclears, benefit was received from vaccines. No estimate of the value of the use of vaccines could be made from the microscopic picture of the tumor cells. The malignancy seemed to depend on the bodily resistance of the patient rather than the nature of the growth, and could be better estimated by a differential leucocyte count than by examination. Experiments were made to see whether an active ferment for splitting malignant cells could be produced in animals and made available for the treatment of cancer. Over 500 animals were used and blood changes carefully noted. The polymorphonuclears and small mononuclears were not generally affected while the proportion of large mononuclears was always increased from 100 to 400 per cent. within two days. Experiments were made on rabbits to determine how this increase affected the formation of the specific ferment. Rabbits were sensitized to the cancer cell and then intravenously injected with the cancer-cell emulsion. In unsensitized rabbits there was no noticeable effect. Those with a percentage of large mononuclears above thirty usually died quickly, those with a lower percentage were made very sick, but recovered. The serum from rabbits thus transitorily sensitized, when mixed with cancer-cell emulsion and incubated for an hour, caused marked symptoms of poisoning when intravenously injected in rabbits. Injections of both sheep and rabbit serum were given in some cases of inoperable carcinoma, and, while there seemed to be some improvement in the condition of the malignant growth in over half the cases the serum complication seemed to render its use inadvisable. An attempt was made to see whether this specific ferment could be separated from the serum. The specific leucocyte extract was soluble but it seemed to be rather too dangerous for use in the treatment of malignant disease, though no absolute facts could be reported at the present time.

6. **Convulsive Seizures Associated with Postmenstrual Gastrointestinal Disorders**—Arthur Conklin Brush discusses the difficulties in differentiating convulsive seizures of toxic origin from those of genuine epilepsy. Four well marked cases in which the seizures occurred apparently in connection with the menstrual period have come under his observation during the past ten years. Examination of the patients during the menstrual interval failed to disclose anything abnormal in the abdominal or pelvic organs. Though the term epilepsy has been used for over two thousand years no one can give an undisputed definition of the epileptic condition, and symptoms once held to be diagnostic of epilepsy are now known to occur in convulsive seizures of other conditions. The difficulty of distinguishing between hysteria and epilepsy is often increased by the coexistence of the two conditions. In the cases reported the seizures first appeared after an unusual exertion or shock in two of the patients, and he considers that in all they were due to gastrointestinal disturbances and menstrual stress on the nervous system. He believes that the patients had a previous irritability of the cerebro cortex. The function of menstruation caused exhaustion of the pelvic and abdominal nervous mechanism and the consequent disturbance of the abdominal viscera led to the production of toxic substances which, acting on the cortex, produced the convulsions. Treatment based on this theory proved very satisfactory.

11. **A Filtrable Agent the Cause of a Second Chicken Tumor, an Osteochondrosarcoma.**—Peyton Rous, J. B. Murphy, and W. H. Tyler describe their method of filtration and report their experiments which show that the osteochondrosarcoma, like their previously described spindle sarcoma, can be started in normal fowls by an agent separate from the tumor cells and capable of passing through a Berkfeld filter. The action of the agent, as in the case of the other tumor, seems to depend upon accessory factors; the addition to the filtrate of sterile infusorial earth to bring about an active tissue infiltration caused a high percentage of tumors, while the filtrate alone had a very limited effect. The nature of the agent causing the osteochondrosarcoma cannot at present be stated. The agent causing the spindle-celled sarcoma is probably a living virus. The demonstration that extrinsic agents are the cause of two connective tissue growths of the fowl which are characteristic malignant tumors renders it necessary to suppose either that such tumors of the fowl have an entirely different etiology from mammalian tumors or else that the latter are of similar origin. In any case the findings with the chicken tumor largely demolish the theoretical basis on which objections to an extrinsic cause for cancer has been built up.

2. **The Bradshaw Lecture on the Diagnosis and Treatment of Incipient Pulmonary Tuberculosis.**—David B. Lees reviews the relative incidence of bovine and human tuberculosis and concludes that the bovine type presents a problem insignificant in comparison with that of the human bacillus. He discusses the diagnosis of incipient tuberculosis and the value of percussion and calls attention to the advantage of keeping an accurate record of the size of dull areas. He says that it is possible for any general practitioner of medicine, by the adoption of a correct method of examination and the exercise of a little care and patience, accurately to diagnose the existence of an incipient tuberculosis long before any bacteriological evidence can be obtained. It is not necessary for him to wait for a positive bacteriological report and he will be foolish indeed if he allows a negative report to shake a diagnosis which is based on an accurate physical examination. For the last seven years he has treated his patients, with the exception of those seen in consultation at an advanced stage of the disease, by continuous antiseptic inhalations, by means of a Yoe's inhaler. The solution used consisted of creosote, carbolic acid, tincture of iodide, spirits of ether, and spirits of chloroform. Out of seventy-eight cases thus treated forty-eight and probably fifty-one resulted in complete recovery; there were ten incompletely cured, seven died, and two have been lost sight of. The treatment was initiated by a rest of a week or two and during the entire course of treatment the usual rules in regard to fresh air and general hygiene should be observed.

3. **The Treatment of Unilateral Cataract.**—Herbert Parsons deals with cases in which the disease is so slight

or quiescent as to offer no decided contraindication to some form of cataract operation. He divides the cases into two great groups according to the age of the patient, for speaking generally the indication is to operate in cases of unilateral cataract in the young and not to operate in the adult or aged. Among the advantages to be expected to accrue to the patient from a successful operation perhaps the greatest is the restoration of the full field of vision. The next advantage would be in regard to central vision. If the patient had originally little or no error of refraction, he would with the aid of a strong convex lens have his central vision restored. It is shown, however, that it is not to be anticipated that the patient will be able to wear a cataract glass. The affected eye will, therefore, be practically useless for central vision and no particular gain accrues in this respect. It is true also that central vision is sometimes improved by operation without the use of the cataract glass, but far from being an advantage this is often a disadvantage, as the improved vision acts as a disquieting feature and tends to obscure the vision of the sound eye. The cosmetic effect is a material advantage which must be taken into consideration in operation in these cases. The operation generally indicated in the young is one involving no risk to the eye. The improvement of central vision in the young, even though the refraction be not corrected, often suffices to prevent the development of squint. In many cases of cataract in the young the cataract will become too mature if left alone and will then be much less amenable to operation. Almost invariably the operation of choice is discission. After twenty or thirty years of age one is liable to have grave difficulties with the lens if discission is employed. Senile, traumatic, and complicated cataracts are considered. On the technical side there is one potent indication for operation and that is the appearance of signs of hypermaturity. Operation is contraindicated when the opacity of the lens is secondary to some general disease, such as diabetes.

1. The Huxley Lecture: Some Problems in Infection and Its Control. Simon Flexner.
2. The Bradshaw Lecture: The Diagnosis and Treatment of Incipient Pulmonary Tuberculosis. David B. Lees.

1. Some Problems in Infection and Its Control.—Simon Flexner chose poliomyelitis as his general theme because it had claimed so much of his attention during the past few years and because it illustrated admirably certain truths to which he wished to call attention. He reviews the experimental investigation of the disease, routes of infection, pathological effects on the spinal cord and brain, the infectious agent of poliomyelitis and filterable viruses It is of great interest to determine the correspondence between the general data reviewed and the special facts of poliomyelitis which have been shown to arise in consequence of an invasion of the nervous tissue by an ultramiscoscopic or filtrable virus. The virus stands midway between the finest and coarsest examples. It is highly resistant to drying, light, and chemical action. In dust it survives weeks and months; in diffuse daylight, indefinitely, and it resists the action of pure glycerin and carbolic acid in 0.5 per cent. solution for many months. Recovery from poliomyelitis is attended and produced by an immunization of the body. Active immunity can be achieved by means of the living virus, but thus far no immunizing effect has been produced with the dead virus. After discussing at length the methods of exit and entrance of the virus of poliomyelitis, Dr. Flexner expresses the view that the nasal mucous membrane is the site both of ingress and of egress of the virus of poliomyelitis in man. Support for this view is found also in the study of microscopic changes in the meninges and the central nervous tissues. The virus survives in the dry state and in one instance has been detected in the sweepings of a room occupied by a patient suffering from the disease. The distribution of the virus in coughing and speaking is readily accomplished and by this means both active cases and passive carriers may conceivably be produced. It should be remembered that we possess no means of discovering the virus except by animal inoculation. Should the experimental results arising from the inoculation of the secretions of the nose and throat of such healthy carriers be confirmed the evidence for the mode of infection as outlined would be complete. Experiments showing the probability of insects and animals acting as carriers of poliomyelitis are reviewed, attention is called to the identity of sporadic and epidemic cases and observations on pneumococcus meningitis and the antipneumococcus serum related. As to treatment the immune serum has thus far acted best when it is injected into the subdural space on several successive days. Such brilliant success has been recently recorded in respect to the specific chemical therapeutics of infection that an effort is being made to attack the problem from this quarter. The point of departure which has been adopted is the drug hexamenthylenamine, which possesses a degree of antiseptic action in the body and is known to be secreted in the cerebrospinal fluid. When the drug is administered by mouth it can be detected in the fluid in a short time. When inoculations of the virus and administration of the drug are begun together and the administration continued for some days afterward the development of the paralysis is sometimes, but not always, averted. Hexamenthylenamine lends itself to modifications by the addition of still other antiseptic groups to its molecule. None of this series of drugs is without some injurious effect upon the sensitive and vital organs of the body. Experimentation has already eliminated some of the objectionable features of the drug and improved the valuable features of the drugs so that they exert their action but little upon the organs and severely upon the parasites. When this effect is satisfactorily accomplished the victory will be won.

October 28 and November 4, 1912.

Defective Development.—Schwalbe has devoted much time to the study of malformations. These naturally originate at definite periods of development, the majority very early in embryonal life. In regard to causes we only know that they may be produced by internal and external factors. We know practically nothing of the nature of the spontaneously occurring malformations. From analogy we should conclude that a number of causes, both internal and external, have to cooperate before some malformations can be produced. The external factors which determine experimental manifestations so readily are brought with difficulty into relationship with natural deformities. Some malformations are transmitted by heredity, but these do not illuminate the other forms, and in any case form the exceptions. It is, however, a fact of some importance, that some of these inherited forms do not become apparent until comparatively late in life—for example precocious baldness. At a period not yet determined, or perhaps at different periods the interaction of organs begins to play a part. Thus a hypoplasia of the brain could be due to some lesion of the thyroid. Whatever else is true it is a fundamental fact that growth and development cannot be considered, or thought of even, apart from each other. We may regard a series of phenomena as an anomaly of growth or of development. To grow old spontaneously ahead of one's time may be regarded as a malformation as well—a defect of development.

Neurogenic Hyperthermia.—Döblin discusses this subject briefly. The phenomenon is recognized as one of

common occurrence but its rationale is unknown. The question naturally arises "to what extent is true fever of neurogenic origin?" In the latter there should be a chemical cause which is thought in most quarters to stimulate oxidation in general. If a toxic substance produces fever merely by stimulating the heat center alone, a neurogenic element must be involved. In such a case there would be great room for individual susceptibility, much more than is evident in true fever. The number of affections in which a neurogenic rise of temperature is recognizable seem to be constantly increasing. We now number adrenalin among the pyretogenous drugs, and the author regards adrenalin fever as neurogenic. When patient is under the influence of adrenalin a small hypodermic of atropine will determine a temperature rise of 2° C. This is doubtless effected through the sympathetic nerve system. If there is great instability of the latter, as in hysteria, we may readily account for the occurrence of purely neurogenic hyperthermia.

Avirulent Tracheal Diphtheria in an Adult.—Beyer reports a case of a very rare condition. A man aged 43, well nourished, admitted for a slight febrile affection with gastric symptoms, was found to have angina, hoarseness, and cough. Before a diagnosis had been made he coughed up a membrane containing among other forms, apparent Klebs-Loeffler bacilli. The patient continued to expel shreds of membrane, containing the same bacilli, but the latter were avirulent in animal experiment. The condition proved to be extremely obstinate, and did not yield to serotherapy nor vaccinotherapy. Staphylococcus vaccine was then tested, as this germ was also present, but no benefit resulted, and the author admits that patient was as far from being well as on the day of his admission.

Tabes and Trauma.—Schultze relates a number of cases which illustrate this relationship, with especial reference to its forensic aspect. One of these cases may be given as a representative instance. Patient was born in 1885. In 1903 after having always been healthy he fell through the ice into an excavation. Within a very short time he experienced a paresis of the left arm and leg and left side of face. He was allowed at first all his indemnity—for total disability. This was reduced to 75 per cent. and 60 per cent. as he continued to improve. Three years after the accident absence of patellar reflex and rigid pupils were noted. In two years more there was well marked tabes. Demand for 100 per cent. insurance allowance refused by his society, who referred him to the clinic. The case was complicated because the earliest symptoms were not of tabes but of hemiplegia, while in the third place there was a psychogenic component (hysteroid contraction of visual field); but all the phenomena could have been ascribed to syphilitic infection. The author as expert declared that a fall could not have produced tabes one and one-half years later; while the disability from the original hemiplegia had long vanished save for subjective weakness it was thought to have been due to thrombosis of the cerebral vessels.

Poisoning from Arsenical Carpets.—Kuttner delivered a full address on this subject and stated that his attention had been called to the subject by the repeated cases of chronic diarrhea seen by him which proved rebellious to treatment. These cases were at first regarded as neurogenic, but it soon became evident that neurasthenia and hysteria could be excluded. A patient, male, aged 32, having consulted him for cramps and diarrhea, he determined to reach the source of the matter. The fecal discharges and blood were studied and a provisional diagnosis was made of enterocolitis and secondary anemia. The condition improved while patient was in the hospital, but as soon as he had returned a relapse occurred. He again improved in the hospital and, as before, without treatment. A second relapse took place on his return home. The carpets were the only articles in the latter place which could be accused of having poisoned him, as all the ordinary sources could be excluded. These, however, do not seem to have been suspected, for the presence of arsenic was first revealed by analyses. After the discovery arsenic was also found in the urine. This also happened in a patient supposed to have pernicious anemia. The cumulative nature of the poison is shown by the fact that one patient had inhaled the arsenical carpet dust for two years before showing signs of poisoning. The laws expressly forbid the use of arsenic in carpet making. Despite this prohibition arsenic colors are largely used to-day for green carpets and even linoleum.

Münchener medizinische Wochenschrift.

November 5, 1912.

Septic Rheumatoid Affections.—Schürer begins his article with an account of Russian investigations into the role of the streptococcus in scarlatina. These show beyond doubt how frequently the latter represents a mixed infection even in nonpurulent manipulations. If the scarlet fever virus can sensitize patients to a low grade infection with streptococci, why should not the latter be the cause, in part at least, of pseudoarticular rheumatism? Many papers have been published during the past dozen years which show that individual rheumatoid affections may be traced to virulent streptococci. When the latter are surely pathogenic in apparent rheumatic affections they have been invariably small, with delicate colony formation and almost nonvirulent to animals. In endocarditis of mild and insidious character, non-rheumatic clinically, the streptococcus viridans is at fault. The two types are closely related, if not identical. The detail of proof the author thinks he can supply by a series of cases in which the viridans was shown to be present in apparent polyarticular rheumatism. The demonstration was by no means easily effected, but nevertheless complete. In these cases the viridans was found in the tonsils during or after a polyarthritis. The crucial test lay in the positive blood finds, thus accounting for the full cycle of infection. Since the viridans is known to be able to cause acute general sepsis and endocarditis ulcerosa it is proper to speak of mild rheumatoid cases as septic. In the mild form of isolated endocarditis caused by the viridans joint pains are often present, and in some cases swelling; so that endocarditis plus arthropathies in the one case approximates the acute polyarthritis plus endocarditis in the other, a final destination being impossible. There is, however, one formidable objection to a unicistic view, to wit, failure of the atypical case to respond to salicylic acid. This influences the author to speak of rheumatoids as distinct from genuine rheumatism. It is characteristic of all rheumatoids that they are not influenced by this remedy. Another criterion is the blood finds, which are always negative in acute polyarticular rheumatism of the familiar type. These demonstrations lead to the view that acute rheumatism of tonsillar or intranasal origin can hardly be genuine in character.

Prevention and Management of Ankylosis of the Joints.—Wahl speaks of the great interest felt in medical circles in preventing ankylosis, for it is an example of the way in which a slight lesion works great and permanent harm. One type follows inflammations of every sort while the other is of traumatic origin. In phlegmonous suppuration earliest incision is the rule, and should be done without any delay whatever upon the twofold symptom temperature and pain. To temporize with poultices is criminal. If patient is seen at the office in this condition he should at once be mildly etherized and relieved. It may save him from a stiff joint. More repose than is absolutely necessary is bad from this view-

point in all acute arthritides. Extension or rotation splints should be applied. On the other hand rest is the indication in chronic tuberculous arthritis, with Biers' hyperemia. It is best to avoid all bloody intervention. When slight adhesions, capsular retractions, and muscular atrophy are developing massage, gymnastics, and baths must be used persistently to limit the disability as far as possible. For the prevention of ankylosis after simple fracture into joints everything depends on the technique of the first management of the latter, which involves the proper use of extension splints.

Deutsche medizinische Wochenschrift.

October 31 and November 7, 1912.

Parinaud's Conjunctivitis.—Möllers writes of the relationship between the tubercle bacillus and this affection. Up to two years ago the nature of the latter seems to have been obscure. Wessely, seeing a case in the child of a butcher suspected a bovine tuberculosis and demonstrated the correctness of his suspicions by animal inoculation. Other authors soon corroborated Wessely's views, but it was not claimed outright that all so-called Parinaud's conjunctivitis represented a local bovine tuberculosis. The subject was then investigated at the Koch Institute by the author. A child with the peculiar cock's comb vegetations on the conjunctiva and a lymph node paquet before the corresponding ear was the first subject studied. Inoculation showed that the bacilli in this case were of the human type. Other cases gave the same finds, and one patient had incipient pulmonary tuberculosis, thus confirming the teachings of Krusius and Clausen that while Parinaud's conjunctivitis is tuberculous it is not necessarily the primary lesion, but results from autoinoculation from an older focus. Möllers believes that the disease is not of bovine origin at all, although it may be found eventually that both forms of bacilli cause it. It is usually a benign affection, which may argue for the fact that patients have become immunized by some earlier localization of tuberculosis.

Forensic Status of Reflex Anomalies.—Singer sums up an article on this subject as follows: Asymmetry, weakening or absence of the patellar reflex always represent pathological phenomena and point to either peripheral or central nerve affections. The diagnostic value of the Achilles reflex is no less than that of the patella reflex; often it gives the earliest evidence of mischief. The Babinski reflex is one of the most important indications of disease of the pyramidal tracts; but its absence does not mean that the latter are intact. It is necessary for the general practitioner to master all the techniques of reflex examination. Repeated examinations may be necessary, and however slight the anomaly it has a diagnostic significance. In all forensic descriptions of subjects there should be mentioned the state of the patellar and Achilles reflexes, foot clonus and Babinski's sign.

Tests for Exogenous Blood in the Gastroenteric Tract.—Boas discusses the problem of eliminating the possibility of foreign blood in the stools, since there is always a possibility that blood has been ingested in the food. The special feature of the problem considered is the source of small quantities of blood constituents in the feces which might be ascribed erroneously to some disease. The most practicable method, since it does not entail any hardships on the patient, is to heat the meat or fish which he is to eat in such a manner as to eliminate the blood constituents. This is done by scraping or chopping some veal or chicken, etc., and then treating it with hydrogen peroxide solution until the dead white color shall indicate that the blood coloring matter has been disposed of. The excess of H_2O_2 is then washed away. The meat may now be made into croquettes.

Therapy of Arteriosclerosis.—Strubell describes the insufficiency of blood pressure measuring apparatus in the early recognition of arteriosclerosis. When this had become apparent radioscopic diagnosis enabled us to detect changes in the aorta previously unrecognizable. Still more recently the electrocardiogram has enabled us to distinguish a number of stages or degrees of this affection. First the pseudo stage, in which high pressure is inconstant; second, persistent high pressure with intact heart muscle doing an increased amount of work; third, stage of beginning hypertrophy of the heart (not perceptible in the Röntgen shadow); fourth, sclerosis beginning in the cardiac vessels and actual injury to the heart substance; fifth, dilatation of aorta; sixth, renal lesion. It is not, of course, implied that every case passes through these stages in succession. Each, however, leaves its mark in the electrocardiogram and each may furnish some indication for treatment. The rational symptoms are apparent at various stages and in various localities. The first stage naturally indicates prophylaxis, which is also to be pursued when the subject has no symptoms. Naturally whatever increases the blood pressure is to be prohibited. Plethora should be combated. The pseudo or spastic vascular symptoms furnish strong indications of what to avoid, because they show what is bad for the individual and theory is eliminated. Since prophylaxis must involve also some remedial measures the author advises the alternating current bath. Weak carbonic acid baths properly given are also of some value. Prolonged warm baths along with massage are much employed. All these measures serve to tranquilize the nervous system and antagonize the psychogenous factor in high blood pressure. These baths may be used during the first three stages. After the individual has been irrevocably damaged the indications are so obvious that they need not be discussed here. The chief measures of interest are those which have prophylactic as well as curative value. The author regards the iodine preparations as belonging here if anywhere. He regards their use as questionable, for he has shown that they lower the opsonic index to the staphylococcus. Our other main resource of late years, the alternating current, has also been assailed on the discovery that it may raise the blood pressure. Should it not lower the latter it is contraindicated.

Copper-Lecithin in the Treatment of Epithelioma.—Strauss states that the recent use of colloid metals in the chemotherapy of cancer has directed the attention of the profession especially to copper in this connection. The author has recently cured two epitheliomata and a lupus-carcinoma with a chemical combination of cupric chlorid and lecithin (copper content 4.5 per cent.). It has been shown that Röntgen rays and radium decompose lecithin with formation of cholin. Czerny has shown that cholin salves have anti-cancerous powers. Hence lecithin as the source of cholin may be of value in cancer therapy. Strauss says that the new substance was used in these cases in the form of a fat-free ointment, and it will probably be tested by subtumoral and systemic injections by those interested.

Is Psoriasis a Tuberculide?—Menzer asks this question indirectly. He claims to have found present in the lesions bacterial formations which suggest Koch's bacillus; also the Much granules. The presence of staphylo- and streptococci he does not regard as an accident, for he seems to look upon psoriasis as a mixed infection with tubercle and pyogenic bacteria. Cases may react to all three of the bacterial products. If his views of the disease prove to be founded on fact the future treatment will be one of immuno or vaccinotherapy. The author has already tested the tuberculin treatment and the use of staphylococcus vaccine. The disease appears to be made worse at first by these measures, after which it improves. The author adds to the treatment by staphylococcus vaccine and tuberculin the application of warm baths and good nourishment.

Insurance Medicine.

Effect of Girth and Chest Expansion on Longevity.—Dr. E. W. Dwight, medical director of the New England Mutual Life Insurance Company, has submitted the following interesting data showing the mortality rate in case of girths equal to or greater than the chest, these figures being taken from the total experience of his company from 1844 to 1905; also the rate of mortality according to chest expansion taken from the experience of his company from 1896 to 1905.

	No. of Cards.	Mortality rate Computed on Am. Experience Table. Per Cent.
Abdomen:		
Girth equal to or greater than chest at rest	14,142	87.0
Girth equal to or greater than chest expanded	1,405	128.2
Chest:		
Expansion less than 2 inches	187	69.3
Expansion between 2 and 3 in.	12,929	65.8
Expansion between 3 and 4 in.	24,714	57.6
Expansion between 4 and 5 in.	13,085	52.0
Expansion over 5 inches	3,538	44.2

The Significance of Obesity in Life Insurance.—Van der Heide says that the question of obesity gives rise most frequently to recriminations among applicant, insurance agent, and the medical examiner; their opinions are usually quite at variance and depend as much upon their own physique as upon any other data on the question. The usual books on insurance medicine give only general information about the significance of obesity for life insurance, but do not indulge in specific directions which could help a beginner in judging his cases. Of course, it is everyday knowledge that many obese persons are doomed to die early, yet many more live to a comfortable old age, and the task of the examiner is to recognize these "varieties" as exactly as possible.

There are several definitions of obesity. Brocca's rule states that the normal weight of a person in kilograms should be equal to the number of centimeters by which his height exceeds one meter. Some companies accept this measure, others have made out their own standard of normal weight and consider anybody unacceptable on usual terms who is over twenty per cent. overweight. Some companies insist that obesity should be judged not so much by the body weight as by the circumference of the abdomen. Florschütz has proposed the following coefficient of obesity: Subtract from double the circumference of abdomen the length of the body and divide the latter by the remainder obtained. If the quotient is five, normal nutrition is present; if under five, obesity exists in inverse proportion to the figure obtained. Poële has declined all applicants in whom the quotient thus obtained was less than three, but thinks that two and seventy-five hundredths as the lowest figure may likewise be acceptable. Norton names such applicants corpulent the circumference of whose abdomen is larger than that of the thorax in inspiration; Mahillon thinks excessive corpulency is present when the weight expressed in kilograms is larger than half the height expressed in centimeters.

It is certainly true that mere body weight cannot be used to judge the degree of overweight, for the size and weight of the body's bony framework is the important unknown quantity. Flesch has made the suggestion that the ankle or the wrist joint should be measured, for here the bones are hardly covered by muscles and fat, and some judgment of the size of the bones may be arrived at. Such measurements for the wrist ran from 15 to 20 centimeters; slight overweight would be considered safe with the higher measurements of the wrist, while with the lower it would mean excessive corpulency. It is possible directly to estimate the amount of fat by measuring an abdominal fold by means of a compass. Oeder has found that 2.75 centimeters is the average thickness of the abdominal wall in a normally developed man (average of 1920 measurements). Such figures would help the home office to judge about the acceptability of a candidate better than mere statement of weight.

As to obesity in itself, that of hereditary type is most unfavorable for insurance purposes. Usually gout or diabetes is frequent in obese families. If obesity appears in a fairly advanced age, however, and there is no family history of diseases of metabolism, its significance is less serious. As a cause of acquired obesity, alcohol plays an important rôle, and a fat applicant addicted to the use of alcohol is an unfavorable risk, for here a vicious circle may have been established. Overeating likewise tends to bring on obesity, and is likewise blamed for early arteriosclerosis; by itself it is not a disqualifying habit, but when combined with addiction to alcohol it makes early degeneration of heart and kidneys quite a probable event. Indeed, the whole gravity of obesity lies in the extra demands its existence puts on these organs and upon the blood vessels. The prognosis of obesity depends a great deal upon the condition of the heart muscle, and very careful examination of the heart should take place in such cases. The blood pressure should always be estimated, and the pulse taken with the body at rest, and after exercise. Of fifty-seven autopsies in obese persons, Chambers found the heart sound in seven cases only; thirteen of the individuals had dropsy, eleven apoplexy, fifteen chronic nephritis, eight peritonitis following strangulation of a hernia, and only ten died of accidental infections. Dr. Moses selected 407 applicants who weighed ten kilograms more than would be expected according to Brocca's rule, or whose abdominal circumference was more than six-tenths of the body length. These applicants had 47 years and 10 months as the average duration of life, while that of other applicants in the same insurance period was 50 years and 1 month. The obese showed greater mortality from diseases of the circulatory system, and likewise much lessened resistance to surgical operations. On the other hand, corpulent persons show a low mortality from tuberculosis, but this is not low enough to make up for other shortcomings.—*Blätter für Vertrauensärzte der Lebensversicherung.* Vol. III, No. 4.

Annual Life Insurance Examinations.—According to statements by the officers of some companies, annual life insurance examinations will soon become part of the ordinary business routine of life insurance work. The life insurance companies, from a business standpoint, are alive to the great opportunities for saving, and thus increasing dividends, though taking advantage of the teachings of preventive medicine. With a disinterestedness almost marvelous the medical man has always taken keen action in the prevention of disease. If annual medical examinations are introduced by the insurance companies, it will be the first instance of the medical profession advocating something in preventive medicine which will redound to their own financial gain.—*Dominion Medical Monthly.*

Book Reviews.

The Medical Record Visiting List, or Physicians' Diary for 1913. New Revised Edition. Price $1.25. New York: William Wood and Company.

The Medical Record Visiting List is issued betimes and, as hitherto, it is useful, compact, and handsome. It contains the customary visiting list, with special blanks for consultation practice, obstetric engagements and practice, vaccinations, register of deaths, addresses of nurses and of patients, and cash account. There is the usual miscellaneous information at the beginning of the volume. So far as the visiting list and other blanks are concerned it is difficult to see how the present volume could be improved. But some of the introductory matter might well be omitted; the table of solutions for subcutaneous injection, for instance, has a somewhat antiquated appearance.

The Physician's Visiting List (Lindsay and Blakiston's) for 1913. Sixty-second Year of Its Publication. Price, $1.25. Philadelphia: Blakiston's Son and Company.

The many physicians who have used this exceedingly practical and convenient visiting list—probably not from its first year of publication, but from their first years of practice—will welcome its reappearance in its old familiar form, for the man who has grown accustomed to a particular visiting list will not be very likely to change even if he thinks another may be in some respects better. He will have little occasion to change, even though he makes no use of the miscellaneous information and aids to memory bound up with the blank pages.

The Practitioner's Visiting List for 1913. Price $1.25. Philadelphia and New York: Lea & Febiger, 1912.

The text of this well known visiting list has been revised and brought up to date. It contains, among other valuable information, a scheme of dentition; tables of weights and measures, and comparative scales; instructions for examining the urine; diagnostic table of eruptive fevers; incompatibles, poisons, and antidotes; directions for effecting artificial respiration; extensive table of doses; an alphabetical table of diseases and their remedies, and directions for ligation of arteries. The record portion contains ruled blanks of various kinds, adapted for noting all details of practice and professional business.

Symptoms and Their Interpretation. By James Mackenzie, M.D., LL.D., Aber. & Edin.; Lecturer on Cardiac Research, London Hospital; Physician to the Mount Vernon Hospital; Consulting Physician to the Victoria Hospital, Burnley; Author of "Diseases of the Heart," "The Study of the Pulse, Arterial, Venous, and Hepatic, and the Movements of the Heart," etc. Second edition. Price $3.00. New York: Paul B. Hoeber, 1912.

It is a hopeful sign in medicine that all the progress that is being made in these days is not in laboratory methods alone. Valuable and, indeed, indispensable as these are in advancing our knowledge of disease, the great impetus they have acquired in recent years has been somewhat disheartening to the general practitioner, especially one in country districts remote from medical centers, who cannot have ready access to laboratories. Perhaps he is not placed at such a disadvantage as he may think. This book, though restricted to a consideration of the diagnostic value of pain and other reflex nervous phenomena, shows how much can be learned from purely clinical observation by the man who has eyes to see and ears to hear. In it Dr. Mackenzie draws attention to the nature of so-called visceral pain, expounding (and proving?) the new theory as to its reflex nature, outlining the origin of these painful symptoms, and explaining their nature. The work is founded on observations of cases seen in private practice, such as come under the care of the general practitioner, and not on the advanced cases coming under the notice of the hospital physician and the consultant. It is, therefore, of special interest to the ordinary medical man who has to deal with disease in its inception as well as with the inveterate cases.

The author is known as one of the foremost exponents of the new knowledge of heart disease, and in this book he has applied the same acuteness of observation to the study of other visceral affections. Those who have profited by his teachings of cardiac maladies will welcome this new work and will study it with equal interest and benefit. It is a small book but it will do more to open the reader's eyes and broaden his mind than many more ponderous tomes. It is original and absorbingly interesting, and whether one is ready to accept its teaching or not it will hold his attention and cause him to think. No author can ask more than this.

Progressive Medicine. A Quarterly Digest of Advances, Discoveries, and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia. Assisted by Leighton F. Appleman, M.D., Instructor in Therapeutics, Jefferson Medical College, Philadelphia. Price $6 per annum. Philadelphia and New York: Lea & Febiger, September 1, 1912.

Progressive Medicine is so well known that we need only announce the appearance of the September issue. In this number Dr. W. Ewart writes on Diseases of the thorax and its viscera, including the heart, lungs, and blood-vessels; Dr. W. S. Gottheil, on Dermatology and syphilis; Dr. E. P. Davis, on Obstetrics; and Dr. W. G. Spiller, on Diseases of the nervous system. It will be noted that all of these writers are old contributors to this valuable periodical. This adds to the worth of their articles, inasmuch as there is a sort of continuity from year to year, with an absence of the repetition which would be inevitable if new contributors were constantly employed.

A Text-book of Practical Therapeutics. With especial reference to the application of remedial measures to disease and their employment upon a rational basis. By Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College of Philadelphia. Fourteenth Edition, thoroughly revised and largely rewritten. With 131 engravings and eight full-page colored plates. Price $4 net. Philadelphia and New York: Lea & Febiger, 1912.

This work is so well known that extended comment on its excellent features is hardly necessary at this late day. It will suffice to state that this, the fourteenth edition, maintains the high standard achieved by the former editions and has been brought strictly up to date in the inclusion of all the newer advances in therapeutic knowledge. The text has been revised, a new introductory chapter has been prepared, and matter dealing with the use of salvarsan, tuberculin, and vaccine therapy has been introduced, together with a description of Bier's method of treatment by artificial hyperemia. The new ideas in regard to the employment of cardiac stimulants are also taken up. As in previous editions, Part I deals with introductory matter; Part II, with the action of drugs; Part III, with remedial measures other than drugs; and Part IV, with the treatment of individual diseases, whereby the employment of the remedies discussed in the earlier part of the book is directly applied, as at the bedside. These parts are linked together by copious cross-references in the text. This book may be recommended without reserve to the student and practitioner.

La Stérilisation de la Syphilis. Par le Dr. Leredde. Price 2 francs 50 centimes. Paris: A. Maloine, 1912.

Salvarsan has received such thorough discussion by present writers that it becomes a difficult task to present much that is new. In this work there are no important additions to our fund of knowledge. The author divides his book into four chief divisions: (1) Introduction and the technique of injection, (2) the dosage and accidents due to salvarsan, (3) Sero-diagnosis and the Wassermann reaction, and (4) the suppression of the syphilitic infection. The first section deals with the frequency and mortality of syphilis, the results of the experimental researches of Ehrlich and Hata, and the various modes of preparation and injection of the medicament. He cautions the operator to use only freshly distilled water and to take care that the solution is of the proper degree of alkalinization. The gastro-intestinal, hepatic, cutaneous, and thermic reactions following its administration are explained and the elimination of the drug are discussed. The second part is given to a consideration of the cures due exclusively to salvarsan, non-fatal accidents, and neuro-recurrences, fatalities due to errors in judgment, errors in technique, and over-dosage. He holds that one should consider as a normal dose and not as a strong dose that amount of the drug which when repeatedly administered causes a disappearance of spirochete in the lesions and brings about finally a negative Wassermann reaction. He advises at least three injections. The third part is devoted exclusively to sero-diagnosis and Wassermann's reaction, an important stone in the arch of modern syphilotherapy which many authors neglect. The last portion of the book states his experiences with salvarsan on syphilis in its different stages. The book fully covers its field, its text is well arranged, and the literary style is easy and flowing.

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Thirty-eighth Annual Meeting, held at Chicago, Illinois, October 22, 23, and 24, 1912.

THE PRESIDENT, DR. LOUIS FRANK, LOUISVILLE, KENTUCKY, IN THE CHAIR.

(*Concluded from page 923.*)

The Operative Treatment of Prostatic Hypertrophy.—Dr. HUGH CABOT, JR., of Boston said the object of prostatectomy was to remove the obstruction to urination with as little risk to life as possible, and as little damage to other structures and functions as may be. Only certain portions of the prostate were involved in the process known as hypertrophy. The prostate itself was compressed by the tumor and lay chiefly on the inferior and lateral aspects of the mass. The vesical and urethral aspects of the prostate in hypertrophy were covered only by the mucuous membrane. The ejaculatory ducts lay wholly behind the tumor which rarely, if ever, extended further forward than the posterior border of the verumontanum. The prostate might be attacked by two routes, the perineal or the suprapubic. If the lower route was chosen, two quite distinct methods of attack still remained, the intraurethral method of enucleation, and the transprostatic method, the operation of Young. Of the suprapubic operation there could hardly be important modification except in technical details as the attack was direct and head-on. It was useless to deny that the mortality of suprapubic prostatectomy was higher than that following the perineal operation. Briefly summarized the relative merits of the suprapubic and perineal operations in their present state of development seem to him to be these: The suprapubic route was the anatomically correct approach. It attacked the hypertrophied portion at the point where it could be reached with less destruction of tissue and with the greatest certainty of complete removal of the obstructing portion. It did less damage to other structures, interfered less with other functions and was followed by fewer complications. It was more certain to result in cure. The perineal operation showed at the present time a definitely lower mortality. It was a more difficult surgical procedure no matter what technic be selected. It was more likely to do damage to other structures and functions and was less certain to result in cure. Of the various types of perineal operation that of Proust combining the prerectal incision with the intraurethral enucleation was best adapted for the uses of the average surgeon.

Consideration of Procedures Adapted to the Exposure of the Structures at the Base of the Skull.—Dr. CHARLES H. FRAZIER of Philadelphia said the majority of the contributions had dealt with the osteoplastic flap as a means of exposing the cortical surface, and the general surgeon was not fully equipped to do what once was entrusted largely to the specialist. The osteoplastic resection of the skull was designed solely for the uncovering of lesions occupying the more accessible regions of the brain, as of the frontal, parietal, or occipital lobes, and in so far as the various steps of the operation were concerned, they had been elaborated to a degree of accuracy and mechanical refinement that admitted of little criticism. There remained, however, structures within the cranial cavity that must be approached in other ways and by other methods, structures occupying positions at the base of the skull in the posterior, middle, or anterior fossa. These structures, situated as they were beneath the cerebral or cerebellar hemispheres near the median line, were very much more inaccessible and required for their exposure the methods especially designed to meet the difficulties peculiar to each. Beginning with the posterior fossa, occasions arose in which the intracranial division of the auditory nerve might be indicated, as in cases of persistent and intractable tinnitus or persistent and intractable vertigo of central origin. He had recently placed on record the case of an elderly lady upon whom this operation was practised, and would dwell here, therefore, only on the important technical features. The operation consisted essentially in a suboccipital craniectomy, unilateral in extent. For these operations on the posterior fossa, Meltzer's method of intratracheal anesthesia was a measure of safety which could not be overestimated and to his mind should be regarded as indispensable in one's equipment for operations in this region. Prior to the introduction of this method he had observed, especially while operating for lesions in the cerebello-pontile angle, how imperfect was the expiratory exertion and inadequate exchange of gases, when the patient was in the prone or face down position, and for this reason he preferred to place them on their side on an especially designed table. With intratracheal anesthesia, all the alarming respiratory difficulties vanished, and what he once regarded as a most serious venture in these operations had now become the simplest and the safest. For the exposure of the auditory nerve, one turned downward a flap sufficient to uncover as much of the occipital bone as lay below the superior curved line. From the level of the lateral sinus down to the foramen magnum, and from the emissary sinus to the medial line, the occipital bone was removed, uncovering one cerebellar hemisphere. One then followed the petrous bone till the internal auditory meatus was recognized into which would be seen entering the auditory nerve. The mechanics of cranial surgery should not occupy too prominent a place in the minds of those engaging in this field. Of still greater import were the factors of safety, the observance and disregard of which made an intracranial operation a reasonable or an unreasonable risk. The high rate of mortality in past times was the outcome of too little regard for the refinement of cranial technic. The casual visitor to the clinic was amazed at the size of the exposure, but overlooked many of the features essential to success. The safest means of administering the anesthetic, the most effective means of controlling hemorrhage from whatever source, as the use of the muscle graft to check hemorrhage from the pial veins, the mastery of the problems of brain displacement, the knowledge of the tolerance of the brain to exploration for subcortical lesions, these and others were some of the factors that made for good or evil results.

Arsenic in Therapy.—Dr. W. F. BARCLAY of Pittsburgh pointed out that the poisonous and injurious effects of arsenic in medicine induced peculiar susceptibility to its action and intolerance. The tolerance of mercury was limited by its poisonous effects which were permanent. The same observation was true of arsenic and precluded its use and beneficial administration after its abuse. It was a well known truth based on actual observation and experience that mercurial poisoning or pytalism induced intolerance and precluded the use of mercury in treatment of diseases. The susceptibility to the poisonous effect of mercury after toxicity had been induced forbade its further use even when it was indicated. The intolerance was manifested in disturbances in the entire digestive system, in loss of appetite, salivary excitation, increase in salivation, diarrhea, malnutrition, and impaired metabolism of the blood. A like tolerance of arsenic was induced by its misuse and abuse even of a more serious character in its immediate and remote effects. There could not be a question as to the evil results that followed the abuse of arsenic in reports and facts made known and accounts given to the profession of medicine by physicians capable to observe and make accurate observations. The mention of a positive conclusion was that arsenic combined so it could be used in medicine without poisonous or injurious effect was chemic and therapeutic scientific skill in medical science. Excessive dosage without rapid elimination was dangerous to life and health and of no therapeutic advantage. Mercury was analogous to its congener arsenic in the treatment of syphilis and was the acme of medical treatment in lasting permanent results. Arsenic, like iodine, modified syphilitic manifestations promptly but never cured the disease. Arsenic in treatment of all skin lesions and diseases of the mucous and serous membranes was of great advantage and gave prompt and permanent results. Arsenic in the treatment of rheumatism was a specific in chemical combinations which insured rapid elimination. No remedy was of more scientific interest and less understood by the profession of medicine.

The Thyrogenic Origin of Graves' Disease.—Dr. J. H. JACOBSON of Toledo drew the following conclusions: 1. Graves' disease can and has been produced experimentally in lower animals by the injection of thyroid pressure fluid by the implantation of the thymus gland and by the injection of the macerated thyroid gland. Gland symptoms resembling Graves' disease can be produced in animals by thyroid feeding. 2. The evidence at hand indicates the close relationship between the thymus and thyroid glands. 3. The symptoms of Graves' disease are either due to an excess or perverted secretion of the thyroid gland, with the primary disturbance existing in the thymus gland, the action of the thyroid being that of a multiplicator according to the theory of Mikulicz. 4. Graves' disease has been produced in man by the excessive administration of thyroid extracts and preparations of iodine. 5. That there are changes in the thyroid gland, chemical, microscopical, macroscopical, which are

characteristic of Graves' disease. 6. Typical Graves' disease or symptoms of hyperthyroidism, so-called secondary Graves' disease, occurs after or in connection with other affections of the thyroid, such as simple and adenomatous goiter, cancer, and inflammation. 7. That there is a characteristic blood picture in Graves' disease, which disappears after the surgical removal of a sufficient amount of the diseased thyroid tissue. 8. The successful treatment of Graves' disease by measures directed toward the thyroid itself, as well as by serum therapy, prove the thyroid origin of the disease. 9. Graves' disease can be cured by the surgical removal of portions of the gland in approximately 70 per cent. of all cases.

The Surgical Importance and Treatment of Hyperthyroidism.—Dr. W. D. HAINES of Cincinnati said that a tragedy which occurred in a patient's life two years previously had been followed by hyperthyroidism. The influence wrought upon the heart was discovered during a period of quiescence, the ash of a process whose identity became known only when again set in motion, this time not by a tragedy but by an acute infection—appendicitis. Relief of the appendicitis did not in any way benefit the hyperthyroidism; on the contrary, the excitement incident to anesthesia, operation and hospital life would naturally tend to aggravate thyroid symptoms. Relief was finally obtained by removal of the right lobe and isthmus and ligation of the left superior thyroid artery. There was a very decided improvement in the heart's action following treatment and operation, the exophthalmos had almost entirely disappeared, and the patient remained comfortable despite a badly damaged heart. A few other cases, including an acute cholecystitis, empyema of the gall-bladder and an acute salpingitis had been observed by the writer coexistent with hyperthyroidism, but the report of the one case above would suffice to illustrate his purpose in bringing up this subject. The frequency with which hyperthyroidism was associated with valvular lesions, compensatory hypertrophy and degenerative changes in the heart muscle and clinically abnormal heart should admonish one to always be on guard for one of the protean manifestations of hyperthyroidism. He formerly did goiter operations through very short incisions, retracting the muscles in preference to dividing them. He now employed a long incision, dividing the sternohyoid and sternothyroid and sternocleidomastoid if necessary for free exposure of the gland and its circulation. Time and certitude were thus gained, and if the muscle be divided well above the entrance of the nerve supply, say on a level with the junction of the middle and upper third and the ends carefully sutured, restoration of function would follow and the resultant cicatricial deformity would be such as would scarcely mar the contour of the neck. By working within the capsule, one would protect the parathyroids and the patient from the serious consequence following injury to these important structures. He used catgut as ligature material and never removed a hemostat without having first ligated the vessel which it controlled irrespective of size. Finally, one should remember the neck as a privileged region and handle its structures with the utmost delicacy consistent with precision and celerity in doing goiter work.

The Surgical Management of Exophthalmic Goiter.—Dr. W. D. HAGGARD of Nashville, in reviewing the surgical management of exophthalmic goiter, said it was not contended that there was not a field for dietetic, hygienic and therapeutic treatment. From a considerable experience, however, and from observation and reports of the work of those of very large experience, the writer believed in common with many other observers, that the surgical treatment of this disease afforded the most effective and lasting benefit. It had stood the test of time far better than the purely medical management. The latter had been largely empiric. No matter at what time of life the early symptoms of hyperthyroidism developed, it was pretty satisfactorily demonstrated that reduction of the blood supply to the hyperactive gland was a rational and effective method of treatment. The ligation of one or more of the thyroid arteries, under local anesthesia, constituted one of the most satisfactory methods of handling this disease. It might be likened to the early operation for appendicitis. It should have a very much wider application. Recognizing the progressive and threatening trend of the malady, it was fortunate to have in pole ligation so safe, simple and positive a method of permanent relief in the early cases. Ligation was also indicated at the other extreme of the disease—when the patient was too ill for a radical removal of the hyperplastic lobe. It should be more generally understood that operation was not to be employed when the patient was in an acute exacerbation, or was rapidly growing worse, but if by rest in bed, with the ice cap over the heart, belladonna, etc., the patient could be gotten in a satisfactory condition and the pulse below 120, the operation could be undertaken. Mayo in the first nine months of last year performed 900 operations on the thyroid with a mortality of 1 per cent. For the exophthalmic cases, however, even in his skilled hands the mortality was more than threefold. Speaking of the end results, Crile says "no person died of the disease after leaving the hospital; one patient was made worse by the operation, otherwise every patient was either benefited or cured." Kocher says that many patients only knew what real mental quietude meant after the fundamental relief by operation. There was no more brilliant surgical achievement than the restoration of these nervous and circulatory invalids to the pursuit of happiness and the paths of peace.

The Urological Aspect of the Microscope as a Localizer of Disease.—Dr. CARL LEWIS WHEELER of Lexington made a plea for a more thorough microscopical examination of the urine, studying the urinary findings under higher magnifying power (500 diameters) with an effort towards differentiating the various epithelia and other features found in urinary sediment, saying in this way we might locate and diagnosticate pathological lesions along the urinary tract. All morbid processes occurring within the urogenital tract were marked by the presence of pus corpuscles, and the location was determined by the character of the epithelia found. Normally, the only epithelia found in the urine were of the flat variety, in small numbers, coming from the bladder, while in the female might be seen flat epithelia from the bladder and vagina. The presence of all other epithelia was pathological. The diagnostic point in differentiating epithelia is absolute size, and the pus corpuscle was taken as a standard of comparison in differentiating the various smaller epithelia, such as coming from the convoluted and straight collecting tubules of the kidney, ureter, kidney pelvis and prostate. He reported numbers of cases in which the diagnoses were made from urinary findings alone, in the absence of any clinical history whatsoever, and the diagnosis being confirmed by cystoscopy, ureteral catheterization, operation, or autopsy. The ordinary methods of the study of the urine under the microscope, beyond the detection of casts, were faulty and almost worthless, and his paper was offered as a defense of the Heitzmann School of Microscopical Urinary Diagnosis; for already, since the advent of ureteral catheterization, many authorities who had denounced Heitzmann's claims had deemed it wise to slightly modify their opinions.

The Value of Direct Transfusion of Blood, Based on Results Obtained in About 500 Cases.—Dr. A. L. SORESI of New York stated that 449 cases of direct transfusion had been collected from publications and directly from hospitals, where surgeons had performed it. Transfusion was useful in 234 cases, and a failure in 215. Failures were due to lack of correct indications, lack of training to do useful work on the blood vessels, to the fact that the physiologically correct technic had not been employed, and to the further fact that transfusion had been used too late. Transfusion had been employed in 217 cases of hemorrhage from different causes and was found successful in 158. The most successful cases were those of hemorrhages of the newborn and hemophilia, where the blood was used also as a hemostatic agent Transfusion was used in 26 cases of shock and collapse, in 15 of which it was a failure. It was used in 37 cases of pernicious anemia, which were all failures, the patients having at the best only a temporary improvement. It was used in the preparation of patients for surgical operations in 39 cases, with 17 failures; in sepsis from various causes, 19 cases, with 16 failures; in diabetic coma, 3 cases, all failures; in eclampsia, 5 cases, with 3 failures; in pellagra, 35 cases were reported in which it was used, and only 14 failures were reported. In undiagnosed conditions 17 cases, with 15 failures; in surgical cases of tuberculosis, 7 times, with 4 failures; in carcinoma and sarcoma, 16 cases, and none modified by the transfused blood; in exophthalmic goiter, 4 cases, all failures; in illuminating gas poisoning, 9 cases, with 6 failures; in pneumonia, 2 cases, with 1 failure; in Bright's disease, 1 case, a failure; in 1 case of starvation due to volvulus successfully. The author recommended the use of his cannula, because the blood vessels were not traumatized and thrombosis was avoided. Vein to vein transfusion, using the external jugular of the recipient and a vein of a limb of the donor; as soon as the blood vessels were exposed they should be kept moist and warm by pouring upon them a continuous stream of sterile warm saline solution.

Eczema as Seen by the General Practitioner.—Dr. A. RAVOGLI of Cincinnati said the general practitioner should look upon eczema as a curable disease. It was wrong to

starve the patients, forbidding articles of food, without scientific ground. On the contrary, the patient had to be well fed, in order to increase albumin in the serum to form antibodies to oppose the toxic elements. Only indigestible and badly preserved articles of food had to be avoided. The general practitioner had to renounce the false idea, or better the superstition that washing and cleansing eczematous surfaces was injurious. The affected parts had to be cleaned and kept aseptic like any other suppurating wound. Solutions of bicarbonate or of biborate of sodium, or even a mild soap accomplish the purpose. For an acute eczema the bathing with a 2 per cent. solution of subacetate of aluminum was very beneficial. After bathing the surface was covered with amylum or talcum powder. For a papular and vesicular eczema the applications of liniment of ichthyol, or of carbonate of zinc were useful. In recurrent vesicular eczema, painting the surface with tincture of iodine to sterilize the surface had given very good results. Rhagades must be touched with silver nitrate, 3 to 5 per cent. solution. Many different preparations in the form of salves, paste, gelatins, lotions, were recommended in text books, but the physician must familiarize himself with their use.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. Albert E. Sterne, Indianapolis, Ind.; *First Vice-President*, Dr. D'Orsay Hecht, Chicago, Ill.; *Second Vice-President*, Dr. Hugh Cabot, Boston, Mass.; *Secretary*, Dr. Henry Enos Tuley, Louisville, Ky.; *Treasurer*, Dr. Samuel C. Stanton, Chicago, Ill.

New Orleans, La., was selected as the place for holding the next meeting.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held October 17, 1912.

The President, Dr. William M. Polk, in the Chair.

This meeting was held under the auspices of the Section on Pediatrics.

Summary of the Report on Vital Statistics and Health Reports of New York City.—Dr. Haven Emerson presented this report from the Public Health Hospital, and Budget Committee of the New York Academy of Medicine.

The Etiology of Convulsions in Early Life.—Dr. Floyd Crandall read this paper. He emphasized the importance of determining the cause of convulsive disorders in children because in the large percentage of cases a knowledge of the causation would lead to prevention. He said the practitioner was prone to look upon these conditions too lightly and to feel that they were but passing episodes which merited little anxiety. While death during a convulsion was a rare occurrence it was sufficiently frequent to demand every precaution. Grave results might follow the neglect to find the cause and to take proper measures to prevent the repetition of convulsions. Gowers had reported 180 cases of epilepsy which began during the first three years of life and Osler studied 460 cases, of which 187 had their beginning in the first three years of life and 74 in the first year. Among the predisposing causes the first was age. The child was born with one-third the bulk of its adult brain, while its body was frequently not more than one-twentieth the adult weight. The brain acquired the second third of its weight during the first year of life and nearly its full weight by the time the child reached its seventh year. During the second year the brain of the child had almost two-thirds the weight of the adult brain, while it had not one one-hundredth of its functional power. Control by the higher powers was very slight at the first; this predisposed to uncontrolled nerve disorders. The pathological conditions incident to this period of rapid development were convulsions, night terrors, stammering, liability to sudden rises in temperature, and numerous other abnormalities. Beginning with the seventh year there came a period of active functional development and the diseases incident to this period were chorea, epilepsy, somnambulism, migraine, and certain eye defects. The second predisposing cause of convulsions was heredity, which was both potent and important. The children in some families were particularly subject to convulsions and nervous manifestations and the practitioner learned to look for them in succeeding generations. This inherent tendency was so strong in some children that it was almost impossible to prevent an occasional convulsion. Nevertheless something could be done for all and some could be saved entirely from these inherited tendencies. The third predisposing cause of convulsions was rachitis. A tendency to convulsive disorders was sometimes an early symptom of this condition, appearing before physical signs were well marked. In every case of convulsions rachitis should be searched for and active measures for its relief instituted. Among the general causes of convulsions the author first considered the organic diseases—meningitis, hydrocephalus, hemorrhages, embolism, thrombosis, abscesses, and tumors. Meningitis presented this symptom oftener than the others. Cortical hemorrhages in the newborn might be due to birth injuries or to septic infection. The second class of exciting causes were the reflex. Children were not infrequently disturbed while cutting their teeth, but he felt positive that dentition alone very rarely caused convulsions. The same might be said of phymosis. The effect of reflex irritation of undigested food masses in the alimentary canal was uncertain. He thought it possible that irritating masses of food might of themselves induce convulsions through reflex action, though more commonly this symptom was due to toxemia. One should get rid of the undigested food and then it might be determined whether the convulsions were due to reflex action or to toxemia. The question as to whether worms could cause convulsions was also open to discussion. The indication in such cases was clear. Eliminate the worms and then evolve a theory as to what they had done. The third group of exciting causes was toxic. Of these the author considered urenia first. Nephritis was, of course, most common, following scarlet fever, but it might follow any of the other infectious diseases. Marked nephritis sometimes followed certain cases of grippe, especially those complicated by intestinal infection. Convulsions occurred more commonly at the outset of infectious diseases. This was particularly true of penumonia. In a young child a convulsion might take the place of a chill in malarial fever. Of the contagious diseases pertussis was the one most commonly complicated by convulsions. In all the infectious diseases the convulsion was apparently due to the specific poison which produced the disease. Of all the exciting causes that of undigested food in the alimentary canal was the most frequent and was usually due to toxemia. The bacteria might not enter the blood, but the ptomaines which they generated were absorbed and acted as true poisons. The proteid elements of the food were the special offenders, their poisons being particularly virulent. In conditions like tetany and laryngismus stridulus the same etiological factors were present. In these two disorders rachitis had been believed to be of special importance, but Dr. Crandall was of the opinion that some other factor must be present. He based his opinion on the fact that these conditions were rare while rachitis was common. The factor of inherited unstable nervous temperament was important. The rôle played by the inorganic salts, particularly calcium, was apparently a potent one. The practitioner was not doing his duty when he was content to merely bring a child through a convulsive seizure. He should determine the underlying cause and the exciting factor, and then use every precaution to prevent further attacks. The attending physician should not forget the dictum that careful investigation would enable him to do something for every patient and everything for some patients.

General Remarks on the Pathogenesis of Convulsions and Allied Conditions.—Dr. Max G. Schlapp said that it seemed to him that they were dealing with a subject which was very complex. They should consider how the epileptic attacks occurred and what were the causes that operated upon the motor nervous system through irritation. It was well known that organic lesions in the cerebral cortex, hemorrhages, tumors, gliosis, etc., produced convulsions in children, but when they considered the fact that convulsions were often due to some reflex action, they were entering upon a big field which required deeper investigation. Epilepsy occurred more frequently during early life, and when it occurred later it was called "epilepsy retardans." Most cases of the latter kind were due to some organic lesion of the brain, especially those lesions resulting from hemorrhage, tumors, gliosis, syphilis, etc. Idiopathic epilepsy developed during early life and not after the age of thirty years. Dr. Schlapp then considered the formative, the functional, and the nutritive activities of the cell in relation to growth and development. There was something in the body which regulated these processes, and that something was a chemical substance. The formative activity marked the fetal period of life, and there appeared certain chemical substances which existed after a certain period of an individual's life. Growth ceased on account of the absence of a certain hormone. There was a certain class of glands in the body which were very important in retarding the growth because they produced and developed these hormones; these were the glands which controlled the sexual characteristics of the individual. There were also sub-

stances which controlled the nutritional and others which controlled the functional activity. There was something in the system that kept the threshold of nerve cells constant. The effect of hyperthyroidism upon the functional activity of the motor neurons and upon those contained in the vagus was tremendous. The administration of strychnine would cause an enormous lowering of the threshold of activity of the peripheral motor neurons. There were many things which regulated this threshold of functional activity. An interesting point in this connection was that all the neurons did not react alike to the different hormones. The nervous system was made up of a number of groups of hormones which reacted to a great number of poisons, such as lead. The musculospiral nerve was one of those especially affected, thus showing that there was something selective and, in addition, there was always a functional activity. Epilepsy was always the threshold of central motor neuron activity. When the threshold was lowered by the presence of some substance in the body, there occurred a progressive gliosis, which resulted in many of the cases in epilepsy. It was curious that hemorrhages or gliosis in certain individuals produced no epileptic attacks. Experiments had been performed on animals which proved that epileptic attacks could be produced by injecting certain substances such as urea or carbonate of ammonium into the blood, and the amount injected was a very important factor in bringing about the attack of epilepsy. Dr. Schlapp called attention to the diseases produced by hypo- and those produced by hyperthyroidism, and brought out the importance of the influence of functional activity in bringing about certain conditions which were unquestionably due to some disturbance of the internal secretions.

Dietetic Treatment of Convulsions and Allied Conditions Occurring in Infants, with Special Reference to the Rôle Played by the Inorganic Salts.—Dr. CLIFFORD G. GRULEE of Chicago presented this paper, in which he first recalled that in a previous communication he had confirmed Finkelstein's findings showing that the irritating portion of cow's milk was the whey. The general belief was held that the calcium and magnesium salts acted antagonistically to the sodium and potassium, the former tending to allay and the latter to increase nervous irritability. When there was a relative increase of calcium and magnesium over the increase of sodium and potassium, one would expect to have a decreased nervous irritability. This might be expressed by the formula $\frac{Ca}{Mg}$ or $\frac{Na+Ng}{Na+K}$. The opposite of this proposition was also true. Nervous irritability in infants and animals could be accurately estimated by the electrical reaction. It had been determined to approach the subject of spasmophilia in infants by endeavoring to produce increased electrical irritability by the use of sodium salts. Before doing this it had been thought that a study of metabolism of the inorganic salts in animals before and after thyroidectomy (thereby showing markedly the reaction of the electrical current) would be of interest. Young dogs, preferably females, were chosen for these experiments. They were observed for a period of three days before operation and for periods of two, three, and four days after the operation. The food consisted of milk preserved with formalin (1-10,000), which at no time showed any sign of decomposition. In all excepting one instance the dog was given as much as it would take. Thus an analysis of the urine and feces was made in twelve cases. Dr. Grulee reported these cases in detail and drew the following conclusions: 1. In dogs in which there was a hyperirritability of the nervous system, as shown by the increased electrical irritability, and as produced by removal of the thyroid gland, there was no regular variation in the formula, $\frac{Ca}{Na}$ or $\frac{Ca+Mg}{Na+K}$ before and after operation, as shown by metabolic experiment. While in three dogs thus examined there was apparently some support of the proposition that the quotient of this formula was increased during the period of hyperirritability of the nervous system, in the fourth dog no such reaction could be noticed. 2. In the estimation of the salt content of the brains of the five dogs, the first being a control, there was regularly found a decrease in the calcium content in the thyroidectomized animals. In one instance, however, the formula $\frac{Ca}{Na}$ was less than that of the controlled animals. 3. No variation in electrical irritability nor severity of the convulsive period could be demonstrated by intraperitoneal injections of normal solium and calcium salts in the quantity of 40 or 45 c.c. of sodium salts to two to four c.c. of calcium salts in twenty-four hours. 4. Even under normal conditions when carefully estimated, the electrical irritability in dogs varied quite widely. 5. While food containing whey was distinctly irritating to spasmophilic infants, the sodium and potassium salts corresponding in quantity to those contained in the whey did not regularly produce the increased electrical irritability which one would have expected were the sodium to be regarded as the irritating substance in the whey. 6. This failure of the sodium and potassium to produce results might be explained either by the fact that the forms in which the sodium and potassium were given, *i.e.*, sodium chloride and potassium chloride, were not readily absorbed by the gastrointestinal canal, or that these salts were not in themselves the irritating factors. The latter proposition would seem to be the more probable. It would seem, therefore, that these experiments had brought little or no confirmation of the hypothesis that the increased electrical irritability in spasmophilia was the result of a disturbance of calcium and sodium equilibrium.

Dr. L. EMMETT HOLT expressed his appreciation of the experimental work done by Dr. Grulee and of his clinical work in the dietetic treatment of convulsions and allied conditions in early life. Careful metabolic observations upon infants suffering from these conditions were needed to clear up the problem. It was difficult to draw inferences from experimental work on dogs as to what took place in the child. Dr. Grulee's observations related to a single type of convulsions occurring in infancy and associated with spasmophilia. These formed but a small percentage of the cases of convulsions met with. Dr. Holt thought that the commonly held opinion regarding the seriousness of single attacks of convulsions was erroneous. In hospital practice single attacks of convulsions were of daily occurrence and were seen in a great variety of conditions, most of them not being especially significant or important. This was probably also true in private practice. In following up these cases to later childhood it was interesting and significant to discover how small a percentage of those who had had a number of attacks of convulsions in infancy developed epilepsy. While it was no doubt true that a very large proportion of patients with epilepsy gave a history of infantile convulsions, in his observations the number of children suffering from infantile convulsions who subsequently developed epilepsy was surprisingly small. Of 157 cases of convulsions occurring in infancy and early childhood observed in private practice which had been followed up, only 10 had subsequently shown evidences of epilepsy. Dr. Holt emphasized the value of lumbar puncture in diagnosing the cause of convulsions and insisted upon its performance in every case of prolonged convulsions; in this way only could it be determined whether the convulsions were due to meningitis, to some other form of cerebral disease, or to some reflex cause. Furthermore, lumbar puncture was of some therapeutic value in cases of severe or prolonged convulsions, since in practically all of these cases there was greatly increased pressure in the cerebrospinal fluid and the withdrawal of from one-half to one ounce often produced marked improvement. Convulsions rarely proved fatal *per se* unless associated with enlarged thymus.

Dr. HENRY DWIGHT CHAPIN said there were convulsions and convulsions, and the kind to which Dr. Holt referred were very frequent in hospital practice and were only ephemeral in their effects. The important point was that in a great number of cases of convulsions it was the prolonged attacks and their ultimate results that were feared. The ultimate result in many of these cases was epilepsy. A rupture of the meningeal vessels of the cortex occurred in many of these cases; as a result there was effusion and irritation which eventually produced a serious irritation of the brain. He had frequently verified this condition at autopsy. He thought that the point brought out that every convulsion occurring in a child should be treated seriously and the child brought out of the attack at the earliest possible moment was very important. Cases of prolonged convulsions should be considered with great care as these cases might be followed by some cerebral disturbance.

Dr. LINNAEUS E. LAFETRA said that as regarded the causation of convulsions and allied conditions, particularly cyanosis, leaving out of account meningitis and intracranial hemorrhage or the onset of acute infections, these conditions arose most frequently from four separate causes; from prolonged pressure at the time of birth, with probable intracranial edema; from gastrointestinal autointoxication; from sepsis, with or without resulting

brain lesion; and from inanition. The convulsions due to intracranial hemorrhage, either meningeal or cerebral, would occur very shortly after birth, though where the hemorrhages were very small they might not manifest themselves for several months. Occasionally where sepsis was accompanied by thrombosis or hemorrhage a bloody fluid was obtained by spinal puncture. One would be led to suspect this condition when there was irregular respiration, the absence of pulsation in the fontanelle, together with bulging and increased tension. He had personally seen two such cases, one in hospital and one in private practice. Premature babies or those too weak to nurse well were subject to attacks of mild convulsions and cyanosis not connected with any brain lesion. Giving breast milk by gavage or by means of the Breck feeder was followed by a cessation of the attacks. He had never seen convulsions in an infant which he attributed to teething alone, but infants that were nervous or of neurotic heredity were much more susceptible at the time of teething to gastrointestinal disturbances and to otitis media. It was likely that this indigestion was at the onset a nervous disturbance of the secretion, or else a result of fever, which in such infants frequently accompanied the eruption of a tooth. In such cases there was always evidence either in the stools or in the ear that the convulsions were due to something more than the irritation of the gums. The convulsive attacks of infantile tetany were usually diagnosticated without difficulty by the appearance of the child, the attacks of laryngospasm, and the facial and elbow reaction. A very unusual complication of convulsions which seemed worth while mentioning occurred in a patient of his six years ago. The child had been subject to attacks of vomiting, convulsions, and intestinal indigestion. After a very severe attack he began to vomit coffee ground fluid having a fecal odor. He went into partial collapse and his appearance suggested acute intestinal obstruction. A stomach tube was passed and lavage of the stomach with hot saline solution caused a cessation of vomiting and the danger was passed. The boy, however, had inhaled vomited material so that he suffered a series of complications—an attack of pneumonia, then abscess of the lung, and finally empyema. Though such complications were exceedingly rare, this case taught that the stomach tube as well as the rectal tube for high irrigations should be ready for use in the case of convulsions in older children.

Dr. Foster Kennedy said that one should not get into the habit of thinking or believing that infantile convulsions so repeatedly seen belonged to any clinical entity. Lumbar puncture was very important in every case of convulsions accompanied with fever. It should be determined immediately whether the case was one of encephalitis or one of cerebrospinal or tuberculous meningitis. Dr. Kennedy entered a strong plea for the early and frequent use of the ophthalmoscope. It was stated that in England there were many children who died before the age of ten years with a history of having had many convulsions at the age of four or five years and many lost their sight. The history of these cases made him believe that one should more often resort to the ophthalmoscope. It was sometimes difficult to tell whether convulsions were the result of epilepsy or whether they were of a hysterical character. If in about an hour after an epileptic attack one got a change in the type of plantar reflex it was significant. This point was not mentioned in the textbooks but should be looked for in every child who had a convulsion. It seemed to him that it was right to give chloral or some other sedative to these children. In cases with a history of infantile convulsions epilepsy followed more often than was thought by many.

Dr. Grulee, in closing the discussion, said he wished it to be understood that the cases he reported were of purely spasmophilic nature and represented but one type of convulsions. Spasmophilia was a very common condition and was often accompanied by laryngismus stridulus. Burke followed 30 cases of spasmophilia from ten to fourteen years and in no case did epilepsy occur; on the other hand, many cases of true epilepsy gave a history of convulsions in childhood, which appeared to occur periodically, but were not the repeated convulsions such as occurred in spasmophilia proper.

The Albumin Reaction in Tuberculous Sputum.—L. Guerra-Coppioli and G. Mansuino conclude from their investigations that the chemical examination of tuberculous sputum for albumin or albumose is of no diagnostic value, either in cases in which tubercle bacilli are present in the sputum or in those in which the bacilli are absent.—*Rivista Critica di Clinica Medica.*

THE MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held October 28, 1912

The President, Dr. Charles Gilmore Kerley, in the Chair.

High Frequency Currents in Medicine.—Dr. Frederick de Kraft read this paper. He said that when using high frequency currents for medical purposes, either a static machine of large output, or a coil with mechanical break, or a rotary converter might be the source of the current supply. If a Leyden jar was attached to each of the two prime conductors of a static machine and the sliding poles were slightly apart and the machine running at fair speed, the rapid passage of sparks was noted at the sliding rods. A pair of electrodes attached to the outer coatings and held the same length apart would also show a shower of sparks. Such was the basic arrangement of all high frequency currents. The frequency of the oscillations depended entirely upon the capacity of the Leyden jars and the self-induction of the discharging circuit. With the multiple spark gap which was now employed they had succeeded in obtaining oscillations of infinitely great frequency and as a result great warming effects. The result from this great number of short fine sparks in increasing the rate of oscillations was truly amazing. They could obtain a gentle warmth or a heat that would desiccate the tissues in the shortest conceivable time. As a result of the greater self-induction produced by these extremely rapid oscillations there occurred the "kick off" or Oudin spiral. The brush effect was more marked, many times larger, and of greater density. Dr. de Kraft then described the methods of using the d'Arsonval current, which were three in number; the direct application, that method where the patient was placed in a large solenoid in such a way that no part of his body touched the solenoid; and the method of autocondensation. By the latter method the patient placed on the autocondensation couch would experience a slight sense of warmth, beginning at the wrist and gradually extending over the whole body. This was attended with flushing of the capillaries of the skin of the hands and wrists, which gradually extended over the whole body. The insensible perspiration of the skin was slightly increased. Patients suffering from gouty or rheumatic pains frequently experienced complete relief during treatment, which lasted sometimes for hours and sometimes for days afterward. An individual with normal pulse rate and temperature showed no change in either; this was true only of currents of moderate amperage. In other words, autocondensation helped to equalize the circulation where it was unbalanced. Raw meat, potato, etc., could be easily cooked by the high frequency currents, and the manner of cooking showed that this action of the current had been in a perfectly straight line between the electrodes. This was an important effect and enabled one to localize the action to any part of the body. There were two kinds of effects to be noted when these currents were applied by the bipolar method. The first was destruction and death of the tissues, and the second, increased function and vitality. To effect the first they heated the tissue to the point of coagulation. To gain increased function and vitality they heated the tissue gently. Not only did the cutaneous glands secrete sweat more freely during this treatment, but the liver secreted a larger amount of bile. They might even precipitate an attack of gallstone colic in persons not previously suspected of having gallstones. If the stones were small, the greater flow of bile might suffice to expel them. The activity of the function of the stomach, pancreas, genital organs, bladder, and kidneys might all be stimulated. In applications to the thorax, deepening of the respiratory excursions might be noted. In asthma the noisy respiration would cease, the expectoration become freer and less sticky, sleep would become easier, the appetite would return, and the bowels become normal. The attacks became fewer and finally ceased. In heart disease, where digitalis had failed to exert its physiological action, the heart responded and the dropsy was seen to disappear with profuse diuresis. In gonorrheal arthritis they heated the joint to the limit of safety. Gonococci died at a temperature of 40° C. and they observed marked relief from pain and swelling. In gout the bipolar method relaxed arterial spasm in the joint, produced an arterial hyperemia, and enabled the phagocytes to attack the urate of sodium needles, which Van Noorden told them were eaten with avidity by the

phagocytes. Dr. de Kraft showed the beneficial results of this treatment in acute alcoholism, the early stages of arteriosclerosis, the healing of old ulcers (even diabetic ulcers sometimes disappearing), in intestinal autotoxemia, and he alluded to the action of sparks and effleuves on bacteria. The healing of abscesses might be hastened by applying the effleuve. Prolonged application might lead to the formation of blisters. A more or less general application of the effleuve might raise the blood pressure several centimeters. The short hot spark, which had been used in destroying papilloma of the bladder, burned like a cautery and formed an eschar similar to a burn from a hot iron. The short spark of lower amperage, as used by William Clark of Philadelphia, fell short of producing an actual incineration of tissue; they simply deprived that part of its moisture. A careless technique, unsuitable apparatus, improper conception of the action of the high frequency currents, and ignorance of the indications to be met would result in failure to obtain the physiological effects described and failure to relieve the patient of his sufferings.

Some Applications of Phototherapy.—Dr. E. C. Titus presented this paper, confining his remarks to the practical therapeutical aspects of the subject based upon his own observations. The remedial action of sunlight was well known, and progress in electricity had placed at their disposal various means of obtaining light which closely approached that of the sun in its remedial action. The general application of phototherapy consisted practically in the use of the electric light bath. Dr. Titus then described the cabinet which he employed which had the advantages that it provided a large volume of light with a minimum amount of heat, that the emanations of noxious gases and odors from the human body were quickly carried off, that the degree of cutaneous hyperemia and diaphoresis was much more intense, and that the usual depression and other unpleasant symptoms were entirely obviated. Among the conditions in which the electric light bath would be found to be most serviceable were arteriosclerosis, gouty and rheumatic conditions, Bright's disease, diabetes, obesity, and acute catarrhal affections of the respiratory tract. The effects of the baths were to induce intense hyperemia of the skin and thus to reduce deep visceral congestion and to increase elimination by way of the lungs and skin. It had been found that during and following the bath the elimination of carbondioxide was practically doubled, while the profuse perspiration carried away much toxic material, thus relieving the overtaxed kidneys. In the local application of light the following means were available: 1. The arc light which was best employed by means of an ordinary searchlight, with its glass front window removed, was what he used. It consumed 25 to 35 amperes of direct current at 40 volts, and projected the light in parallel rays by a twelve-inch parabolic reflector and had a light power of about 5000 candle power. 2. The high power incandescent lamp fitted in a suitable dome reflector with a carbon or tungsten filament and of 500 candle power might be employed. The carbon filament used 12 amperes at 110 volts, while the tungsten lamp consumed only amperes at 110 volts. The former gave much more heat with the radiations, while the latter produced the greater degree of white light with a minimum amount of heat. The sum total of the combined effects of the thermal and actinic rays was an increased local activity as manifested by a pronounced hyperemia and an augmented tissue oxidation and elimination. The effects of the radiant energy were not confined to the site of application, but were so diffused that remote effects were produced in distant organs and nerve centers as a result of peripheral stimulation. It had likewise been shown by physiological investigators that the heat production in the tissues increased phagocytosis and thus enhanced the vital resistance. The rapid relief of pain and local spasm experienced from light therapy was due in a great measure to the reduction of congestion and to tissue relaxation. These decided effects were brought about with the least risks to the patient, a statement not applicable to other methods of treatment. The conditions in which the local application of phototherapy in his experience had yielded the most satisfactory results were many forms of spinal congestion, the acute stages of bronchitis or pulmonary congestion from any cause, pleurisy with effusion, acute and subacute inflammation of the gall bladder, congestion of the liver and other abdominal viscera from alcoholism, and persistent intestinal autointoxication, myalgias, acute otitis media, frontal or orbital headache accompanying acute coryza and especially involvement of the frontal sinus and ethmoid cells, acute appendicitis, various types of septic conditions such as phlebitis following labor or intrapelvic operations, infected wounds of the extremities. From his experience thus far there seemed to be a brilliant future for this measure in hastening repair in cases of delayed union of fractures. Subsequent experience had verified his observations made some time ago that the deleterious effects of the *x*-ray might be prevented by following its application with the rays from a marine searchlight.

Physical Therapeutics from the Modern Point of View.—Dr. William Benham Snow read this paper, in which he expressed the opinion that there was no department of medicine which was more neglected by most physicians than the use of electricity and other physical measures in therapeutics. Until recent years electrotherapeutics had been limited to the use of the constant and induced currents and a generally indiscriminate use of the static currents. Under the empiric régime of Erb and his followers the employment of electricity fell into disrepute, except with a few physicians who used it scientifically with a knowledge which enabled them to meet indications. These men had developed electrotherapeutics into a science which rivaled surgery or any other recognized medical procedure. There were three specific effects of electric currents which met distinctly different indications. These were: (1) Mechanical, (2) therapeutic, (3) electrolytic effects. It was generally desirable that currents be employed which practically produced but one of these effects in order to meet definite indications. In the static, the high frequency, and the constant currents they had three distinctly different classes of currents, which were peculiarly well adapted to meet the different indications respectively. Electrical currents which produced mechanical effects induced contraction of muscular tissue alternating with release when the rate of interruption was less than 600 per minute; above this rate contractions became tonic. For these effects the static methods excelled all others and were practically devoid of thermic and electrolytic effects. Such currents applied to infiltrated tissue forced out through the lymphatic channels the products of inflammation retained in swollen and indurated tissue. A part or organ which might have suffered a local trauma or sprain or was the site of local congestion was thus softened and the swelling reduced with a restored metabolism. In addition, the static current materially improved general metabolism and relaxed local muscular spasm by a selective action on the muscle cells and prevented its recurrence by having removed the causes of the spasm. The thermoelectric high frequency current, or the d'Arsonval high frequency current, produced an effect which was purely thermal without mechanical or electrolytic action. Its value from a therapeutic point of view was of comparatively recent recognition. When a tissue was irritated or heated it became promptly hyperemic, which result in either case arose from reflex stimulation of the vasomotor centers. The extent and degree of the hyperemia produced would depend upon the size of the electrodes and the volume of the current passing. The current would pass through and heat all of the tissues which were in the interval immediately between the electrodes and nowhere else. Electrolysis, with or without ionization, was the third property of electric currents which served a distinctly different purpose from the others in that it was a destructive process by which the tissues were disorganized. Salt solutions and organic bodies might be acted upon and separated into their ultimate elements and ionized into the tissues. The opposite poles were, therefore, distinctly different in their actions and indications, and a knowledge of these effects and an intimate familiarity with dosage and technique was imperative; for no current in the hands of a novice was so dangerous as the constant current. Radiant light and heat were important therapeutic agents, the value of which depended upon the effects of transformation of radiant energy into heat units and other vibratory effects when applied to the tissues. The effects of the higher frequencies were antiseptic or actinic and from the lower frequencies stimulating or inhibitory. The luminous effects undoubtedly increased the oxidizing powers of the blood with an increase in the hemoglobin. The heat effects arising from the absorption or transformation of radiant energy into heat vibration, locally increased metabolism, nutrition, and phagocytosis by the induction of hyperemia. This latter was the most important effect of radiant energy. After considering the *x*-ray with regard to its power of penetration and its inhibitory effects, Dr. Snow spoke of

convective heat, which, he said, was not capable of producing hyperemia beneath the skin. When employing high temperatures with the dry hot air apparatus, however, with the parts protected by Turkish toweling for the purpose of absorbing the perspiration, thereby preventing blistering, it was capable of producing an intense hyperemia in the deeper structures. By means of the depressing effects of the heat and the hyperemia thus induced, this method was valuable and uniformly successful in from two to four days in the treatment of pyogenic infections in an arm or leg. Mechanical vibration and concussion were important therapeutical measures which rendered the processes of massage much easier and more practical and were capable of producing deep penetrating vibration with stimulation or inhibition of the spinal centers and of the various organs in the abdominal and thoracic cavities. Dilated arterial trunks might be contracted and the stomach, kidneys, or other organs, relaxed or contracted at the will of the operator. Wherever inflammation was present without the presence of germs or malignancy in the inflammatory zone, the static modalities—the static wave current—the static sparks, brush discharge, and all other static modalities were preeminently the most effective means known to medical science for promptly restoring swollen and infiltrated tissues to normal. In nearly all conditions, except where fracture or rupture of bone or ligament or muscle was present, the results were remarkable. Noninfected cases, including a large number of conditions such as neuritis, sciatica, brachial, facial, or herpes zoster, noninfected synovitis, and the toxemias affecting the joints, were all relieved. Synovitis arising from intestinal toxemia demanded removal of the source of toxemia together with the electrical treatment. Gonorrheal arthritis in the male was promptly relieved by the application of the static wave current, preceded by the vacuum tube current, applied to the vesicles and prostate gland in the rectum. Dr. Snow said he had succeeded in relieving over two hundred such cases to date. Subinvolution and dysmenorrhea also yielded in 90 per cent. of the cases to the static wave current applied with a metal electrode in the rectum. The treatment of varicose ulcers, phlebitis, chronic eczema, and numerous other superficial skin conditions might be added to these. For efficiency in relieving these conditions the static machine holds this field preeminent. The mechanical effects were feebly produced by currents from other apparatus, but they did not compare in efficiency with the effects of the static current. The treatment of inflammation due to local infection by the combined effects of the *x*-ray, radiant light, and heat, and the high frequency currents, was one of the most satisfactory of modern therapeutic methods. Tuberculous infections, superficial and deep seated, might be effectively relieved in the first stages by these three potent agents used in proper combination. In tuberculous adenitis and the two types of lupus they seemed to be specifics. In pulmonary tuberculosis they undoubtedly filled an important place. In tuberculous peritonitis they comprised the rational treatment and there were many records of success from their employment. They were no less successful in the treatment of pyogenic infections, and had been effective in early and chronic appendicitis and in gonorrheal vesiculitis and epididymitis. These statements might seem too optimistic, but they would bear critical investigation. He also spoke of the effect of the d'Arsonval current upon hypertension and stated that it was possible to control the blood pressure in all except the most advanced cases of arteriosclerosis, to prevent apoplexy, and often to defer nephritis. In inflammatory processes with developing hyperplasia and adhesions it was always possible to arrest the process and promote absorption of such lowly vitalized tissue. Among other conditions which might be favorably affected by electrotherapeutics were pelvic hemorrhages arising from fibroids, menorrhagia arising from atonic conditions of the uterus, profuse menstruation, and all conditions of hypersecretion of the ductless or other glands, and also in cancer.

Dr. Emil Heuel asked Dr. de Kraft what he really meant by the term "high frequency current," and what Dr. Titus meant about the various color lights he used in his work. He could not agree with Dr. Snow in all that he said in his paper. He was still using drugs and was not depending entirely upon the use of physical therapeutics in spite of the fact that he had been interested in this sort of work for more than thirty years. In attacks of appendicitis and some other conditions the action of the light was very similar to, in fact, simply the same as that of Wertheim.

Dr. John H. Brandth limited his remarks chiefly to Dr. de Kraft's paper, and said that the paper was to him the more interesting because for many years he could not understand why high tension currents of electricity should pass along the surface and not directly through a body, for rapid moving forces were not easily deflected from their course. Electricity could be deflected to a degree by obstructions if the pressure was relatively small. X-rays could be slightly deflected by a magnet. Sunlight could be deflected to a degree by refraction of the conductor, which was glass or any translucent substance. Heat penetrated slowly, but directly. Still Houston and Maxwell made this claim regarding high tension currents. Some years ago Dr. Brandth demonstrated this error by sending a high tension current through rubber, glass, and water. He quoted a paragraph which he read at that time. Now, while he proved that these currents passed through the body in a straight line, acting consequently on the organs in this line, and as a result proved that this remedial action was of value, Dr. de Kraft, above all others, showed that the vascular motion induced by the electric vibrations evolved heat on the line of current passage. This heat was greatest in the middle between the two poles. The cooking of a potato or of a piece of liver showed this, and it showed, above all, that the current did not travel on the surface. To make use of this remedial agent, it should not be placed in the hands of a tyro, for one should know how to apply this remedy. In untrained and unskilled hands electricity was a dangerous weapon like a keen edged surgical knife. He had used the high frequency and high tension currents in cirrhosis of the liver with success. In one case which he reported the abdomen had been tapped every eight or ten days with the removal of from twenty-four to twenty-eight pints of fluid; this collection was caused by portal vein obstruction induced by the cirrhotic liver. This patient was now well. He also reported another case of atrophy of the liver, where the tappings obtained anywhere from sixteen to twenty-four pints of fluid every eight to fourteen days. This patient, too, was relieved and to-day was well. Dr. Brandth expressed his admiration of Dr. de Kraft's work along these lines. His achievements broadened their field of action in combating disease, in the establishment of orderly and healthy metabolism in place of pathological metabolism (which meant illness). They should not forget, however, that electricity was by no means a cure-all; it was only one remedy and must be applied only by those who were skilled and experienced in its use. He had found that static electricity promoted healthy metabolism, as, for instance, in chlorotic girls. To some of these patients one might give iron in any quantity, but assimilation was so defective that all the iron passed off by the stools and did not help the patient. But, in many cases, when static electricity was added the following healthy metabolism would invite the absorption of the iron and then only small doses need be given; then the stools would have a natural color. This assertion held good in nearly all forms of medication, perhaps even more so in the administration of mercurials.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held October 21, 1912.

The President, Dr. Reynold Webb Wilcox, in the Chair.

A New Method for the Direct Transfusion of Blood and Its Possibilities; Theoretically Considered.—Dr. Alfred Kahn said that the object of this paper was to consider theoretically a new method of transfusion, or a further development of methods now in vogue and discuss its possibilities. For want of a better name he would call it continuous transfusion, or transfusion between two or more subjects. This transfusion might take place between two subjects or between several subjects, and continue as long as the blood was kept in continuous circulation between the giver, or givers, and the receiver.

He spoke first of transfusion between two people, or cross transfusion. Vessels were to be connected in the following way: artery of donor to artery of donee and artery of donee to artery of donor; so that the blood would flow, for instance, from subject A to subject B, and back from B to A; making a crossed and complete

continuous circulation. Instead of making an artery-to-vein or vein-to-vein connection, as was now done, and ligating the two ends of vessels not entering into the transfusion, all ends of vessels were to be used; so that the blood would flow from the upper end of the artery of the donor to the lower end of the artery of the donee, while the blood from the upper end of the artery of the donee would flow to the lower end of the artery of the donor. The veins could possibly be utilized in the same way, but it was doubtful whether the transfusion could be kept up for as long a time as where the arteries were employed. He next spoke of transfusion between more than two subjects. Here a connection was to be made, say, between the left arm of A and the right arm of B, another connection between the left leg of C and the left leg of A, and still another between the right leg of C and the right leg of B; making a complete circulation. The connection in each instance was artery to vein; the blood flowing from B to A, to C, to B, and so on. The idea was to allow healthy blood to flow from the donor to the recipient, and after it had remained in the latter's body for a longer or shorter period, according to the object of the transfusion, the condition of the patient, etc., the return vessel was to be unclamped and the blood allowed to flow back to the donor. This would enable the donor to retain his strength and at the same time permit the patient's diseased or weakened blood to pass through a healthy body, where it received fresh sustenance, and then return to the diseased body. This method would secure an unlimited supply of fresh blood and for an indeterminate length of time. It had all the advantages of the present method, with the additional advantage that all the organs of the healthy subject participated in the act. The therapeutic possibilities of direct blood transfusion had been clearly set forth by other writers, especially Hartwell, and Cole and Winthrop had reported a series of cases of pellagra, in which this was employed with excellent results. As to the additional possibilities of continuous transfusion, if our laws of immunity, as now recognized, were correct, the possibility of curing most of the infectious diseases through this method could well be imagined. In this connection he had in mind the transfusion of blood, from a person immune (through a natural or acquired immunity) to a certain disease, to a person suffering from such disease, especially where the transfusion could be continued, back and forth, from one to the other; thus allowing the blood to be acted upon by healthy immune organs. Again, continuous transfusion might be employed as a means of nutrition. Of course, this would be an extreme measure, but the method possibly had a future before it in cases where a patient was unable to take food, as after gastrointestinal operations, or where patient was unable to digest his food. Third, there was the possibility of administering by this means a general anesthetic to a patient to be operated upon, through the medium of a healthy individual. This applied particularly to operations on the upper air-passages and the thoracic organs. Fourth, in cases where the respiration or circulation failed during a general anesthesia, continuous transfusion might be tried as a last resort. Fifth, it might be employed (after other means had failed) for the purpose of exciting circulation and respiration in the new-born. Among the disadvantages of continuous transfusion were the possible necessity of having the blood of three subjects (instead of two) hemolytic, and the number of connections required. In this method, as would have been seen, the blood of the donor was not entirely sacrificed, as was the case in transfusion as now performed. There was in reality an exchange of blood, so to speak; the patient receiving healthy blood and having his own blood flow into the system of the healthy subject.

Transfusion of Blood with Technique Recently Much Improved and Simplified.—Dr. ALEXIS CARREL, of the Rockefeller Institute, made an address, illustrated with lantern slides, on this subject. He said that transfusion by Crile's methods was simplified by employing the saphenous vein of the recipient, by making only a small incision in the arm of the donor, and by anastomosing the vessels with a thin-walled tube. The advantages and main points of this improved technique were the following: (1) It was very much easier to unite the radial artery to the saphenous vein than to the basilic or cephalic. The lower part of the internal saphenous could be extensively dissected very readily. (2) If a long segment of the saphenous were used it was not necessary to make an extensive dissection of the radial artery of the donor. A short incision in the skin and a dissection of the radial which would permit a lateral opening would be sufficient. (3) The gold-plated silver tubes employed, which were three or four centimeters long, were made by M. Gentile in accordance with the suggestions of Dr. Tuffier and Mme. de la Marine, and were similar to those used by Dr. Brewer. Before being used the tubes were paraffined. The radial artery was cut laterally and the tube introduced through a three-branched dilater made by M. Collin, as proposed by Dr. Dehelly. These improvements in the technique, the speaker said, would doubtless contribute to the method of blood transfusion originated by Dr. Crile.

Dr. GEORGE EMERSON BREWER said that for the idea of the method of transfusion which had been referred to by Dr. Carrel as the "Brewer method" he was in reality indebted to Dr. Carrel himself. It seemed very desirable to have a plan of procedure simpler than that of Crile, and with this end in view a series of experiments on animals was undertaken. With two or three others he had made some thirty or forty such experiments, paraffining the tube which was employed. In only one instance did coagulation of the blood occur, and in that case it was found that the paraffin coating had become loosened. Altogether, the results obtained seemed very satisfactory and convincing; but when they came to employ the procedure in the human subject they found that it was impossible to make use of the same large cannula as in the case of dogs. It therefore became necessary to use smaller tubes. The method was simpler and easier than that of Crile, but in one instance it failed absolutely. This was because the radial artery of the donor was so small that only an ounce or two of blood could be secured. Since then, consequently, he had been afraid to try this plan, and in the last four or five cases he had had he had resorted to the Elsberg method. Now, however, with the improvement devised by Dr. Carrel we could employ an ordinary tube with a very much larger caliber than we had before; one in which the lumen was practically of the same size as the external diameter. Within forty-eight hours after Dr. Carrel had shown him this improved tube he tried it in a case, but he had to confess that it failed, on account of the small size of the artery. He had, however, no dilator, such as Dr. Carrel had described this evening, and he was confident that if he could have had the assistance of this dilator the operation would have been successful. It seemed to him that if we could have a tube a little longer than that advised by Dr. Carrel it would be an advantage, as it would be considerably easier to handle. Dr. Carrel certainly deserved great credit for his improved technique, and he agreed with him that with the use of the large-caliber cannula this was now the simplest and easiest of all methods. Dr. Brewer went on to say that in one case he had made use of the ulnar instead of the radial artery, and he believed that it had certain advantages over the radial. Thus, it was usually rather larger, and there was not so much dissection required as in the case of the radial arterioles. He would like to inquire of Dr. Carrel as to the quantity of blood advisable.

Dr. JOHN DOUGLAS said that everyone who had done transfusion by the ordinary suture method, with cannulæ of various sorts, had sometimes failed. Most of his own operations had been done with the Crile or Elsberg cannulas. In one or two instances he had tried tubes such as Dr. Brewer had employed, but he had not found their lumen large enough, as they became clotted. He therefore believed the silver tube employed by Dr. Carrel a great improvement in simplifying the method of transfusion; as was also the anastomosing of the radial artery to the saphenous vein instead of the median basilic or median cephalic vein, the employment of the saphenous vein not only being easier for the surgeon but also making the positions of both the donor and recipient more comfortable.

Dr. FRANZ TOREK said that his experience included the use of the external jugular vein in the case of the recipient. He had employed this only a few days before, and was induced to do so by the consideration that a free flow of blood depends not only upon the size of the donor's artery but also upon the resistance to the flow in the body of the recipient. That resistance would be less in the jugular than elsewhere; in fact, the pressure at the jugular was negative. The position of the donor (radial to jugular) was somewhat uncomfortable, but the flow was satisfactory. In the case mentioned he used the Soresi apparatus for transfusion. Dr. Carrel's new method, he said, impressed him very favorably as being a simplification of former methods.

Dr. ALFRED KAHN said he did not see the great importance of having the limbs of the donor and recipient in close contact if an intermediate body such as a tube were used. He then stated that Dr. Fauntleroy, a surgeon in the United States Navy, had successfully employed

glass tubes, which were of some length, in the performance of direct transfusion. He also mentioned the fact that Dr. Frank of New York had been successful in making a direct transfusion experimentally, using the carotid artery of a dog. It was Dr. Kahn's opinion that if an intermediate body were to be employed a tube composed of animal matter, like the carotid artery of a dog, would make the best intermediate connection. He went on to say that some difficulty might arise as to the possibility of being able to distinguish when bubbles or obstructions formed in the tubes mentioned by Dr. Carrel, where paraffin was used. He thought that these tubes must be of such small caliber that it would probably be impossible to see through them and be able to discern the obstructions.

Dr. CARREL, in closing, said that as to the length of the tube he felt sure that we could make use of one four or five centimeters long without danger. In his experiments with animals he had once employed a glass tube one foot long. The tubes which he had given Dr. Brewer he did not hesitate to say, were too large. In regard to the use of the external jugular vein he had had no experience whatever. He was sure that the blood would flow freely into this vein, but it would appear that the procedure was more complicated than when the saphenous was employed. In reply to a question by Dr. Lindeman, in regard to the difficulty of ligating the arterioles, Dr. Carrel said if we made a dissection of the vein it was not necessary to ligate the radial arterioles. As to the amount of blood, this was impossible to say. Dr. Kahn had expressed the opinion that the tubes described were of such small calibre that it would probably be impossible to see through them and discover when bubbles or obstructions had formed in them, but Dr. Carrel had never had any trouble in seeing through these tubes and discovering the bubbles made by paraffin.

The Effect of Drainage on the Prevention of So-Called Typhoid Perforation.—Dr. FORBES HAWKES, in this paper, said that it too frequently happened that the surgeon was called upon to operate on a patient suffering from typhoid fever complicated with a diffuse purulent peritonitis arising from one of the ulcers, which later on had given way, allowing the fecal material to be scattered broadcast in the general peritoneal cavity. The mortality records of such cases, even in the hands of the most skilful and experienced operators, was deplorable. In a general way, the longer the time that had elapsed between the production of the pus in the peritoneal cavity and the operation, the less was the chance of recovery. From the time that the condition first came to be recognized as a surgical one special attention had been devoted to the early recognition of this so-called perforation. It was soon found, however, that in many cases there was no symptomatic line of demarcation between a purulent peritonitis arising from the ulcer and the giving way of the ulcer, with the escape of fecal material into the peritoneal cavity. But a so-called preperforative stage of the disease was conceived of, and attempts were made to recognize such a stage as a sharply defined one. While the term was a loose one, which did not give any indication of the pathological changes which had occurred, he was not in favor of discarding it at the present time, because it might help to draw the attention of physicians generally to the conditions existing about the ulcers as soon as they had invaded the muscular coat of the bowel—suggesting, on the one hand, an early process which was not without distinct hope of recovery if properly influenced, and, on the other, overwhelmingly rapid changes, soon passing to a fatal issue, if the conditions were unrecognized. What, then, was this so-called preperforative stage? It was simply that of the peritonitis which began about the site of the ulcer and progressed with it. Its symptoms, therefore, would be simply those of this peritonitis, and the peritonitis would assume either the dry or the wet form, with adhesic or fluid exudate according, apparently, to the nature of the infection. One, then, might say: "This sounds very simple. If all that I have to do is to recognize peritonitis, I will have my patient operated on as soon as I find it, and thus give him the best chance of recovery." Dr. Hawkes said this was certainly true, and that he firmly believed that anyone having his patients operated upon as soon as signs of peritonitis appeared would have an admirable line of recoveries to report. Unfortunately, however, we did not see such lines of recoveries reported. They were not to be found in the literature on the subject, and for a very good reason. This early peritonitis was not being recognized as it should be by medical men in general. It seemed to be recognized only by men who had devoted much time to this special matter and who had the opportunity of constantly handling a large general abdominal service. He would venture the remark, based on his observations in teaching the subject of abdominal surgery to medical students, that there was no one thing of greater importance in abdominal surgery than the recognition of the earliest signs of commencing peritonitis. He then quoted from an article which he had published in the *Annals of Surgery for* May, 1911, in which he described the early diagnosis and stated that many cases had now been reported where operations were done early in the process, before the peritonitis had become purulent and before the ulcers had broken through, and that almost all these patients had recovered. Having cited an illustrative case the details of which were given in the article referred to, he went on to say that a sufficient number of early cases had been reported to justify the statement that an early exploratory operation, with the establishment of proper drainage, seemed to exert a beneficial influence in several ways: (1) If the fluid exudative type of peritonitis be found, the drainage will either arrest it or convert it into the dry, exudative type. (2) The relief of tension will favorably affect the peritoneal inflammation here, as it does elsewhere; stopping it entirely in the mild cases, hindering the development of pus in others, and localizing the pus in or near the drainage tract in the more severe cases. (3) The ulcers themselves seem to be favorably influenced by the peritoneal drainage. Local anesthesia seemed best for some cases. The shock of simple opening of the peritoneal cavity, and introducing a drain into the right iliac fossa or into the pelvis, ought not to be a marked one. If we waited until pus was produced in the peritoneal cavity our patient's chances of recovery would probably be diminished by at least 50 per cent. The cases with free feces in the peritoneal cavity almost all died.

Dr. VICTOR A. ROBERTSON said it seemed to him that this diagnosis of the preperforative stage offered many difficulties, and personally he was free to confess, he had never been able to recognize it. We should look for its occurrence at the end of the third week, when the sloughs from the intestinal ulcers were beginning to separate, but it was possible later on in the disease, and even when convalescence had begun. There might be a local inflammation of the serosa, with slight adhesions, which would give the symptoms of which Dr. Hawkes had spoken. The important matter was not so much to decide positively on perforation, or even impending perforation, but that some abnormal abdominal condition was developing which required operative interference. If exploration were undertaken, any intraabdominal condition could be properly dealt with, irrespective of its location. It was interesting to note that as far back as 1884 Mieulicz had operated for typhoid perforation, and he then stated that, if suspicious of perforation, one should not wait for an exact diagnosis, and allow peritonitis to reach a pronounced degree, but at once institute an exploratory operation; which in many instances was free from danger. He (Dr. Robertson) could readily understand that in hospital cases, where the patient could be kept constantly under observation, when every feature of the patient's condition had been carefully scrutinized, any change in his condition, however vague, could be noted, and even a slight change might serve to arouse the suspicion of an impending perforation and lead to a physical examination which would indicate this. In private practice these circumstances were not present, and slight, though important, symptoms of impending trouble might be overlooked. The value of an early diagnosis and early operation could not be overrated. He could not agree with the reader of the paper that in the case cited a beginning purulent peritonitis was converted into a general adhesive inflammation of the peritoneum, with agglutination of coils of the intestines and a prevention of perforation in this way. It seemed to him that the relief afforded was the relief of tension by drainage and the setting up of adhesions in the intestines in immediate contact with the drain. At autopsies he had often remarked the rarity of adhesions in typhoid, as compared with those in perforation from gastric or duodenal ulcers or perforation of the gall-bladder. In most of the cases of perforation in typhoid seen by him diarrhea was a marked symptom, and he thought this was apt to come from the overfeeding which was now commonly practised in the treatment of this disease. Dietetic errors, with secondary gastrointestinal irritation and abnormally increased peristalsis and meteorism, were responsible at times for perforation; while some types of infection might be more violent, and lead to more ulceration of Peyer's patches. In some of the diets employed there was given too large an amount of proteids, which were prone to cause putrefactive changes with tympanites and diarrhea. More carbohydrate foods, such as cereals and gruels, added to milk, were preferable. He realized that

one could not by antiseptics destroy the intestinal flora, but believed that their overgrowth could in some degree be inhibited by intestinal antiputrefactives. A routine use of a mild laxative, such as castor oil, he had frequently prescribed, and it seemed to him that the mechanical unloading of a distended bowel, with the consequent evacuation of large amounts of bacteria, materially lessened the toxemia and tympanites.

Dr. HENRY ROTH said that some years ago the mortality statistics of intestinal perforation were collected, and these showed that no less than 25,000 persons died in the United States from typhoid perforation alone. Since then the results had not improved very much, because in most of the cases the condition was not discovered until too late for surgery to be of much service. The mortality in the operated cases was about 75 per cent. The only way of improving this state of affairs was by an early recognition of the condition; if possible, in the preperforative stage. This could be done only, he thought, by devoting day by day as much care and attention to the discovery of abdominal rigidity and tenderness in typhoid fever patients as was now commonly done in examining for enlarged spleen, a much less important matter. Just as soon as either of these two signs was disclosed an operation should be performed, provided that other conditions capable of causing them could be excluded. He feared, however, that surgeons would not be very successful in getting the cases at this early period, because physicians as a rule were not willing to consent to have an operation done unless actual perforation was shown to have taken place.

Dr. A. ERNEST GALLANT said that the late Dr. Van Arsdale, under whom he used to work, had always laid stress on the value of delicate manipulation in the examination of the cases. With a light touch segments of abdominal resistance could often be made out where this would be impossible under rougher handling. He could not quite agree with Dr. Hawkes that the fingers should be flexed in making the examination. Better results could be obtained, he thought, with the fingers laid flat on the abdomen, or even with their ends slightly tilted up. It was also advisable that the examiner should be as much as possible on a level with the patient, instead of bending over him. With the high hospital beds commonly in use the physician might make the examination standing, but in private practice, where the beds were low, he could examine most successfully while in a sitting posture. The use of the term rigidity in this connection seemed to him a mistake, and he preferred, especially in teaching, to call the condition localized resistance. It would be interesting and valuable, he went on to say, to know just what kinds of infection resulted in adhesions. The pure typhoid infection, he believed, was not one of the type which caused adhesions. When he had a case of non-adhesive peritonitis, he always felt that he had a death certificate to sign.

Dr. EDWARD WALLACE LEE said that adhesions did result from typhoid, and in some instances he had observed quite extensive ones. Adhesions following peritonitis from typhoid fever he believed, however, were not as deadly as had been supposed.

Dr. HAWKES, in closing, said that if in any case there was distinct rigidity we should operate at once, just as we would in a case of appendicitis. The value of the treatment he had advised lay, he believed, in the production of a distinct adhesive peritoneal tract; so that perforation was either prevented or delayed. If it occurred, the fecal matter was thereby prevented from flowing into the general abdominal cavity. In typhoid fever we had toxic and non-toxic cases, and the toxic cases almost all proved fatal, whatever treatment might be employed. In the non-toxic there was the best chance for drainage, and if perforation did occur, the intestinal contents came out into the adhesive tract of which he had spoken. The great point for successful treatment was the recognition of the rigidity. As to the method of digital examination for rigidity (which might be termed localized resistance if one preferred), some examiners would no doubt find one position of the fingers of most service, and some another position. As to the advisability of the examiner being on a level with the patient, he thought Dr. Gallant's suggestion a good one.

In reply to a question by Dr. Lee as to whether the drainage referred to acted as a prophylactic for the prevention of continued ulcerations, Dr. Hawkes said that further ulceration might occur at other points. He had not seen this, however.

CLINICS, DEPARTMENT OF PUBLIC CHARITIES

Calendar, December, 1912

MONDAYS

City Hospital	Ophthalmology	Dr. Strouse	2.00 P.M.
	Gynecology	Dr. Child	2.00 P.M.
	Surgery	Dr. Dawbarn	2:30 P.M.
Neurological Hospital	Neurology	Dr. McPhee	2.00 P.M.
Cumberland Street Hospital (Brooklyn)	Surgery	Dr. Walmsley	2:30 P.M.
	Laryngology and Rhinology	Dr. Stewart	4.00 P.M.
	Oral Surgery	Dr. Shea	4.30 P.M.
Kings County Hospital	Gynecology	Dr. McNaughton	9.00 A.M.

TUESDAYS

City Hospital	Surgery	Dr. Collins	10:30 A.M.
	Dermatology	Dr. Bronson	2.30 P.M.
	Medicine	Dr. French	3:00 P.M.
Cumberland Street Hospital (Brooklyn)	Gynecology	Dr. Burnham	3:00 P.M.
	Surgery	Dr. Iler	3.00 P.M.
Kings County Hospital (Brooklyn)	Surgery	Dr. Bristow	2.00 P.M.
	Genito-urinary Surgery	Drs. Norton and Fraser	2.00 P.M.
Coney Island Hospital	Surgery	Drs. Fisk and Bogert	10.30 A.M.
	Medicine	Drs. Hall, Nash, Hegeman and Byington	3.30 P.M.

WEDNESDAYS

City Hospital	Surgery	Dr. Dawbarn	9:00 A.M.
	Genito-urinary Surgery	Dr. Fuller	2:00 P.M.
	Obstetrics	Dr. Dorman	2:30 P.M.
Metropolitan Hospital	Surgery	Drs. Ostram and Harrington	2.30 P.M.
	Genito-urinary Surgery, Dec. 4	Dr. Carleton	2:30 P.M.
	Dermatology, Dec. 4	Dr. Dearborn	2:30 P.M.
	Dermatology, Dec. 11	Dr. Dearborn	2.30 P.M.
	Ophthalmology Dec. 11	Dr. Boyle	
	Medicine, Dec. 18	Drs. Klots and Laidlaw	
	Genito-urinary Surgery, Dec 18	Dr. Carleton	
	Pediatrics, Dec. 18	Dr. Wallin	
Neurological Hospital	Neurology	Dr. Maloney	9.00 A.M.
Cumberland Street Hospital (Brooklyn)	Ophthalmology and Otology	Dr. Schmuck	4:00 P.M.
Kings County Hospital (Brooklyn)	Orthopedics	Dr. Truslow	9:00 A.M.
	Dermatology	Dr. Winfield	1:00 P.M.
	Orthopedics	Dr. Napier	2:00 P.M.
Coney Island Hospital	Pediatrics	Drs. Beck, McQuillan, Pendelton and Van Wart	3:30 P.M.

THURSDAYS

City Hospital	Medicine	Dr. Evans	9.00 P.M.
	Surgery	Dr. Collins	10:30 A.M.
	Gynecology	Dr. Child	2:00 P.M.
	Medicine	Dr. Brooks	2:30 P.M.
Cumberland Street Hospital (Brooklyn)	Gynecology	Dr. Burham	1.00 P.M.
	Surgery	Dr. Walmsleep.	3:30 P.M.
Kings County Hospital (Brooklyn)	Obstetrics	Dr. Judd	10.00 A.M.

Kings County Hospital (Brooklyn)	Obstetrics	Dr. Commiskey	10:00 A.M.
	Surgery	Dr. Bristow	2.00 P.M.
	Medicine	Dr. Stivens	3:30 P.M.

A Specific Immune Lipase.—J. W. Jobling and C. G. Bull conclude that erythrocytes have definite lipoidal constituents and lipoidal combinations peculiar to the species. Certain lipoids and lipoidal combinations act as specific antigens. The increase in serum lipase which occurs upon immunization of animals to foreign red cells is, at least in part, specific. This specific lipase plays, no doubt, an important part in specific serum hemolyses.—*Journal of Experimental Medicine.*

Miscellany.

The Alienists as Caricatured by Molière.—B. M. Randolph presents the following extract from Molière's comedy ballet, M. de Pourceaugnac, in which the father of the French drama indulged freely in his usual raillery against physicians. M. Pourceaugnac is a wealthy, fat, middle-aged bourgeois from a provincial village, whom Oronte has selected as husband for his daughter. The latter being in love with Eraste, her lover plots to have M. Pourceaugnac attainted in the estimation of Oronte. To do this he engages two physicians to declare M. Pourceaugnac insane. Their method of procedure is as follows:

First Physician. "Come, sir, take a seat."
(The two doctors make M. P. sit between them.)
Pourc. "Your very humble servant." (They each take a hand to feel his pulse.) "What does this mean?"
First Phys. "Do you eat well?"
Pourc. "Yes, and drink still better."
First Phys. "So much the worse; this great appetite for cold and moisture is an indication of the heat and dryness that is within. Do you sleep soundly?"
Pourc. "Yes, when I have supped well."
First Phys. "Do you have dreams?"
Pourc. "Sometimes."
First Phys. "Of what nature are they?"
Pourc. "Why, of the nature of dreams. What the devil is this conversation?"
First Phys. "How are your dejections?"
Pourc. "Faith, I understand nothing of all these questions; I would rather take a drink."
First Phys. "A little patience. We are going to reason on your case in your presence, and we will do it in French to be more intelligible."
Pourc. "Why so much reasoning in order to eat a little?"

The first physician enters into a long-winded, learned discourse on the diagnosis of the supposed malady, which he declares to be a hypochondriacal melancholy. The second physician, after a long and complimentary tribute to the one who has just spoken and after congratulating M. Pourceaugnac on having fallen into the latter's hands, proceeds:

" . . . All I should wish is that the bleedings and purgations be of an uneven number—*numero deus impare gaudet*—to take the whey before the bath; to place a salt bandage on the forehead, as salt is the symbol of wisdom; to whitewash the walls of his room, to dispel the dark shadows of his mind, and to give him every hour a small clyster to serve as a prelude and introduction to these judicious remedies, from which, if he is going to get well, he ought to receive relief. Pray heaven, sir, that these remedies that are yours, may conquer the disease according to our intent."
M. Pourc. "Gentlemen, I have been listening to you an hour; is this a play?"
First Phys. "No, sir; we are not playing."
Pourc. "What is all this, and what do you mean by this bosh?"
First Phys. "Good. Abusive. That is a diagnostic sign that was lacking to establish the disease; this may easily turn into mania."
Pourc. "Where have they placed me?" (He spits two or three times.)
First Phys. "Another diagnostic sign—frequent spitting."
Pourc. "Let's stop this and get out of here."
First Phys. "Still another sign—restlessness."
Pourc. "What is all this business? What do you wish with me?"
First Phys. "To cure you acccording to our orders."
Pourc. "Cure me?"
First Phys. "Yes."
Pourc. "Zounds, I am not ill!"
First Phys. "A bad sign when the patient is not conscious of his malady."
Pourc. "I tell you I am well."
First Phys. "We know better than you how you are; we are physicians, who can see clearly into your constitution."
Pourc. "If you are physicians, I will have nothing to do with you; I mock at medicine."
First Phys. "Hm. Hm. This man is crazier than we thought."
Pourc. "My father and mother never wanted any remedies; they both died without the assistance of physicians."
First Phys. "I am not surprised that they have given birth to a son who is insane. (To the second physician.) Come, let us proceed to the cure: and by the exhilarating sweetness of harmony let us assuage, soften and calm the spitefulness of his spirits, which I see are ready to burst into flame." —*Old Dominion Journal of Medicine and Surgery*, October, 1912.

The Army Medical Officer in Ancient Times.—Sir Henry Morris notes that in times as remote as that of the siege of Troy army doctors were held in the highest esteem. The two sons of Æsculapius, Machaon and Podalirius, were, according to Homer, very important persons in the Greek army. A stir was made in the third great Trojan battle, when Paris, "the spouse of Helen, dealing darts around," struck Machaon in the right shoulder. The wounded surgeon was carried off the battlefield by Nestor in the old warrior king's own chariot; and Achilles, sulking in his ship, having watched the progress of the battle, sent Patroclus to inquire what had happened. It was when describing these events that the poet exclaimed:

> A wise physician skilled our wounds to heal
> Is more than armies to the public weal.

Amidst all the greatest heroes of the Greek army —Agamemnon, Ajax, Ulysses, Achilles, and many others—Machaon was always spoken of as "the great Machaon," as in the following lines from Pope's translation of the *Iliad:*

> Of two famed surgeons, Podalirius stands
> This hour surrounded by the Trojan bands;
> And great Machaon wounded in his tent
> Now wants that succor which so oft he lent.

In the sixth and fifth centuries, during the wars of Persia with the Asiatic States, Darius I (521-485 B.C.), the "King of the whole civilized world," and "the King of Kings," as he called himself, as well as his successors, had Greek physicians and surgeons in their suites. In the accounts of the wars of the Persians against the Greeks we read of the physician Ctesias of Cnidus as being for seventeen years (414-398 B.C.) in the service of the kings of Persia. Ctesias is specially remembered, not as constantly accompanying Artaxerxes II (404-359 B.C.), but as being a great historian, like Herodotus and Xenophon, of the Persian wars. The Persians, to their honor, conducted their wars with great humanity, and treated their prisoners with kindness, and in many instances even with liberality and favor.

Philip, an Acarnanian, was physician and surgeon to Alexander the Great, and accompanied him through his Asiatic wars. There is an interesting story told of them. When Alexander was lying seriously ill at Tarsus a letter reached him warning him that Philip had been bribed by Darius III to poison him. Having read the letter, Alexander handed it to Philip to read, and after doing so swallowed a potion which Philip had prepared for him. This proof of the unshaken confidence of the king in his physician was soon followed by Alexander's recovery.

In the second century of the Christian era the illustrious Galen was specially summoned by Marcus Aurelius to be with him in his campaign in Northern Italy.—*The British Medical Journal.*

THE SANITARY CONQUEST OF THE PHILIPPINE ISLANDS.*

By COLONEL L. MERVIN MAUS, Medical Corps, U. S. A.

CHIEF SURGEON, EASTERN DIVISION; FIRST COMMISSIONER OF PUBLIC HEALTH, PHILIPPINE ISLANDS.

THE military conquest of Cuba, Porto Rico, and the Philippines by the United States in 1898 cannot be measured by her brilliant triumphs on land and sea, her large extension of productive territory, her increased wealth and added national prestige, but by her priceless victories over tropical diseases and conditions which for centuries had hovered over those favored isles of the southern seas as angels of death, and converted them into a charnel house both for native and foreign born.

When the stars and stripes first floated over Moro Castle, Havana, Santiago, and Manila, the sanitary conditions of those famous tropical capitals resembled that of European cities during medieval times. Pestilential and filth diseases stalked unrestrained through the fair "Pearls of the Antilles and the Orient," sacrificing hundreds of thousands of valuable lives and running up a death rate appalling in its excess over that of other civilized portions of the world.

Besides ignorance, poverty and squalor existed on every side and the benighted population saw no ray of hope or light until America intervened and gave them a progressive form of government, which infused new life and vouchsafed political, educational, and religious liberty.

The splendid triumphs of the Yellow Fever Board in Cuba, which have encircled the globe, have brought more national prestige to the United States than the victorious clash of arms since the creation of our Great Republic. Through the scientific and painstaking work of Read, Carroll, Lazear, and Agramonte, yellow fever has been practically banished from the Western Continent, thousands of valuable lives have been saved annually and untold millions added to the wealth of the world.

In our laudations of those gallant men who risked their lives daily for months to prove that the mosquito was the host of yellow-fever infection, let us not forget Doctor Carlos J. Finlay, the distinguished hygienist of Havana, who had promulgated that remarkable theory almost twenty years before, and indeed was mainly responsible for the governmental investigation.

The watchword of American activity in Cuba and the Philippines was "Cleanliness," and in our fight against diseases and insanitary conditions all rancor of battle and strife was lost. Indeed, such an impression was created in the minds of the simple-minded natives over "limpieza," the Spanish word for cleanliness, that they regarded it as a new tutelary protector added to the long list of saints, before whom they had bowed for centuries.

Advanced sanitary and educational methods were also introduced into Porto Rico and the Panama Zone, with corresponding improvement in health and general prosperity. Through the splendid work of Ashford, hookworm infection, that underlying cause of anemia and poverty in Porto Rico, has been practically eradicated, and the construction of the Panama Canal has been rendered possible through the antimalarial work of Gorgas and his colaborers in the Canal Zone.

Before discussing the great sanitary work accomplished in the Philippine Islands, let us glance at the general conditions of their peoples at the date of American Invasion.

Before the Spanish war few of the natives could read or write, as shown by the American Census of 1903-4. The educational institutions of the islands were practically confined to Manila and two or three of the larger provincial towns. With the exception of the wealthy natives and mestizo classes, few of the inhabitants enjoyed the privileges of education, although Spain had attempted on several occasions to organize a public-school system for the masses, which had been frustrated by the controlling authorities. During the centuries of Spanish domination and misrule, the slogan had ever been, "Amuse the Indian, but keep him ignorant."

Generally speaking the domestic environment of the Filipino was confined to a two or four-room nipa house, elevated on bamboo poles eight or ten feet above the ground. His furniture was primitive and simple and rarely included chairs, tables, or bedsteads, while the illumination was secured through tallow or cocoanut oil dips. Rice and fish formed the staples of his dietary, and a home-made straw hat, cotton shirt, and trousers, his wardrobe.

Drinking water was taken from an infected well within a few feet of the kitchen door, surrounded by a setting of garbage, filth, and human excreta. The family caraboa, hog, dog, and domestic fowls were domiciled under the house, and the adjoining fences were overgrown with woods and dank vegetation. The sanitary conditions and habits of the people at that time might very aptly have been compared with those of the Pueblo Indians of Arizona and Mexico.

Practically all of the country people lived in small, poorly lighted towns and villages with wretched streets, and it will take no stretch of the imagination to realize the dreariness and monotony of their surroundings. There were few social distractions or amusements to make life pleasant; besides, they were deprived of the elevating and entertaining influences of education, books, magazines, and newspapers, and it was no wonder that they had become tired of their old masters and were

* Address delivered before the Lake Mohonk Conference of Friends of the Indian, and other dependent peoples, October 24, 1912.

willing to accept any other government fate chanced to send.

Much that is contradictory has been said and written of the characteristics of the Filipino as a race. He has been charged with intelligence and incapacity, virtue and vice, veracity and mendacity, honesty and roguery, fidelity and treachery, industry and laziness. In this connection it must be remembered that for over three hundred years the Filipino had been a vassal of Spain and the monastic orders, and what he was at the time of American intervention can be safely laid at the door of his exemplars and masters.

Naturally light hearted and with a love of home, family, and music they may be regarded as a happy people upon whom the responsibilities of life sit lightly. While not fond of work, one never finds the able-bodied Filipino a beggar. For centuries he staggered under the exacting labor of rice paddy, forest, or mine without reward or compensation save the brutal oaths and lashes received from his task masters, the Spanish encomenderos.

Should he by chance have acquired education, independence of thought, and wealth, he was not left long to enjoy it. Swiftly and surely he would awaken some morning to find himself under the ban of filibusterismo, his property confiscated, and a sentence of banishment awaiting him to some distant penal colony from whence he never returned.

With no incentive to acquire property he preferred the sports of the gaming table and cock-pit, the entertainment of church processions and fiestas, and the relaxation afforded by the numerous saint's day holidays. During the lapse of these cruel centuries of ill treatment the Filipino has ever maintained strong racial qualities of pride, ambition, and independence, and it is through these characteristics that he is destined at no late date to become a great factor in molding the progress and civilization of the Orient.

The Philippine Board of Health was organized in 1901 under the administration of President William H. Taft, the first civil governor, who appointed the speaker the first commissioner of Public Health. The provisions of the bill creating the Insular Board were extremely liberal and it was due to this fact that the Board was enabled to frame health laws and create a department which practically revolutionized the sanitation of the islands and reduced the annual death rate of Manila 50 per cent. within the year. The death rate per 1,000 in Manila in 1900 was 60 to 70, while in 1902 it was reduced to less than 30 per 1,000.

Among the many vital questions with which the Philippine Board had to deal, may be mentioned the epidemic of bubonic plague in Manila in 1901-2, the public vaccination of over 3,000,000 of natives and the control of a widespread epidemic of smallpox, the segregation and colonization of over 4,000 lepers on the island of Culion, combating the great epidemic of Asiatic cholera in 1902, which carried off hundreds of thousands of the ignorant natives, the control of tropical dysentery and malaria, creation of health laws for the practice of medicine, dentistry, pharmacy, and veterinary medicine, the organization of provincial and municipal health boards, besides the care of the insane, public sick, and the domestic animals of the archipelago which were suffering from surra and rinderpest at the time.

The laws pertaining to medicine and allied professions in the Philippines stand to-day as models of their kind, and it was due to their speedy enactment that the flood of quacks and imposters were barred from the islands and the ignorant and poverty stricken natives saved from their merciless deception and importunity.

The Philippines have never been popular with the American people and consequently little has been said or written of our sanitary and colonial successes in the Far East, while the public has been kept in close touch with the work in Cuba, Porto Rico, and the Panama Canal by every newspaper, magazine, and penny-a-liner in the land.

When one considers the many millions spent on the malarial crusade in the sparsely settled strip occupied by the Canal Zone, with the comparative pittance disbursed on the complicated and colossal sanitary problems of the Philippine Islands, a territory as large as Great Britain with a population as great as Holland, Belgium, and Switzerland combined, it will be seen that the sanitary successes in the Philippines outweigh by far those of the Panama Canal. It will be remembered that the Canal Zone contains a population of only 70,000 with an area of 380 square miles, while the Philippines have a population of 8,000,000 and an area of 127,000 square miles.

Besides, the sanitary work in the Canal Zone has been practically confined to the suppression of malaria, and the well beaten paths of drainage, oiling, and screening, and is elementary in character in comparison with the constructive work of the many complicated sanitary and economic problems encountered in the Philippines.

The successful campaign against bubonic plague in Manila in 1901, which involved the destruction of the rodents of the city through traps and rat bane, was the first practical demonstration in the history of that disease, of the theory that infected rat fleas served as the host of the plague bacillus. A low estimate of the rats destroyed during the crusade places the number at 800,000 and the number examined microscopically to detect the presence of infection among them at 30,000. Time forbids the details of house inspection, remodeling, immunization of the natives through serum vaccination, and other sanitary measures employed during the campaign. Within six months after its commencement the disease was eradicated from Manila, and with the exception of a few sporadic cases, attributed to reinfection from China, the city has remained immune ever since.

Smallpox, which had been in evidence in the Philippines for a century or more, was one of the most serious sanitary problems the Americans had to contend against during the days of early occupation. The disease was general throughout the archipelago and was encountered in its most infectious form on the streets of every pueblo and even in Manila, the capital itself. Indeed it became such a serious menace to the health and lives of our troops, that many of them contracted the disease and died. In justice to the protection afforded by vaccination against smallpox, it is only necessary to add that those men who contracted the disease had not been properly vaccinated.

Few of the natives were protected and the disease was not only very fatal among them, but was regarded as inevitable through their belief in fatalism, a creed common to the Malay race. The funerals were conducted publicly, and the community litter coffin in common use among them, was returned to its niche in the church without disinfection

after conveying the corpse to the Campo Santo.

In 1901 a compulsory vaccination law was enacted and put in operation, and within a few years over 3,000,000 of the natives were vaccinated. Virus was prepared by the Board of Health from caraboa heifers, and the vaccinations were made by instructed natives. As a result of this benign law against that repulsive and fatal disease thousands of valuable lives are saved annually and smallpox is reduced to a negligible factor among the diseases of the Philippines, even more so than in many sections of the United States.

Oriental leprosy, until recently, has occupied a conspicuous position among the tropical diseases of the Philippines. According to some historians it came from Japan. It is said that a shipload of lepers was transferred to Manila early in the seventeenth century by the Tokugawa Shogun Ieyasu, as a gift to the friars whom he heard were fond of caring for the sick. The afflicted from this terrible plague were numerous throughout the archipelago during Spanish domination, and many of them occupied positions of importance as village presidentes, councilors, treasurers, and notaries-public. No restriction whatever was enjoined against attendance at church, fiestas, cock-pits, bailes, and neighborly visitation.

Under the direction of the Insular Board of Health a census was started in 1901 which disclosed the presence of 4,000 of these unfortunates in the archipelago. A law was passed for their segregation on the island of Culion and funds were appropriated for the construction of suitable hospitals and quarters for their reception. The island of Culion is about the size of the Panama Strip and contains sufficient suitable lands for the cattle industry and agriculture of the colony. Hospitals, churches, schools, and places of amusement have been provided, with competent physicians, teachers, nurses, and administrators.

The law has been in operation since 1907, during which period practically all of the lepers in the archipelago have been collected. The colony at present represents about 2,500 souls, the annual death rate of whom is close to 100 per 1,000. Few new cases have occurred since their segregation on Culion island and it is believed that the disease will disappear from the islands with the present generation.

Asiatic cholera, that twin sister of bubonic plague in its most fearful mortality, had made frequent visits to the Philippines during the nineteenth century, and returned to the islands again in 1902. During its presence in 1884 it is said that over 3,000 deaths occurred in Manila in one day, and hence its return was announced with the gravest apprehension.

Following in the steps of the insurrection among a half famished people, whose primitive habits, wretched sanitary conditions, and surroundings served as an excellent pabulum for infection, the problem appeared almost hopeless, especially as racial and political prejudices ran high and little confidence was felt in the motives of the Americans, many of whom were believed to be agents of the Evil One.

A certain class of Spanish physicians and friars even went so far as to deny the existence of cholera on account of the small number of cases which occurred in Manila as a result of the prompt sanitary measures enforced by the Board of Health. Rather than have their houses quarantined and subjected to fumigation after disposal of the cases, they drove infected members of the family into the street and secretly buried their dead under heaps of old lumber, in the rice paddies, or threw them into the Pasig River. Should my memories of the Philippines fade one by one, the last to leave would be my recollection of the great cholera epidemic which scourged the islands in 1902.

Many radical changes have occurred among the Filipino people along sanitary, educational, and sociological lines since 1898. Local boards of health have been established throughout the towns and villages of the islands, and a campaign of sanitary education introduced which has revolutionized the customs and habits of the people. Artesian wells in many communities have supplanted infected surface wells with perennial amebic dysentery, and the conservancy pail system, the obsolete and insanitary closet arrangements.

Through the beneficence of a public school system the light of American civilization has filtered into the darkest corners of the archipelago, even into the benighted regions of the Igorot and dreaded head hunter. Where one heard the jargon of fifty dialects ten years ago, choice English is now spoken by the rising generation. Illiteracy which claimed 98 per cent. of the population in 1898 has been reduced to less than 50 per cent. among the young people. Athletic sports have been encouraged among both sexes with marked improvement in their physical condition. Tennis and baseball have been accepted as the national games, not only in the Philippines but also in Japan and China, and no one can tell how soon the day may come when the pennant will be wrested from the victorious "Red Sox" by an Oriental team.

Manila, with its modern sewer system, splendid water supply, electric street cars, commodious wharves and harbors, large public buildings, new hospitals, magnificent hotels, beautiful parks and streets, has become the pride of Oriental cities and leads them all in its low death rate. Medical Inspector George A. Lung, U. S. Navy, who passed many years of service in the Far East, claims Manila as one of the healthiest and cleanest cities in the world.

The capital of the archipelago now possesses a great university with colleges of medicine, pharmacy, veterinary medicine, law, engineering, agriculture, forestry, and the liberal arts. A bureau of science has also been established, with well equipped chemical and biological laboratories for the study of diseases affecting both man and animals, as well as for general medical and scientific research. Besides this the government has constructed a modern concrete hospital of 300 beds, which affords ample hospital facilities for employees and families of the civil service, as well as for the general public.

Baguio, on the plains of Benguet, at an altitude of 5,000 feet above the sea, has become the summer capital of the Archipelago, the Simla of the Philippines. There in the cool and refreshing atmosphere of a temperate zone, and under the shade of stately pines, the Executive and Civil Commission conduct their sessions during the hot and sultry season of the year.

Commodious sanitaria for our troops as well as for civil officials and employees have been established in Benguet, and with the commission buildings, army post, hotels, schools, residences, macadam roads, and fine parks, Baguio presents an entirely different appearance when compared with the scattered Igorot village of less than ten years ago. Tele-

graph lines, railroads, and well constructed highways have taken the place of blazed trails and bind in one common brotherhood distant tribes whose very existence was unknown to each other a decade ago.

The acquisition of the Philippine Islands will always be associated with the name of our martyred President William McKinley, and the organization of their model civil government with that of President William Howard Taft, their first civil governor, whose legal and constructive mind is responsible for their splendid laws. Among other prominent Americans who have rendered conspicuous and distinguished service in the upbuilding of the Philippines may be mentioned the Honorable Luke E. Wright, who succeeded Mr. Taft as civil governor, Commissioner Dean C. Worcester, Secretary of Interior and right arm of the Insular Board of Health, the late Colonel E. C. Carter, Doctors Frank A. Meacham and Paul E. Freer, former members of the Board, all of whom died as martyrs at their posts of duty, or from diseases contracted while in that service. The Honorable W. Cameron Forbes, the present Civil Governor, Dr. Victor G. Heiser, who now has charge of the Bureau of Health, and a host of heroes, who sacrificed their lives in behalf of the Filipino people, while courageously fighting against the plague, smallpox, Asiatic cholera, and the insanitary conditions of the islands.

Much has been said and written by opposing parties about the great financial cost and loss of life entailed in the acquisition of the Philippines, the grave strategic and economic mistakes in their retention, and the industrial bondage of the Filipino people in spite of their helpless and universal protest. The Philippine Islands came into our possession as an incident of the recent war with Spain and it became our sacred duty to retain them until they became self-supporting and their peoples qualified to administer the affairs of the new republic, whose star is slowly but surely rising in the Far East. How well we have acquitted ourselves of this national obligation must be left to the unbiased judgment of succeeding generations.

It has been impossible within this brief summary to give more than an outline of the wonderful work achieved in the Philippines during the past ten years through American brains and brawn. No colossal waterway has been constructed over there connecting the two great continents of the world, but a model government has been planted and a new race born, whose progressive and civilizing influences are destined to permeate the darkest corners of the Orient, and make the name of America blessed for centuries to come.

A STUDY OF CHEST AND ABDOMINAL MEASUREMENTS IN RELATION TO BUILD.*

By FANEUIL S. WEISSE, M.D.,

NEW YORK.

MEDICAL DIRECTOR THE MUTUAL LIFE INSURANCE COMPANY OF NEW YORK.

This study is based on the weights and measurements of 3,035 healthy male adults, on whose lives policies were issued by the Mutual Life Insurance Company of New York during the years 1907-1911.

*Read at the twenty-third Annual Meeting of the Association of Life Insurance Medical Directors of America, on October 10, 1912.

These men were examined either at the Home Office of the company or at one of the agencies. In every case the examination was made by one of the home office staff or by one of our referees, all of whom have been trained at the home office.

The weights in every instance were taken by scale, and the measurements made with a steel tape on the bare skin or over one garment—both chest and abdominal measurements being made under the same conditions.

After throwing out all individuals under 25 years, I found the numbers for each inch under 5 feet 3 inches and over 6 feet to be so few that I have not considered them at all in this study.

This left me the group of 3,035 individuals—all over 24 years of age—ranging in height from 5 feet 3 inches to 6 feet inclusive.

I divided each of my largest height groups into three age groups—25 to 29, 30 to 39, and 40 and over—and found that between 10 per cent. below and 15 per cent. above the graded average weights for men as given in Table III—Build—Men in Vol. I of the *Medico-Actuarial Mortality Investigation* gave me the largest and most evenly distributed selection of individuals.

I applied this method of selection to each of my height groups. This gave me ten height groups from 5 feet 3 inches to 6 feet, aggregating 1,869 individuals—all within the same weight limits as regards the average for age. I then obtained an average weight and an average set of measurements—expiration, inspiration, and abdomen—for each height group.

TABLE I.

Average Weights and Measurements For All Ages.

Height	Weight	Expiration	Inspiration	Abdomen	Number
5 ft. 3 in	138	32.43	35.95	31.55	42
5 " 4 "	141	32.68	36.00	31.39	84
5 " 5 "	148	33.16	36.45	32.07	124
5 " 6 "	149	33.17	36.65	32.09	263
5 " 7 "	154	33.43	36.92	32.38	319
5 " 8 "	158	33.49	37.12	32.36	278
5 " 9 "	163	33.93	37.64	32.97	262
5 " 10 "	164	33.84	37.74	32.63	236
5 " 11 "	169	34.10	37.89	33.01	152
6 " 0 "	178	34.92	38.84	33.86	109

For purposes of comparison I have depended principally on the deflated chest measurement as giving the truest index of build. The inflated chest measurement is often increased by muscular effort, while the abdominal measurement depends largely on the posture or the desire of the individual.

After finding the average weight and measurements for my height groups I divided each of them into two classes—one containing all the individuals below, and the other all the individuals above, the average weight. I then obtained an average weight and an average set of measurements for each class for each inch.

The factor of increase or decrease per pound was obtained by dividing the difference in measurement of the two classes by the number of pounds difference in their weights.

Table No. II. shows the averages of the two classes and the factors per pound for each inch.

On comparing these high and low averages it is apparent that each changing pound in weight at a given height causes a definite change in the measurements.

To prove the accuracy of these increases and decreases in measurement per pound weight, I took all the individuals in the three large groups—5 feet

TABLE II.

Height	Weight	Expiration	Factor per Lb.	Inspiration	Factor per Lb.	Abdomen	Factor per Lb.	No.
5 ft. 3 in.	130	31.48	.132	34 91	.129	30.19	.187	26
	149	33.98		37.36		30.75		16

	151	33.83		37.23		33.40		30
5 ft. 5 in.	141	32.28	.133	35.66	.119	30.81	.190	69
	156	34.28		37.44		33.66		55
5 ft. 6 in.	140	31.92	.140	35.48	.131	30.50	.177	139
	159	34.58		37.96		33.87		124
5 ft. 7 in.	144	32.36	.109	35.88	.107	30.74	.168	163
	164	34.54		38.02		34.09		156
5 ft. 8 in.	149	32.57	.104	36.23	.100	30.81	.174	154
	169	34.64		38.22		34.29		124
5 ft. 9 in.	153	32.82	.112	36.52	.114	31.26	.172	144
	175	35.28		39.02		35.05		118
5 ft. 10 in.	154	32.82	.102	36.66	.109	30.91	.173	124
	175	34.97		38.94		34.54		112
5 ft. 11 in.	159	32.90	.120	36.72	.117	31.10	.191	86
	182	35.66		39.41		35.49		66
6 ft. 0 in.	167	33.62	.119	37.60	.113	31.80	.187	63
	193	36.71		40.53		36.67		46

7 inches, 5 feet 8 inches, and 5 feet 9 inches—between 131 pounds and 185 pounds, and found an average set of measurements for each five-pound group, the weight being taken at the mid-point of each group—133, 138, 143, etc. By means of the factor of change in measurements per pound weight I estimated the measurements for each weight. The following table (No. III) shows how closely the average measurements approximate the estimated measurements:

TABLE III.

Weight	EXPIRATION		INSPIRATION		ABDOMEN		Case No.
	Av. Meas.	Est. Meas.	Av. Meas	Est. Meas.	Av. Meas.	Est. Meas.	
			5 Feet 7 Inches

178	35.57	*35.76*	39.12	*39.27*	35.86	*35.85*	14
183	36.09	*36.44*	39.62	*40.12*	36.73	*36.56*	18
			5 Feet 9 Inches				
133	30.57	*30.36*	34.22	33.99	27.81	*28.99*	18
138	31.13	*31.04*	34.79	34.65	28.67	*29.13*	27
143	31.69	*32.14*	35.36	35.72	29.53	*30.13*	53
148	32.25	*32.21*	35.93	35.83	30.39	*30.77*	40
153	32.81	*33.23*	36.50	36.69	31.25	*31.33*	54
158	33.37	*33.30*	37.07	37.14	32.11	*32.17*	40
163	33.93	*33.58*	37.64	37.34	32.97	*32.85*	35
168	34.49	*34.70*	38.21	38.34	33.83	*33.57*	21
173	35.05	*35.23*	38.78	39.35	34.69	*34.39*	28
178	35.61	*37.11*	39.35	41.06	35.55	*36.50*	28
183	36.17	*36.42*	39.92	39.91	36.41	*36.84*	20

This shows fairly conclusively that my factor of increase or decrease in measurements is correct—at any rate, in so far as these three height groups are concerned.

The balance of my material—1,166 individuals each weighing less than 10 per cent. below and more than 15 per cent. above the graded average weight for age—I divided into height groups and found an average weight and set of measurements for each class—one under 10 per cent. below and one over 15 per cent. above the average weight.

These classes are used to make a comparison at a higher and a lower point with Tables I and II.

The following table shows the comparison of the estimated and average measurements at four points for each inch—two above and two below. These I will designate as,

Class A—Average of weights under 10 per cent. below average for age.

Class B—Average of weights within 10 per cent. below average for age.

Class C—Average of all weights in classes B and D and average measurements.

Class D—Average of weights within 15 per cent. above average for age.

Class E—Average of weights over 15 per cent. above average for age.

TABLE IV.

The next and final table gives the average weights and measurements for each inch from which to estimate measurements at any given weight for the same height and the factors per pound to use for finding such measurements.

Take an individual 5 ft. 9 in. tall weighing 148 pounds as an example. The average is 163 pounds—expiration 33.93 inches—factor 112.

TABLE V.

Average Weights and Measurements and Factor of Change Per Pound for all Ages.

Height		Average Weight	Expiration	Factor per Lb.	Inspiration	Factor per Lb.	Abdomen	Factor per Lb.	No.
Ft.	In.			In.		In.		In.	
5	3	138	32.43	.132	35.85	.129	31.55	.187	42
5	4	141	32.68	.112	36.06	.114	31.39	.195	84
5	5	148	33.16	.133	36.45	.119	32.07	.190	124
5	6	149	33.17	.140	36.65	.131	32.09	.177	263
5	7	154	33.43	.109	36.92	.107	32.38	.168	319
5	8	158	33.49	.104	37.12	.100	32.36	.174	278
5	9	163	33.93	.112	37.64	.114	32.97	.172	262
5	10	164	33.84	.102	37.74	.109	32.63	.173	236
5	11	169	34.10	.120	37.89	.117	33.01	.191	152
6	0	178	34.92	.119	38.84	.113	33.86	.187	109

163 pounds — 148 pounds = 15 pounds.

15 × .112 = 1.680 inches.

33.93 inches — 1.68 inches = 32.25 inches.

The inspiration and abdomen measurements can be obtained in the same manner—using, of course, the proper factor in each case.

By using this table one can determine with reasonable accuracy what the measurements should be for a man over 24 years of age of any weight, whose height falls within the limits of the table.

None of the figures in the preceding tables—or in the work done in preparing this article—have been altered or graded in any way.

APPENDICITIS IN INFANCY AND EARLY CHILDHOOD.

By CHARLES GREENE CUMSTON, M.D.,

BOSTON, MASS.

On account of the relative infrequency of cases of appendicitis diagnosed in infancy and young children the report of the following cases may not be out of place:

Case I.—Male, twelve weeks old. Normal birth. Breast-fed, healthy infant. Five days before I saw the patient he developed a severe diarrhea, the stools being very offensive and contained much mucus. Temperature 36.5° C. Some intestinal distention. Various changes in diet were tried by the family physician without any result; the child vomited, the pulse reached 140 and over, but the temperature remained subnormal. On the fifth day after the commencement of the disturbances, the doctor thought he could detect a distinct mass in the right iliac fossa, and the writer was asked to see the child. Examination (May 3, 1902) revealed a very distended abdomen, by percussion, dullness over the right iliac fossa, the rest of the abdomen tympanitic. By palpation a mass was thought to be detected in the cecal region. Heart and lungs normal. Pulse 147, temperature 37.1° C. The diagnosis of probable appendicitis was made and operation performed at once. Incision in the right semilunar line. On opening the peritoneum a little free fluid escaped. The cecum, very greatly distended and injected, bulged into the incision. It was adherent by neoformed thin adhesions to the iliac fossa, but by carefully working these were broken down and the appendix delivered. This was found bent upon itself at the middle, about as large as a lead pencil, and its peritoneum markedly injected. It was bound to the cecum by numerous adhesions After some difficulty it was freed and removed. The incision was closed without drainage. The baby made an uneventful recovery and is at present a very fine boy. Examination of the removed appendix presented several points of interest. On opening down to the acute angle formed by the bend, the mucosa was swollen, grayish-red in color, and covered with numerous gray-colored ulcerations. The lower half of the organ after it had been unbent was found distended with a small amount of thin yellow feces. The mucosa was dark purple and presented several ulcerations, one of which had almost perforated. Total length of appendix, 5.5 centimeters.

Case II.—Female, aged 3 years, 20 months. Seen with Drs. Schofield and Sylvester of Wellesley, Mass., August 15, 1912. Patient had been ill with diarrhea, vomiting and right-sided abdominal pain for several days. Keeps right leg flexed. Temperature remained around normal, pulse varying from 120 to 140; mass formed in right iliac fossa. When the writer saw the child on August 15 in consultation, she was restless and complained of pain when pressure was made over the cecal region. Facial expression good, pulse 120, temperature normal. Under ether a distinctly localized hard mass could be made out in the outer portion of the right iliac fossa. A diagnosis of retrocecal abscess was made. When the peritoneal cavity was opened it was found perfectly free from infection. The cecum was bound down by a mass of rather tough adhesions and, after freeing these carefully to obtain sufficient space to open into the retrocecal abscess, this was done. About 30 cubic centimeters of thick, stinking yellow pus escaped and a large drain was inserted back of the cecum in the abscess cavity. Recovery uneventful, the patient being kept for the first six days in Fowler's position, after which drain was removed.

Case III.—Male, 21 months old, always had been in good health since birth. Bottle-fed. Had been more or less constipated for the past three months. For several days before seeing the child he had been vomiting off and on, was very restless and bowels only moved by suppositories of soap. No blood or mucus in stools, abdomen became distended, and colic was severe. Examination (July 17, 1907): Well-developed infant, pulse 130, temperature 37.9° C. in axilla. Abdomen distended and tympanitic; no area of dullness. Heart and lungs normal. Vomiting continuous, bilious nature. no stools for twenty-four hours. On account of the very serious condition, which pointed to some intraabdominal lesion, the nature of which was doubtful, operation was undertaken at once. The abdomen was opened in the right semilunar line, giving issue to a large amount of thin serum containing flakes of lymph. The distended intestine was greatly injected and there was evidence of high grade general peritonitis. The cecum was delivered and a gangrenous appendix found. There were practically no adhesions and the organ was rapidly removed. Drainage. The child rallied and lived about eight hours after the operation. The appendix measured 4.3 centimeters. It was dark purple, but perforation had not taken place. The mucosa was disorganized and the walls were so thin in places that only the peritoneum prevented the contents from escaping into the peritoneal cavity.

In infants, as with adults, the appendix varies in length. Ribbert gives 3.4 cm. as the average length, while in the newly born Tojts found an average of 5 cm. and in adults 10 cm. Both these figures agree approximately, so that one may conclude that the processus vermiformis is very much longer in relation to the entire intestinal tract in young infants

than in the adult. The very great richness in follicles is also a characteristic of the appendix in young subjects. They are distinctly developed in the infant and increase until about the twentieth year of life, after which they begin to undergo atrophy. In spite of the relatively large size of the appendix in infants and young children fecal concretions are hardly ever found in the lumen of the organ. The strong muscular structures expel the contents, which, on account of the nature of the diet in early life, is fluid. Consequently, conditions for the formation of fecal concretions are wanting, at least until the age of four or five years. I know of only one instance, that reported by Schüle, in a milk-fed child where a fecal concretion was found in the appendix at autopsy. The content is mucus, undigested thin liquid ingesta, or parasitic ovi. Post-mortem examination has shown that there is no general rule that can be applied to the position occupied by the appendix in infants. In some few cases it has been found dipping directly down into the pelvis, occasionally it lay directly on the cecum in the right iliac fossa, or it may point upwards. In one case its tip reached the right lobe of the liver. Therefore, it is evident that there must exist unknown developmental conditions influencing the position of this rudimentary organ. It has been pointed out by Matterstock that in children the appendix is often placed in some abnormal position or may present kinks or bending.

That inflammation of the appendix cannot be so infrequent in early life as is generally assumed, must be evident to all if the large number of follicles be taken into consideration. In all inflammatory processes of the intestine, the lymphatic system becomes involved at first, namely the solitary follicles and Peyer's patches. Now, since the appendix is in reality merely a large Peyer's patch, it seems only logical that it should become involved early in inflammatory lesions of the gut, and when one considers the readiness with which the intestinal track tends to react by an inflammatory process when there is a relatively slight qualitative and quantitative change in diet, it would seem that many opportunities must be offered for the lymphatic system of the appendix to become involved. Attention has been directed to the anatomical similarity between the tonsils and appendix, and with evident good reason. Both organs are composed of lymphatic tissue grouped around a cavity rich in bacteria; both share in the inflammatory processes of the structures with which they are related.

In considering the type of inflammatory changes in the appendix, the simplest for our purpose, although not perfect, is to divide the process into three large groups as follows: (1) appendicitis simplex; (2) perforative appendicitis, and (3) appendicitis gangrænosa. Of these, the second group must be of great infrequency in infants and young children if perforation is due to a fecal concretion, while appendicitis simplex is rather more common, with swollen, congested mucosa, and superficial or deep ulcerations. From cases reported in the literature, it would seem that the gangrenous type is the most frequent in infants and young children. There is a rapidly progressing partial or total necrosis of the organ. It is usually due to thrombosis of the artery of the appendix by direct extension of the inflammatory process in the intestine, thus cutting off the entire nutritive supply to the organ. On the other hand, the bacteria penetrating into the mucosa and muscularis may produce rapid necrosis of the tissue elements, the occurrence of perforation depending upon the virulence of the organism present and to some extent the position of the appendix in which gangrene occurs. In infants and very young children inflammatory processes in the appendix tend to progress rapidly, that is to say, necrosis of the mucosa and muscularis occurs promptly, so that the bacteria reach the serosa quickly before protecting adhesions have had time to be thrown off. For this reason it was found that in 50 per cent. of cases of appendicitis in infants and young children extensive peritonitis developed, this being based on the combined statistics of Schüle, Rotter, Lenander, and Sonnenburg.

The toxemic form of appendicitis is a frequent cause of death in infants. Here there is no peritoneal reaction, or, if there is any, it is very mild. Death occurs rapidly from absorption of the bacterial toxins, the body being actually flooded with the poisons. I am led to assume that many instances of death from enteritis are in reality due to an undiscovered appendicitis giving rise to a rapidly developing intense bacterial toxemia with little or no evidence of intraabdominal trouble. Then a thrombophlebitis of the vessels of the mucosa takes place, the bacteria become attached to the thrombi, liquefy them and thus enter into the general circulation, producing metastatic foci in distant organs, such as the lung, kidney, or myocardium.

I feel so strongly on the subject that I should take it for granted that in all likelihood the appendix is the seat of inflammation in infants and young children who are constantly having intestinal upsets. The process may not cause any alarming symptoms at the time, but undoubtedly paves the way for a future marked attack when the child is older. How frequently does one find, when operating on older children, strictures of the lumen of the organ resulting undoubtedly from former catarrhal ulceration or from contraction of the interstitial tissue caused by a former inflammatory process, resulting in a bend of the appendix. Likewise, the presence of old, thick adhesions can only be accounted for by some previous inflammatory process. As far back as 1867, Willard Parker, in a paper published in the MEDICAL RECORD, stated that perityphlitic abscesses were far less common in children than in adults and that necrosis with rapid perforation was frequent in the former.

In young children from three to five years of age the diagnosis can be made in many cases from abdominal pain, colic, particularly referred to the ileocecal region, occasionally anorexia and vomiting, with temporary constipation or diarrhea. Unfortunately, the real cause of these symptoms is overlooked and the case put down as intestinal indigestion, or what not, and then later in life the subject develops an unmistakable attack of appendicitis.

Considering more in detail the symptomatology of appendicitis in early life, close attention should be paid to the digestive tract. It is true that the symptoms point rather to gastric catarrh, which, in point of fact, may very probably be the introduction to future trouble in the appendix. Vomiting, which is so frequently an early symptom, cannot be considered as of any importance, as it is so common in digestive disturbances in infancy and early childhood. Cyclical vomiting is important, and, as I have pointed out,* is frequently a symptom of chronic

*"The Relation of Cyclical Vomiting in Children to Appendicitis." *American Journal of Obstetrics and Diseases of Women and Children*, Vol. LIX, 1909.

appendicitis. The condition of the stools also varies greatly, all degrees between marked constipation and severe diarrhea have been noted, but it would appear from recorded cases that constipation is more frequent as a real symptom of *appendicitis per se* in children under two years of age.

Pain in the right iliac fossa, such a valuable symptom in adults, is frequently absent or cannot be located on account of the inability of the subject to express this sensation. Undoubtedly, in some young intelligent children the pain on palpation in the right iliac fossa may be made out, but when this cannot be done it is no reason for excluding the diagnosis of appendix trouble. In cases of catarrhal disturbances of the intestinal tract in infants, tenderness can oftentimes be made out in the cecal region by palpation, undoubtedly due to an inflamed appendix participating in the general intestinal process. As localized abscess formation is less frequent than a generalized peritonitis a distinct tumor is not so often found, but it is always suspicious if abdominal distention with abdominal walls more tense on the right side can be made out.

A digital rectal examination may be of use where appendicitis is suspected, when vomiting and diarrhea are marked. A palpable resistance may sometimes be made out in the right pelvis, or, if pus has formed, a tumor surrounding the rectum is discovered. Too much reliance must not be placed on rectal examination as it is most often negative, but should not be neglected in doubtful cases. The temperature curve is by no means reliable because in even the worst septic cases it may remain around the normal. However, if an abscess has formed the chances are that the chart will show septic absorption going on. Evidence of peritoneal involvement is given by a rapid pulse with a low temperature.

As already pointed out, most cases of appendicitis in infants are not diagnosed. Vomiting, constipation, or mild diarrhea, mucus in the stools, restlessness as a result of colicky pains without definite localization are usually so prominent that appendicitis is not thought of and a diagnosis of enteritis is made; vomiting occurs several times, while the stools which at first were loose become normal by proper feeding and medication. But suddenly they become liquid again, the infant rapidly sinks and finally dies without offering a single symptom pointing to the appendix. Had the right iliac fossa been carefully palpated in these cases, some slight resistance or pain might have been elicited which would have led the physician to suspect the true condition of affairs.

The presence of bacteria is of utmost importance in the development of appendicitis. These are found within the first twenty-four hours after birth in the intestinal tract of healthy infants, but when the epithelium of the intestine is normal and lymphatic system active they do not develop their pathological properties. Not until a catarrhal process has caused desquamation of the epithelium do they react on the mucosa and set up deep seated changes. Macaigne* and the writer† were among the first to show that cultures of the *Bacterium coli* obtained from dejections of patients suffering from intestinal disturbances, are much more virulent than those grown from dejections in healthy subjects. The highly virulent bacteria, rendered so by intestinal catarrh, set up pathological processes in those places in the intestine especially predisposed to inflammation, particularly the appendix. This explains why the appendix is so frequently involved in infantile diarrheas. Undoubtedly the streptococcus is the most important because in the milder cases it produces a serous catarrhal process in the small intestine; in severer cases an inflammatory process localized in the large intestine results. The cocci enter the blood stream and may be seen in clusters in the intestinal wall, lung, etc. The *Bacillus coli* is the commonest organism found in appendicitis but not infrequently the streptococcus is also present, causing a mixed infection. As already mentioned, the presence of intestinal bacteria alone is not capable of producing appendicitis and other causative factors must arise. The most important of these in infancy is improper feeding resulting in intestinal disturbances and coprostasis.

The extremely poor prognosis of appendicitis in infants and young children is due to the fact that the true nature of the case is recognized either not at all or too late. The case not being understood treatment is administered which causes the process to rapidly progress. It is hardly necessary to observe that in the gangrenous type there would be a very rapid extension of the inflammation to the serosa, as is well illustrated by the third case reported in this paper.

In concluding let me repeat that in all cases of gastrointestinal disease in infants and young children, as well as in other abdominal conditions whose nature is not clear, the physician should turn his attention to the ileocecal region. If this is done undoubtedly a diseased appendix will be diagnosed and by early operation the baby may be saved.

871 Beacon Street.

†Cumston: Thèse, Geneva, 1893.

THE AFTER TREATMENT OF SYPHILIS.

By EDGAR G. BALLENGER, M.D.,
AND
OMAR F. ELDER, M.D.,
ATLANTA, GA.

As the absence of clinical symptoms does not afford evidence that the syphilitic is cured it becomes necessary for us to utilize all available methods in determining if latent infection is still present and to administer further antisyphilitic remedies before recurrences develop. It is the consensus of opinion among syphilologists that in the past very few patients have been cured absolutely. This view is substantiated by the fact that a very large number of syphilitics develop late lesions or functional diseases that respond to antisyphilitic measures while many also develop parasyphilitic affections. Many, too, probably remain free from evidences of disease, yet may harbor latent foci of spirochetes which only develop when subjected to trauma or when the resistance of the patient is lowered by intercurrent disease or other conditions. Another fact in the support of the view that in the past many patients have remained uncured was the scarcity of reinfections.

If we are to obtain creditable results in the future it must come through a careful study of clinical symptoms and in addition we must secure and maintain a permanently negative Wassermann reaction and a negative luetin test. Careful observers now state that it is impossible to administer satisfactory antisyphilitic treatment without using the Wassermann test, and from our experience during the past two years compared with our ex-

perience antedating this period we are becoming more and more convinced of the correctness of this view.

The recent advances in the treatment of this disease have stimulated active work in answer to a constant question and that question is, what shall we do with the patient who is apparently well? The time test is too slow, and may result in the development of serious affections unless we anticipate and prevent them. The syphilologist must consider the actual administration of antisyphilitic remedies as only part of his obligation—certainly not more than one-half—the other and equally important part being to utilize all approved methods to determine when treatment may be discontinued. One thing has become more and more apparent and that is that hard and fixed rules cannot be made as to the amount of treatment required to cure patients. Each case should be studied individually, both in regulating the size of the dose of salvarsan or neosalvarsan, the frequency of its repetition, the advisability of supplementary remedies, as mercury and potassium iodide, and after all clinical manifestations have disappeared, the application of tests to show the presence of latent infection if such exists.

The potency of neosalvarsan and the mildness of the systematic reaction open the way to a very thorough course of treatment which, if properly administered, disturbs the patient very slightly. It is upon the repetition of the dose of salvarsan or neosalvarsan that permanent results depend. The repeated doses should follow in such a manner as to continue the improvement and then to clinch the cure. We can easily conceive of an indefinite number of treatments resulting in failure, provided a recurrence is allowed to supervene before each subsequent treatment is administered. It is to prevent such occurrences that judgment should be exercised in the administration, care in the spacing of the treatments and careful tests made to determine the probable completeness of the cure before dismissing the patient to return only occasionally until sufficient time has elapsed to prove that a recurrence is unlikely.

We have administered 570 injections of salvarsan and 475 injections of neosalvarsan without a death and with but one neurorecurrence, which was clearly due to insufficient medication. This freedom from ill effects we attribute to the repetition of the remedy, and to the fact that we have given nearly all of it intravenously and started with small doses when in doubt as to the physical condition of the patients. Always, too, the patients were urged to drink freely of water both before and after the injections so as to dilute well the medicine during its elimination by the kidneys.

As regards the administration of mercury simultaneously with salvarsan and neosalvarsan recent reports seem to indicate its advisability, especially if there is reason to fear neurorecurrences, and when much induration exists in the lesions. A disadvantage in its continuation is its masking the symptoms and thus preventing more active dosing with salvarsan and neosalvarsan. Where the patient can receive careful observation, controlled by luetin and Wassermann tests, and appears to have had an adequate course of the latter remedies we have omitted supplementary treatment until its indication became apparent. If the patient cannot be watched doubt must exist and it would be well, therefore, to administer mercury and iodides until tests show the disease to be probably cured.

The Wassermann Reaction.—Gennerich of Keil and Milian of Paris simultaneously reached a conclusion of far reaching importance in their observation that the Wassermann reaction became more positive soon after injections of salvarsan. The practical application of this principle in apparently cured or latent conditions is probably the greatest advance in the scientific management of syphilis since the discovery of salvarsan, unless it be the cultivation of the *Spirochæta pallida* by Noguchi. Undoubtedly this so-called provocative injection of salvarsan or neosalvarsan greatly enhances the value of the Wassermann in that it makes it much more delicate and thus renders it useful at the very time we need it most, that is, in the obscure and latent conditions. It stirs up, as it were, the spirochetes and brings their products into the circulation. In from eighteen to thirty-six hours after the injection of neosalvarsan the specimen of blood should be taken as then, as a rule, it seems to contain the largest amount of "reagin," the substance which is detected by the Wassermann test. McDonagh of London has confirmed these observations and is convinced of their importance. If the patient is nearly cured the strength of the reaction diminishes and within ten days or two weeks it may become negative. Treatment should be continued as long as it remains positive when the provocative test is used. Such a test should also be made about six months and again one year after the patient appears to be cured. Since using the socalled provocative Wassermann tests we have been able to discover latent infections with much greater accuracy than when the usual method was followed, as will be seen from a few brief clinical reports to be given.

Kaplan, in 1910, called attention to the fact that ox-bile added to negative blood serum would render it positive. As an injection of salvarsan or neosalvarsan may at times cause jaundice we should regard a positive provocative Wassermann under such circumstances of doubtful significance and make other tests when the urine is free from bile. Craig has also observed that immoderate drinking of alcohol would render a positive Wassermann temporarily negative. It is also generally admitted that leprosy, yaws, malaria, scarlet fever, and scleroderma will give positive or pseudo-positive reactions.

The Luetin Test.—From a pure culture of the *Treponema pallidum*, Noguchi has prepared a substance (like tuberculin) which is specific in the detection of the condition of allergy or hypersensitiveness produced by occasional systemic invasion of syphilitic products. Through the kindness of Dr. Noguchi we were furnished a supply of luetin several months ago and are much pleased with the results so far obtained in 75 tests with it. It seems of special value when latent foci exist and especially if it is made about ten days after a provocative or sensitizing injection of neosalvarsan has been administered. It seems more delicate at times than the Wassermann reaction, and we use the tests together hoping thus to eliminate sources of error and to detect very slight infection.

Technique.—The bottles of luetin and the control are first well shaken and the desired amount is taken from the bottle with sterile tuberculin syringe. It is then diluted with an equal quantity of sterile physiologic salt solution; of this .07 c.c. is injected into the skin of the upper arm with a fine needle. It should be carefully placed just beneath the epidermis. With a separate syringe a similar injection

of the control is made in the other arm with another syringe; the same amount and dilution with salt solution being used. The luetin and control should be kept in an ice chest when not being used. The result noted within the first twenty-four hours should be disregarded and observations continued for three or four weeks. The most reliable reactions usually develop five to eight days after the injection. The control preparation is identical with luetin except it does not contain the *Treponema pallidum*. The reaction is regarded positive if the site of the injection of luetin becomes red and hard. A papule about the size of a split pea or larger develops and may be surrounded by an area of redness three or four millimeters in diameter. The pain is slight and there appears to be very little if any systemic reaction. The control usually disappears after two or three days, occasionally it may increase in size and remain the same as the luetin. This seems more likely to occur in untreated syphilitics whose resistance is lowered and in whom any slight injury may be followed by more than the ordinary reaction. Where both remain the same and otherwise seem positive, the condition should be considered as suspicious and the test should be repeated ten days after a provocative injection of neosalvarsan. The luetin test is of chief value in more or less latent conditions when the systemic invasion of syphilitic products is occasional and not constant, as under circumstances the state of allergy or hypersensitiveness develops.

We feel that no patient should be given permission to marry or if married to bear children until these tests are found negative six months and a year after what has seemed an adequate course of treatment.

A few instances will be reported to show wherein the above methods have been of value in deciding whether to continue or discontinue medication.

Case I.—Uncertain history of lues twenty-five years ago, hemiplegia seven years ago, not feeling well recently, nocturnal headache. Wassermann negative, luetin positive. Provocative injection of 0.4 gram neosalvarsan was followed by cessation of headache and improvement in the patient's general health. Blood taken twenty-four hours after the injection was positive (++).

Case II.—Age twenty-five, lues four years ago, mercury and potassium iodide for two years, followed by three injections of salvarsan during past year. Has been clinically free from syphilis for two years, several negative Wassermann reactions during this period. Wassermann now negative and luetin positive (+). Provocation Wassermann positive (++).

Case III.—Lues six years ago, several years of mercury and potassium iodide. Three injectons of salvarsan during past year. Clinically cured and appears in splendid health, Wassermann negative, luetin positive (+). Provocative injection of 0.55 of a gram of neosalvarsan, Wassermann then becomes strongly positive (++++).

Case IV.—Lues nine months ago, five injections of neosalvarsan, no signs of disease except slight glandular enlargement. Wassermann negative. Luetin positive (++). Provocative Wassermann (+).

Case V.—Patient clinically cured, Wassermann positive (+), luetin positive (++), provocative Wassermann positive (+++).

Case VI.—No signs of lues which was contracted ten years ago and has been actively treated with mercury, potassium iodide and salvarsan. Wassermann positive (+), luetin positive (+++); provocative Wassermann positive (++++).

Other more or less similar observations have been made but as a rule the Wassermann and luetin test have been in accord where there was slight, though evident luetic manifestations. About 55 tests have been negative by all methods and we feel that at present we are safe in assuming that the patients incur no risk in waiting until further tests are made in six months and one year or later.

LE CHARLATANISME DE L'EXACTITUDE.

By W. B. KONKLE, M.D.,

MONTOURSVILLE, PA.

"Charlatan as much as you please, but where is there not charlatanism?" So, says Saint Beuve, exclaimed Napoleon when he heard somebody spoken of as a charlatan. In truth, there is charlatanry and charlatanry. Over against each other appear the crude, vulgar sort characterizing the uncultured mountebank in the market place, and the refined, casuistic kind that in the person of some polished Cagliostro with its sorcery befogs and befools courts and solons. Then there is the unconscious, well-meaning charlatanry of teeming dogmas and systems and isms which is mere error, the while there drives and thrives the deliberate, premeditated charlatanry of voracious imposture, the vampire that fattens on human blood.

And all these many and many-phased charlatanries have very freely domiciled themselves in the domain of medicine. But what is this strange thing about which speaks the erudite and brilliant Bouchut?—*"le charlatanisme de l'exactitude!"* Yes, the astute Frenchman has unmasked even such a species. He has been making a critique of the so-called iatro-mechanical and iatro-mathematical doctrine originated by Sanctorius, elaborated and specialized by Descartes and practically established by Borelli. After according to the theory full credit as containing a true idea as being a valuable means of research and method of experimentation, and as having *une raison d'être* in the body structures, he then stoutly protests that "it is gravely wrong in that it does not take enough into account organic and vital properties." He further insists that "in order to create an exact and mathematical medicine it does not suffice to estimate or measure forces, to calculate them in figures, or to apply the laws of mechanics to the functions of organs and to the manifestations of sickness; this is often but an illusion; and for many men it is only a means of self-aggrandizement—it is the charlatanry of exactness."

The wont or lot of medicine has been, like a child, to be, using St. Paul's forceful metaphor, "tossed to and fro, and carried about with every wind of doctrine, by the sleight of men, and cunning craftiness." Iatro-mechanicalism is not alone in embodying some principle good and helpful in itself and within proper limits, but misleading and pernicious when vigorously and rigorously pushed to extremes beyond its sphere. So, too, iatro-chemicalism subjugated and enslaved medical practice, changing itself from a scientific instrument into a delusive wand of magic. From Paris was hurled at Sylvius the charge that his method had cost more lives than the thirty-years'

war. *Le charlatanisme de l'exactitude* is again strikingly evident in the doctrine of *"strictum"* and *"laxum"* in all its eventful course and in all its various forms. Given birth by Asclepiades of Prusa, evolved and exploited by Themison and Thessalus of Tralles, coming down to modern times in the garb of the "spasm" and "atony" of Hoffmann and Cullen, the "sthenia" and "asthenia" of Brown, and the "irritability" of Broussais, from first to last it stands as a mournful monument of the ill-advised and futile attempt to find in disease a general, constant and exact unity. There has been a tendency of the school in question to deny the tenet which constitutes the base and soul of the Hippocratic system, and which the great Master so strongly and so grandly maintained—the tenet, namely, of the healing power of nature. Asclepiades bluntly and flatly averred that the physician alone cures. Brown flung out the same black banner under whose sinister folds he won a fame that rapidly dimmed and darkened into half-disfame.

Thus pinning their faith to a single and invariable classification, and holding that nothing goes without the doctor, the votaries of "strictum" and "laxum" dosed enormously and treated heroically. With some it was more "strictum" and less "laxum," with others more "laxum" and less "strictum." Brown and the distillers were close confederates on account of his predilection for stimulation; while during the Broussais régime in one year alone 41,500,000 leeches were imported into France under the spell of the mania for depletion. And the whole scheme was as simple as it was exact—so simple, indeed, that its propogandists might well have published that "the wayfaring men, though fools, shall not err therein." Le Sage's ever-diverting description of how Dr. Sangrado made a physician out of Gil Blas *sur-le-champ*, by fiat as it were, is not such exaggerated imaginative farce as on the surface appears. As a matter of actual medical history, Thessalus boldly boasted that with him six months were long enough for the inculcation of correct and adequate principles of medicine. His numerous disciples Galen contemptuously dubbed, "the asses of Thessalus."

Medicine by reason of its very nature can not be a pure or an exact science. Sprengel holds that the physicians both of ancient and recent times who have sought to so dignify it have gravely misconceived their art. Art preeminently it is, and will ever remain. Sir Dyce Duckworth insists that the great physician is a great artist; and that for one to demand mathematical accuracy in therapeutics is to show one's self devoid of *mens medica*. "The province of the clinic," says Renouard, "is the doctor's battle field, the theater where he unfolds not only all the resources of his art, but more those of his genius, as well as the qualities of his soul."

In his *"Notre-Dame de Paris"* Victor Hugo depicts Archdeacon Claude Frollo as having inscribed on the wall of his cell this legend, purporting to be quoted from Jamblichus, a Neo-Platonist of the fourth century—*"La médecine est fille des songes."* How far true it is that medicine is the daughter of dreams will be apprehended as one surveys the immemorial bent of medicine toward infatuation for, and subserviency to, speculative philosophy. Celsus affirmed that "medicine is a conjectural art." Modifying the idea of Celsus, Cabanis declared that "medicine is a conjectural science." Said Baglivi, "To deify and unduly extol the Moderns is becoming to no reasonable man. Medicine is not a production of human reason, but a daughter of time, originating in long experience." Yet to whatsoever other maternity or paternity it may be referred, medicine at any rate is *not* the daughter of exact science. There are many exact things in it, and this is increasingly true; but still it is not, can not be, all exact. More and more, exactneess marks its procedures; but the ground on which it operates is shifting and unstable. It was the highest wisdom which led Ali Abbas to demand that the physician control the findings and leadings of book knowledge with bedside observation. Without the application of a series of proofs and checks the most exact method may go wrong, and make for us a monster in the moon out of an insect on the lense of our telescope, as happened to Sir Paul Neal, according to the respective satires of Butler and La Fontaine.

As indicated, the constantly and permanently debarring factor in any attempt to pass from rational art to exact science in the practice of medicine is found in the infinite variability of the material operated upon. We have to do with persons, and persons are so many differing and undetermined quantities. All that he came from, all that he is, all that he is related to, forms the complex whole of the person. And how complex! And how endlessly manifold the combination of the component elements! And from this it follows that, outside of differences of type and of malignity in diseases themselves, which add yet another element of variation, every case of sickness has its own individual qualities and requirements. Says Renouard again, "It is unheard of that a practitioner should have met during his life two morbid cases absolutely identical." Condillac cautions us against imagining that there are species and genera in nature because there are species and genera in our manner of conceiving of things. Then, besides, the same thing and the same person are subject to mutation. Old Racan utters the plaint—

"Rien au monde dure
Qu'un éternel changement."

And Börne, echoing the sentiment, writes, *"Nichts ist dauernd als der Weschsel."* So that even with exact methods and instruments of precision exactness of result is precluded in medical practice.

Many of the practical errors attributable to this complication of conditions medicine might avoid, might spare itself the discredit of many a vagary and absurdity, if only the history of the healing art were more closely studied with reference to the commission of such *faux pas* in the past. Certainly more thorough historical study "wad frae monie a blunder free us, and foolish notion." Cicero calls history "the witness of time, the light of truth, the life of memory, the high-priestess of life, the messenger of antiquity." But in spite of, or in ignorance of, the lessons of the past we go on making the same old mistakes—the same, though committed in a new way. *Le charlatanisme de l'exactitude* in particular is especially in evidence to-day. Says a shrewd, clever writer anonomously, "It seems as if the trend of modern pathology was toward the study of disease as a practically unvarying entity and the patient himself becoming more and more a negligible factor." This is but one departure of a movement quite common. Is it not true that in our craze for exactness we have considerably lost our heads?—as lost theirs the Vienna school of the days of Skoda concerning diagnosis.

There is much unintentional charlatanry of exactitude about the purification and refinement and standardization and accuracy of dosage of drugs. Care in this matter is well enough to any extent and essential to a certain extent. But the dose and the effect of medicines must be largely worked out for the person in question. Several of our best medicaments are among those various and varied products indifferently compounded by nature herself. And there was something challenging admiration and respect in the masterful manner of the physician of yore who mentally estimated the features and indications of his case and administered drugs to his patient in doses measured by the combined appliances of penknife and brains.

Inadvertently a large amount of hocus-pocus is palmed off regarding the clinical thermometer. In point of fact, it is the most useful device employed in the practice of medicine. It is, indeed, simply indispensable—it is the right arm of the present-day doctor. But its renderings should not be construed too rigidly—some latitude should be allowed to the meaning of its markings. What can tenths of a degree import where so many elements of disturbance and variation influence its testimony? Why haggle and carp about fine shades as to its index when its evidence must, at any rate, be interpreted from the shifting standpoint of disease caprice, wide age-range and personal idiosyncrasy?

"A novelty useful enough for scientific purposes, but readily dispensed with in practical life," is what Baas says of Marey's sphygmograph. One would hesitate to speak in the same way of the up-to-date instruments for the investigation of the pulse. Frankly, these must have a definite and especial value. But they have their decided limitations and imperfections. And they are subject to the same factors of modification as is the thermometer. In no event can they in practice take the place of the trained finger on the pulse. The touch of the intelligent, skilled physician is worth more than all they can possibly tell. What they are exceedingly liable to do is to promote *le charlatanisme de l'exactitude*. Let the palpation of the pulse receive renewed attention and be granted greater distinction. If Galen in ancient, and the Chinese in later, times did make too much of it, we of the present hour make altogether too little of it.

The examples cited in illustration of charlatanry of exactness are meant as a representative, rather than an exhaustive list. From the whole discussion some morals may be drawn. In frenzied quest of accuracy let there not occur neglect of what is practically important and advantageous. A dire and doleful epitaph for the tomb-stone of a patient would be, He died of an effort upon the part of his doctor to make applied medicine rigorously scientific. Practice must be ever below the ideal. When we look too far we overlook the near. Says our Shakespeare, "Striving to better, oft we mar what's well." Voltaire frames the thought thus—"*Le mieux est l'ennemi du bien.*" And Tennyson expresses the spirit of the sentiment, if not the letter, in these lines:

"Hold thou the good; define it well:
For fear divine Philosophy
Should push beyond her mark, and be
Procuress to the Lords of Hell."

On twin thrones higher even than the throne of science must we set judgment and experience. Science below anything else? Yes, in practice. From Baglivi came the maxim, "He who diagnosticates well cures well." An excellent rule, truly. And, yet, Skoda became so engrossingly devoted to exactness of diagnosis that there was bred in him a feeling toward therapeutics akin to contempt. When asked at a consultation about the medicine proper to the case he replied nonchalantly, "*Ach, das ist ja alles eins!*"

Judgment and experience. Judgment without experience is like talent without training. Judgment strengthens and ripens as experience broadens. On the other hand, experience without judgment is a child choosing coins—size and shine win. Remarks Bouchut, "One ought always distrust the experience of ignoramuses and of fools." And Morgagni insisted that "observations should be weighed, not counted."

No; pure, exact science is not the ranking characteristic of the competent and effective physician. Hufeland maintained that "successful treatment requires only one-third science and two-thirds *savoir faire*." Cold, mechanical, routine method is essential in laboratory investigation, and, also, in the practice of a specialty. But when in general it is a question of restoration to health from ordinary sickness in the particular and individual case of Monsieur A——, or Fräulein B——, or Baby C—— then good sense, sound judgment, enlightened experience, *l'empirisme rationnel ou philosophique* of Renouard, these then are trump forever.

PARALYSIS OF THE RIGHT RECURRENT LARYNGEAL NERVE FROM ACCIDENTAL TRAUMA.*

By D. BRYSON DELAVAN, M.D.,

NEW YORK.

Paralysis of the recurrent laryngeal nerve due to various kinds of injuries of the neck is not very uncommon. Thus, in the course of operations upon the thyroid gland and of other surgical procedures in its vicinity the recurrent has more than once been so injured that its function has been permanently destroyed. From whatever cause such an accident has taken place, however, the victim has usually been a person in adult life and it has not been possible to follow the history of the case for any considerable length of time. With regard to the cases here reported, the injuries were received early in life, before the larynx had matured and in patients whose history subsequent to the injury was easily obtained. In both cases the ultimate effects of the loss of function of the nerve have had abundant time to be completely developed. The histories therefore are not only uncommon, but possessed of unusual interest, and are therefore worthy of being placed on record.

Case I.—Elizabeth X. Aged 23. Patient otherwise healthy; speaks in a hoarse tone of voice of peculiar quality; this is worse in bad weather, when she is fatigued, or when she has a cold. States that when 12 years of age and fairly well grown, she tripped in crossing a railway track and fell, striking her throat upon the inner edge of the opposite rail. The fall was hard and the shock severe. Upon striking the rail she uttered a loud cry, but in attempting to speak immediately thereafter found that she had lost her voice. Subsequently she had been treated at various times and places, but principally at the Masaschusetts General Hospital. Applica-

*Read at the thirty-third annual meeting of the American Laryngological Association, May 30, 1911.

tions had been made to her throat in great variety and the use of electricity employed for considerable lengths of time. No good result had followed any attempt at relieving her.

Eleven years after the accident the patient was examined by the writer. She appeared normally developed, well nourished and healthy. She occupied the position of waitress in a summer hotel and filled her place satisfactorily. Laryngoscopic examination showed the right side of the larynx fixed, with the vocal band drawn a little to one side of the median line. The length of the right vocal band was distinctly shortened, to the extent of about one-third, as compared with its fellow of the opposite side. Fixation was absolute. The cord was slightly hyperemic and the whole of that side of the larynx appeared contracted. The left side of the larynx was in every respect normal, both as to appearance and physiological function, except that it seemed overdeveloped as compared with what might have been expected under normal conditions.

It seemed evident that at the time of the injury to the larynx the right recurrent laryngeal nerve had been completely paralyzed.

The patient was advised of the importance of avoiding laryngitis and it was suggested to her that she report back to the Massachusetts General Hospital for periodical examination of the throat at intervals of not more than a year, so that the history of the case might be kept in mind and that she herself might be under the supervision of some competent specialist.

Case II.—Mr. Y. Age 50, of excellent family history, but of delicate constitution and highly nervous temperament. Voice is somewhat hoarse and its tone feeble. Finds difficulty in phonation, especially when in poor physical condition. His vocal defects are evidently accentuated by highly faulty use of the breath. Has never suffered from any marked indications of dyspnea.

Patient states that he has been hoarse and has had difficulty in speaking since childhood, and attributes this to one of three possible causes, namely: An attack of diphtheria, one of whooping cough and a possible traumatism. The latter was acquired in the following way:

When a small child he attempted to climb a tree, but part way up lost his hold and fell in such a way that his neck was pinioned in the crotch between two limbs, where he hung for a few moments before being rescued. No accurate observations or examinations were made at that time, but following the accident changes in the voice occurred, as mentioned above.

At the present time examination reveals a complete paralysis of abduction on the right side of the larnyx. The vocal band on this side is shorter than its fellow and in every respect less well developed. Immobility seems complete, the vocal band resting a little to the right of the median line, but apparently not quite as far outward as in the so-called cadaveric position. The movements of the left side of the larynx in adduction are exaggerated to the extent of allowing the free margin of the band to pass the median line and meet its fellow of the opposite side. The left vocal band is apparently somewhat overdeveloped. It is not likely that this condition could have resulted either from diphtheria or whooping cough. On the other hand, such a traumatism as that described might easily be supposed to have inflicted an injury upon the right recurrent laryngeal nerve so severe as to cause complete loss of its function. The fact that it was the right recurrent which suffered may have been purely accidental. Nevertheless, it is possible to suppose that with equal opportunity for injury on both sides the position of the right would render it more liable to injury from external violence than the left. Instruction in the proper use of the voice, especially with regard to breathing, has resulted in distinct improvement in tone quality and control.

The prognosis in these cases as to recovery is absolutely bad. There is no reason, however, why the patient should not enter upon any of the ordinary avocations of life with success, the great point being to avoid all sources of irritation to the larynx, and in case of the occurrence of a laryngitis of the simplest type to resort to proper measures for its relief at the earliest moment, as a laryngitis from any cause might so reduce the lumen of the glottis as to produce dyspnea. Physiologically, the overdevelopment of the healthy side of the larynx in its effort to perform its own function and to supplement that of the paralyzed side suggests the value of systematic vocal exercise for all.

40 East Forty-first Street.

REPORT UPON A CASE OF ACUTE BULBAR PALSY, WITH AUTOPSY AND HISTOLOGICAL FINDINGS; TYPE: ANTERIOR POLIOMYELITIS.*

By ALFRED WIENER, M.D.,

NEW YORK.

The thorough investigations which have been going on recently in connection with anterior poliomyelitis have made us all very keen in its recognition. The odd types which we formerly failed to recognize and considered as obscure cases we now have no hesitation in classing as rare forms. Most authors are now willing to believe that an acute infectious malady may attack the grey matter of the brain as well as that of the spinal cord. Such a condition, known as encephalitis or polioencephalitis, was first described by Strümpel. When it attacks the brain it bears such a close resemblance to anterior poliomyelitis of the cord that it seems there should be no doubt in our minds that if they are not one and the same disease they are at least very closely allied. The acute onset with fever associated with drowsiness, stupor, coma, and convulsions, pronounced irritability, nausea, and headache, attended by paralysis, are all characteristic of the onset of anterior poliomyelitis. What seems most convincing is that a clinical picture which might be entirely representative of a brain lesion in some cases is in other cases closely associated with the characteristic picture of anterior poliomyelitis of the cord.

The evidence both clinical and pathological has demonstrated the fact that, whether the malady attacks the brain or cord, it is one and the same disease and probably toxic in nature. It occurs in epidemic form and it has also been shown that when several members of a family are attacked one may present the cerebral type, and another the spinal type. A purely bulbar type is rare. As it has been my privilege to observe such a case and at the same time to report upon the autopsy with macro- and microscopic findings, I feel warranted in placing the case upon record.

C. D. P., Female, 21 years of age, unmarried.

*Read before the American Neurological Association, May, 1912.

Born February 20, 1888. Died August 15, 1909. Family history: Mother and father living and well, one brother, aged 19 years, died of peritonitis following appendicitis; two sisters living and well. One brother died in infancy. Patient is youngest child of family. Personal history: Patient had measles when about ten years of age. She had always had trouble with her hearing. This trouble increased rather than diminished in recent years. Otherwise she had been well, yet never was robust. Present illness began in August, 1909. The patient had not been feeling well for two or three weeks and had been at work indexing in Boston. She came to New York on a visit in the latter part of July; she did not feel as well as usual, but was up and about. On Saturday, August 6, she complained of headache in the evening. On Sunday she felt rather poorly, but was well enough to go to the seashore and to go in bathing. When she attempted to drink at lunch she found she could not swallow, and from that time on she was barely able to swallow anything, the fluid regurgitating through the nostrils. On reaching home she went to bed and had a slight rise in temperature with headache. She was nauseated, and vomited, but was able to take calomel. The following day she felt no better. On Tuesday, August 9, she was seen by her physician. Her throat was examined several times and the possibility of a laryngeal infection, probably diphtheritic, was considered. Antidiphtheritic serum was given August 11, at 7 P.M. Although the possibility of typhoid was in mind, the peculiar throat condition was not explained. On August 14 she was seen by another physician, who thought there was cerebral trouble, and the possibility of a brain abscess was discussed. On the following day I was asked to see the patient with the possibility that an examination of the eyes, ears, nose, and throat might assist us in arriving at a diagnosis.

To me the patient presented all the symptoms of an acute bulbar palsy. There was present dysphagia with paresis of the soft palate and laryngeal muscles, allowing fluids to regurgitate through the nostrils. The speech was indistinct and the voice nasal. The tongue as yet was not paralyzed but was tremulous. A decided increase in the pulse rate and respiratory movements was noticed at times without any lung involvement to account for it. With the exception of the emphasized disturbance in hearing, the ear was normal. An examination of the fundus of both eyes showed a beginning optic neuritis. There was no involvement of any of the other cranial nerves. Considering the clinical facts in this case, *viz.*, distinct prodromal symptoms with a rise of temperature, followed by a sudden onset of bulbar symptoms, not the slightest evidence of diphtheritic infection, and in view of the fact that all previous examinations had proven negative to the various diagnoses in question, a lesion in the medulla, of the type "polioencephalitis inferior" appealed most strongly to me. The diagnosis of polioencephalitis inferior was accordingly made. The patient was experiencing great difficulty in breathing, due to a great extent to the large accumulation of mucus which was mechanically obstructing the larynx. As she could neither swallow nor expectorate this mucus, and as it was wiped away only with difficulty, I advised a tracheotomy. In addition, antiphlogistic and tonic measures were suggested. A surgeon called in did not wish to operate on account of the danger of pneumonia but left an intubation set in readiness. He thought that the whole group of symptoms might be accounted for by some severe metabolic disturbance, and advised the use of thyroglobulin. The patient gradually passed into a comatose condition and was unconscious for several hours until her death early Sunday morning.

Blood examinations were made at various intervals during the illness. August 11 the leucocytes were 16,000 and the polymorphonuclears 84 per cent. August 13 the leucocytes were 12,000, the polymorphonuclears were 84 per cent., and the red blood cells were 4,624,000. Urine examination on August 11 showed a trace of albumin, no sugar, an increase of indican, and the presence of acetone. The Diazo reaction was negative. On August 14 the specific gravity was 1,020, there was a marked trace of albumin, no sugar was present, indican was increased, and acetone and diacetic acid were present. On August 11 a culture taken from the throat was negative for diphtheria bacilli.

Report of the autopsy by Dr. Pappenheimer: The body is that of a rather poorly nourished, slenderly built young woman of small stature. Rigor mortis is well marked. The abdomen is scantily covered with adipose. The thorax is long and unusually narrow, the costal angle being very acute. The diaphragm is at the level of the third interspace on the right side, and at the fourth rib on the left. Both pleural cavities are free from fluid and adhesions. The pericardial sac contains a few cubic centimeters of clear fluid. The thymus gland is small and fleshy. The heart is of normal size; the cavities contain cruor and chicken fat clot. The tricuspid, pulmonary, and aortic valves are normal. The mitral segments are delicate; on their auricular surface there is a row of very minute translucent, pinhead-sized vegetations. The myocardium is firm, of good color, and shows no hypertrophy. The aorta is of rather small caliber, delicate, and elastic. Just above the sinuses there are a few small areas of intimal degeneration. The lungs, apart from marked hypostatic congestion and edema limited to the right lower lobe, are everywhere well aerated. There are no pneumonic or tuberculous lesions. The bronchi, bronchial lymph nodes, and pulmonary vessels are normal. The liver is normal in size and consistency. On section, the parenchyma is slightly paler than normal, the lobular outlines being rather indistinct. The spleen is small, the capsule wrinkled, the pulp firm, the trabeculæ on section distinct, and the follicles are not enlarged. The pancreas is pale and firm. The left adrenal is normal. The kidneys are of normal size, the capsule strips readily leaving a smooth surface. The cortex is of normal relative width, the color is somewhat pale, and the markings are not distinct. The pelves are normal and the glomeruli are not unduly prominent. The bladder, genitalia, and organs of the neck were not examined. The gastrointestinal tract was not examined. The dura mater is not adherent, and the longitudinal sinus is free from antemortem clot. The pia mater is neither thickened nor edematous, the cerebrospinal fluid at the base being apparently not excessive. The basilar vessels are free from atheroma. The cortical veins are moderately congested and on section the brain tissue is somewhat hyperemic. On cross-sections through the medulla after preliminary hardening there are found a few small irregularly distributed reddish areas. Otherwise the brain tissue appears normal. The ventricles are not distended and the ependyma is smooth. The middle ears and sphenoidal sinuses

are normal. Anatomical diagnosis: Acute verrucous endocarditis. Parenchymatous degeneration of the kidneys. Acute bulbar encephalitis?

The lesions found on histological examination were limited to the medulla and pons. Sections taken from various parts of the cortex showed nothing of interest. The lesions in the medulla and pons consisted of the following: (1) Perivascular round-celled infiltration. Many of the capillaries and smaller arteries are enclosed in a thick mantle of small round cells. The endothelium is frequently swollen. (2) Areas of recent softening, some of which attain a size of several millimeters, and are readily visible on gross inspection of the section. These areas consist chiefly of accumulations of fatty granule cells (Fett-Kornchenzellen), among which are scattered polymorphonuclears and lymphocytes, and in addition some hemorrhagic extravasations. (3) Various stages of degeneration in the ganglion cells. The leptomeninges show the same hyperemia and perivascular infiltration around the blood vessels as mentioned above. There are no thrombi in the vessels and no hemorrhagic extravasations. The lesions are distributed irregularly through the gray and white matter and are present in all sections taken from different levels of the pons and medulla. Thionin preparations show no bacteria. The liver shows numerous areas of focal necrosis, infiltrated with polymorphonuclear leucocytes. The spleen, pancreas, adrenals, and kidneys show nothing of interest. Bacterial examination: Cultures were made from the spleen at the autopsy, and a pure culture of a Gram-positive bacillus, subsequently identified as a pseudodiphtheria bacillus, was obtained. Histological diagnosis: Acute polioencephalitis inferior, or rather an acute bulbar palsy of the type "anterior poliomyelitis."

PSORIASIS—A NEUROSIS.

By WILLIAM P. CUNNINGHAM, M.D.,

NEW YORK.

CLINICAL LECTURER ON DERMATOLOGY AT FORDHAM UNIVERSITY; CLINICAL ASSISTANT AT THE NEW YORK SKIN AND CANCER HOSPITAL; ASSISTANT PHYSICIAN, DERMATOLOGICAL DEPARTMENT, HARLEM HOSPITAL.

"Put your case of psoriasis to bed, give him hypodermics of arsenic, get him cleaned up as quickly as possible—and collect your bill before he relapses." This advice, given to a post-graduate class by a very eminent dermatologist, sums up our knowledge of the disease under discussion. It means that we cannot cure psoriasis; that all we can do is to produce a retrogression of the lesions, more or less protracted.

The plain unvarnished truth is, we have been in utter ignorance of the cause of psoriasis and have been unable to proceed intelligently to control its manifestations. Its parasitic origin has been urged with much fervor by its advocates on the ground that parasiticides have the most deterrent effect upon the lesions. Chrysarobin, tar, and ammoniated mercury will do more to plane down the thickened scaly eruption than anything else used externally. But this treatment does not cure. It is palliative only, and clearly does not get to the root of the difficulty, namely, the etiology. There are others who believe with Dr. Bulkley that the ingestion of nitrogenized food is provocative of psoriasis. This contention is valiantly disputed by many eminent men, and it certainly would appear to be true only in part, because many cases of psoriasis go blithely on their way in spite of the most radical modifications in diet. I will admit most cheerfully that the best method hitherto devised, of holding back the eruption in those predisposed, is by omitting animal foods, but this does not cure, and therefore does not indicate the etiology.

Any observer who has seen much of psoriasis cannot fail to be struck by certain definite and constant characteristics in its manifestations, whether these be sparse or profuse.

First he will find sites of election pretty constantly affected. Again, he will find a rough symmetry of distribution. Again, he will find a constantly identical configuration of unit lesions. Again, he will find a simultaneous outbreak at many different and distant points. These peculiarities associated with the occurrence of the disease in persons often of a robust, hardy type, in whom no discernible vice of metabolism exists, point pretty clearly to a central controlling agency—in other words, to the nervous system. It is not possible to say (in the obscurity of our present ignorance) just what vitiated impulses are coming along the nerves to the affected areas in the skin, but it is rational to suppose that they exist and that they are the etiological factor in psoriasis. Something happens to a patient's nervous system and he gets a perforating ulcer of the foot. Something else happens and he breaks out with herpes zoster. Something else happens, and he develops leucoderma or angioneurotic edema, or dermatitis herpetiformis. A little thought will call up many other conditions where the nervous system is admittedly at fault in the production of cutaneous diseases. Why may not psoriasis be reasonably included in the same category? The helpful effect of arsenic can be explained by its well-known tonic action on the nervous system. The helpful effect of a non-nitrogenized diet can be explained by the greater placidity of the nervous system under such a diet. The improvement often noted after a change of climate can be explained by the improved condition of the nervous system. There is a bracing of the nervous system due to a renewed interest in one's surroundings. The well-known effect of surf bathing is explicable through its action on the nervous system. Salt water baths taken at home would never bring about the same improvement as the same number of baths in the surf with the impact of the waves on the body, the sunshine, and exhilaration of the exercise. And truth to tell, the effect of all those agencies cannot be explained in any other way.

So it would appeal to me that instead of plastering the patients with repulsive ointments we should devote our minds to discovering what is amiss with their nervous systems and seeking to put them in as normal a condition as possible by whatever means, medicinal, hygienic, climatic, and moral we may be able to employ. We will probably come sooner by this method to the discovery of the cause and the remedy for psoriasis. All this about treatment may be sufficiently vague, but I am only seeking to indicate a road, not to elaborate an exhaustive plan of treatment. All the methods hitherto employed have been sorry enough in their results, and any change in our way of handling these cases promises at least as much as they.

It is quite impossible in dispensary practise to resort to measures calculated to improve the nervous tone. But in private practice much can often be done along that line. I have only three cases to

offer, but I am sure they are sufficiently suggestive to be worth describing.

Case I.—Woman of 40, not particularly robust, but strong-fibered and self-reliant, burdened with much responsibility. Had had psoriasis for twenty years. It yielded and relapsed, yielded and relapsed, after the manner of psoriasis always, but it never got entirely well. Finally it got to her face, encroaching from the hair line. Her business position was at once in peril. Hitherto she had borne her affliction stoically because it could be hidden, but when it appeared on her face her morale collapsed; she became peevish and fretful and her eruption grew apace. All the remedies that had helped her before failed her now. Arsenic was pushed; she ate only things that grew in the ground, and drank only milk; all the heretofore effective external applications were employed, and the only noticeable result was a steady invasion of previously unaffected territory. I finally persuaded the patient that if she would quit worrying, forsake her accustomed surroundings for a time, and take a trip into the country she would get well. This assurance was given in desperation, because I was at the end of my resources and no other avenue of escape was open. She took me at my word. She went into the woods, took to roughing it, paid absolutely no attention to her diet or her eruption, and in eight weeks her skin had entirely cleared. Is the result permanent? I do not know, but it established clearly enough that the cause of her outbreak was located in her nervous system and the care-free life she had led in the open had restored her nervous equilibrium. She had been several months entirely well when I saw her last, which was in the early winter.

Case II.—Young man with an enormous patch of psoriasis on his arm. It was a fixture—never disappearing—yielding a little once in a while, but as often returning with encroachment. The one peculiarity about it was that it always improved when his hopes were high and relapsed when he was despondent. All the remedies with a reputation proved ineffective here except for a short time. He bade fair to become a chronic, hopeless case (as most of them settle down to be) when he received news of an inheritance that relieved him of all financial responsibility and enabled him to take a trip through Europe. The end of that trip saw the end of his lesions. He used no treatment of any kind while he was away. He had time only for sightseeing and pleasure. Is the result permanent? I do not know, but here, again, the etiology would seem to be established.

Case III.—Girl, aged 12. Psoriasis for two years. Eruption in all the classical situations. Face not involved. Lesions heavily scaled. One of the cases that itched. Child appeared to be well enough, although she had large tonsils and adenoids. She lived with her stepmother and was not a very happy child, being very sensitive about her condition. Usual results of usual treatment. Recession, relapse, recession, relapse, under all forms of therapeutics. I advised removal of tonsils and adenoids. This was done, but the child did not get well, though her disposition improved. Finally her stepmother died. The child was removed to the care of a paternal relative in the country. Here she ran wild and became a perfect hoyden. Her mental condition rapidly changed; she grew cheerful and hopeful. After six months under these distinctly different conditions with no treatment at all devoted to the eruption it cleared off entirely. Is the cure permanent? Again, I do not know, but it confirms my opinion of the etiology of psoriasis. It may be excepted that I am attributing to nervous influence what was caused by improved metabolism. The point I contend for is that none of these cases showed the slightest disposition to do well until the nervous system received a vigorous uplift, and the one pronounced symptom attending their convalescence was the heightened hope and brightened view. Of course, it is not practicable to apply such treatment to very many cases because of financial limitations, but the seeking of the cause in the direction of nervous derangement may bring to light, sooner or later, a method of treatment within the reach of all. This idea is not new, nor is it widely accepted, but I am convinced that we shall hear more of it before very long. With a disease of this sort offering absolutely no hope of permanent results along the old lines of endeavor, it will be perfectly justifiable to experiment on any new lines suggested, and the road once indicated our enterprising physicians will follow it quickly to a definite conclusion.

315 West Fourteenth Street.

Epinephrin in the Circulation.—T. C. Janeway and F. A. Park state that the modified Meyer method of parallel tests upon segments of surviving carotid and coronary arteries from the ox, is a satisfactory means for detecting epinephrin in complex body fluids like blood. At the present time there is no evidence that epinephrin, in amounts sufficient to produce its physiological effects upon any hitherto used test objects, exists in the circulating blood, with the exception of blood from the suprarenal vein. The examination of uncoagulated blood from six persons with high blood pressure has failed to show the presence of epinephrin or other constricting substances. The constrictor substance in defibrinated blood and serum is not an epinephrin-like substance. In its point of action and its effects it is similar to barium chloride. It is a direct stimulant to smooth muscle and seems to have no relation to the sympathetic innervation of muscle.—*Journal of Experimental Medicine.*

Sarcoma of the Thyroid Perforating the Trachea.—D. R. Paterson reports the case of a woman, aged 46, who was admitted to the hospital complaining of difficulty of breathing with a swelling in front of the neck for about six weeks. There was a considerable degree of dyspnea with cyanosis. There was a flat, hard, painless swelling over the thyroid, and involving that organ. In the larynx the cords moved not very freely, and in the subglottic region a greyish irregular mass was seen filling up the greater part of the tracheal lumen. Tracheotomy was performed under a local anesthetic. The incision went through soft friable tissue, the trachea being found deeply placed, having been pushed towards the spine by the growth. A portion of tissue removed showed it to be a small round-celled sarcoma. Its complete removal was considered impossible. At the end of a fortnight the growth had invaded the skin wound, and pieces of growth were coughed up from time to time. The opening was kept patent by a rubber tube. The patient died suddenly in the night about a month after her admission to hospital. The growth involved the thyroid gland and the neighboring parts. The upper part of the trachea above the opening was filled with round masses of growth which had apparently perforated the anterior wall. Death had taken place by hemorrhage escaping into the lungs from one of the intratracheal growths.—*Proceedings of the Royal Society of Medicine.*

RECENT ADVANCES IN THE INTERPRETATION AND TREATMENT OF PRURITUS ANI.

IN studying the more serious diseases of humanity it is possible to overlook the importance of the minor ailments which, although not life-threatening, are, nevertheless, responsible for a great amount of suffering and disability. In this field of work the general practitioner who is not adept in the refined methods of laboratory research may by close observation and careful study of his cases accomplish useful and unexpected results. The so-called functional disorders are the ones that furnish a vast and unexplored territory for the enterprising physician.

As an example of an ailment that ranks among the commonest that afflict mankind may be mentioned pruritus ani. Apart from the cases in which this condition is merely a symptom of easily recognizable structural changes in and about the lower end of the alimentary canal, such as hemorrhoids, fissures, fistulæ, and eczema, or is the result of the presence of intestinal or other parasites or of such metabolic derangements as diabetes and gout, there remain a large group of cases of anal pruritus which have been regarded as of purely functional or neurotic origin. It is these cases that have remained the despair of patient and physician alike.

Recently there have been a number of important contributions to this subject that bid fair to restrict the boundaries of the last group of cases. One of the most valuable of these contributions is the work that has been done by James P. Tuttle of New York, who has recognized and described practically a new morbid entity of which pruritus ani is the main symptom. The paper in which his interesting results are reported was read at the last meeting of the American Gastroenterological Association and was published in the *American Journal of Surgery*, June, 1912. This disease, which is termed "cryptitis," consists of an exaggeration and inflammation of the crypts that dip down from the sinuses of Morgagni beneath the mucocutaneous margin of the anal outlet. These crypts are irritated by the presence of retained fecal matter, and present all the phenomena of blind internal fistulæ. The hypertrophied anal folds and the skin tabs that are present in so many cases of what has been regarded as idiopathic pruritus, are not as has been erroneously supposed the result of scratching or of the excessive moisture of the parts, but are the external manifestations of the inflammation of these crypts. The detection of these exaggerations of normal anatomical structures is exceedingly difficult because of their peculiar topography. The use of a shepherd's-crook probe enables one to determine the presence of these crypts. The effective treatment of this condition requires a dilatation of the sphincter ani under general anesthesia, a careful search for the pathological crypts, and their complete obliteration as in the case of blind internal fistulæ.

In the new edition of his book on diseases of the rectum the late Sir Frederick Wallis,* who died just after he had corrected the proof sheets, stated that in 90 per cent. of his inveterate cases of pruritus ani there was a small ulcer, abrasion, or submucous tract which was found usually between the two sphincters, more often in the posterior half than in the anterior, and generally near the dorsal midline. These lesions rarely heal of their own accord and become chronic ulcers covered by granulation tissue which exudes an irritating secretion causing pruritus ani.

One of the most valuable features of Wallis's work is the emphasis which it places upon the pathological importance of the ano-proctodeal line or junction between the proctodeum and the lower bowel. "This lining membrane is not skin," states Wallis, "and it is not mucous membrane, and consequently it has not the tough resisting power of the one nor the vascular supply, which is a great power, in the other." It is a matter of importance to recognize that some lesion of the ano-rectal junction is the starting point of the majority of rectal troubles. Effective removal of this danger zone produces the greatest benefit.

There is another phase of this subject that merits attention. In a letter in the *Lancet*, September 28, 1912, D. H. Murray of Syracuse, N. Y., states that as the result of his second year's study of the question, he has been able to confirm his previous opinion, namely, that a streptococcic skin infection is the predominating element in pruritus ani. Cultures made from the site of the lesions in thirty-two cases of pruritus ani showed colonies of streptococci, usually of the fecalis variety. The use of autogenous vaccines made from these organisms caused a relief in the itching and a concomitant disappearance of the streptococci from about the anus.

This brief review of the modern status of the knowledge of pruritus ani indicates at least that there are many subjects in medical science, particularly relating to common ailments, in which new and important discoveries are to be expected as the result of careful observation, and as the result of casting aside the blind adherence to traditional teaching.

*"The Surgery of the Rectum for Practitioners." By Sir Frederick Wallis, M.B., B.C., Cantab., F.R.C.S., Surgeon Charing Cross Hospital, St. Mark's Hospital, and the Grosvenor Hospital for Women and Children. London: Henry Frowde, Oxford University Press; Hodder & Stoughton, 1912.

THE UNIVERSITIES AND MEDICAL RESEARCH.

Recently President Pritchett of the Carnegie Foundation for the Advancement of Teaching has addressed the public on the necessity of universities controlling hospitals as a means for medical education. No one can take issue with him on the necessity of bedside instruction and experience for undergraduates in medicine. It is where he advocates scientists, in contradistinction to practitioners, as teachers of medicine, surgery, and obstetrics that his opinions become open to criticism, especially his objection to the present faculties as being "with a few notable exceptions only incidentally and secondarily interested in medical education and less interested in medical research." The modern movement in medical education, of which President Pritchett is an advocate, aims for research work and investigation in the medical sciences. This is well and proper, but it must not be lost sight of that the fundamental aim of medical education is to teach the student how to practise medicine. If a university sets forth on the basis that the practitioner knows nothing worth teaching, it values as nothing a profession for which it promises to prepare the student.

This confusion of medical education with research work could be corrected by reviewing the progress of medical science. There it can be seen how the great advances came. The first came with the teachings of Redi, the naturalist, who revealed the animal parasites and upset the cherished theories of medical authorities. The next also was not initiated by a medical authority but by a chemist, Pasteur. Both of these great scientists were great teachers, but they could not have prepared the student for the practice of medicine. On the other hand, the physician and surgeon were able to at once use the results of their discoveries and to teach them.

The present desire for greater progress in the treatment of disease brings the problem of how this can best be accomplished. Considered in an abstract way it might seem to be readily solved by putting all hospital patients in the hands of the proposed investigators; but in reality the variety of diseases and conditions presented would make very busy practitioners of them, and it is doubtful if much time would be left for research, especially if they are also required to teach students. Without disturbing the present methods of medical education the universities could obtain some of the desired investigation by limiting the activities of each investigator to a definite problem and by drawing on the talent of the entire university for help. The possibilities of the combined helpfulness of the different departments in a university have never been placed at the disposal of the researcher. To-day any one problem may for its solution require some help from the bacteriological department, the zoological department, the department of physical chemistry, etc. There is no way provided by the university whereby the researcher may have proper assistance from these strictly separate departments, except, perhaps, in a very small way and then as a personal favor of the department to the researcher. These possibilities could be developed by having a director of medical research who should have authority to request conferences, material, and help from the different departments as the several researchers might require them. To show that such a plan is not fanciful and would not be barren in results it is only necessary to refer to one of many instances of very efficient research work accomplished by such cooperation. We refer to the work of Hoffmann, the medical investigator of the disease syphilis, and his brilliant collaborator, Schaudinn, the protozoologist.

UNNECESSARY NOISE IN CITIES.

Among the matters dealt with at the recent International Congress on Hygiene at Washington was that of unnecessary noise in cities. Dr. Clarence John Blake of the Harvard Medical School read a paper in which he stated that the bad effect of unnecessary noise is evidenced not only in the changes occurring in the organ of hearing as the result of continued exposure to loud noise, but also in the fatigue showing itself generally and evidenced by various forms of disturbance of function of the nervous system. Blake further said that a great part of the noise incidental to the mechanical operation of modern life, especially in community centers, is avoidable. The suppression of unnecessary noise is therefore advisable for economic reasons, both in the safeguarding of the human machine and in the saving of wasted mechanical energy, of which noise is an evidence—a saving of waste in both directions.

No phase of modern civilization impresses the Oriental more unpleasantly than the ceaseless din and clamor of our crowded streets. The philosophic and perhaps wise visitor from the Far East asks himself if the undignified, ceaseless scurrying to and fro of men and women, the blare of discordant bands, the metallic nerve-racking rattling of street cars and elevated trains, the weird and ear-splitting sounds emitted from rushing, smoking automobiles, and the various other disagreeable noises that go to make up the bedlam of a modern Western city are the outward and visible signs of an inward and spiritual grace or are merely significant of the vulgar materialism and mad rush for wealth which distinguish modern civilization. The Eastern philosopher craves the brooding peace of the old Orient. Of course, it will be asserted that the dweller in the lotos-eating East is no fitting judge of what is meet for the strenuous striver after money and notoriety, but at the same time it may be said that the latter can strive as strenuously, more pleasantly and with less injurious effect on himself and fellow citizens if he does not make so much noise about it. Moreover, it is not only the supposedly lethargic and apathetic Oriental who decries the modern methods of noisy bustle. There is a large body of men and women even in America firmly of the opinion that most of the noise accompanying modern life is both unnecessary and in a high degree harmful. In the *Canadian Journal of Medicine and Surgery* for November, 1912, is an editorial note discussing the noise in cities, and drawing attention to the fact that an eminent Australian visitor to Toronto was

distracted by the noises which assailed his ears by night and day. It would be bad enough if unnecessary street noises were restricted to the daytime, but unfortunately night is often made hideous by various insistently rest-breaking sounds. Clocks, cats, street cars, bells on the engines of trains, milk carts, and so on all add their quota to the disturbances which by night often render sleep difficult to the healthy and impossible to the sick.

The Society for the Suppression of Unnecessary Noise has done good work in the city, but there still remains much to be done. When the public is educated to the fact that noise is not synonymous with progress, but, on the contrary, impedes useful effort and is hurtful to health, then radical reforms in this direction may be looked for. In the meantime the campaign against unnecessary noise should be conducted persistently.

MALIGNANT PUSTULE THROUGH THE AGES.

Many good clinicians upon reading ancient and medieval descriptions of disease have straightway expressed their final conviction that attempts to connect these with diseases as we know them to-day represent a mere waste of time. The chief blame is naturally placed on crudeness of description, and it is not difficult to show that since a given episode may be reduced to an absurdity, the subject is not one for research. The plague of Athens, for example, agrees with none of the great epidemics of to-day, although it has been identified with a dozen of these by irresponsible writers. But there is evidently room here for a school of higher criticism if a set of men can be interested in this work who possess certain qualifications. The value of all criticism depends upon the sum of the actual attainments of the critics, duly tempered of course with good judgment and scientific use of deduction.

These requirements appear in part in a paper recently read by Richter before the Section for History of Medicine of the German Society of Naturalists and Physicians (*Münchener medizinische Wochenschrift*, October 22). The subject was "the significance of malignant pustule for the history of epidemics." The author makes full use of both induction and deduction. Nothing can be more certain, from analogy, than the former wholesale prevalence of malignant pustule—a severe constitutional polymorphous affection epidemic in both mankind and animals, and transmissible from one to the other in various ways. But unimaginative historians have ignored this almost self-evident probability. In such impressive epidemic affections as "sacred fire," "Persian fire," etc., etc., they have seen nothing beyond such everyday conditions as simple carbuncle and erysipelas.

One year ago before the same body Richter announced that malignant pustule was of great significance for the history of epidemiology, and now he adduces fact upon fact in support of this view. If it once be admitted that this affection prevailed as a scourge in ancient times its phenomena are readily recognized in several episodes of classic and sacred writings, to say nothing of technical works. It is moreover not difficult to show that after the earliest observers had given good accounts of this condition, their successors in translating from one language to another allowed those errors to creep in which persist to the present day.

In our own era epidemics of malignant pustule have sprung up in out of the way localities, attacking man and animals, and have received gruesome names from the public to whom the disease had been unknown. A Swiss poet once wrote a lay tribute to the "black spider," as he termed the malady. The disease in its general aspect has often been confounded with another gangrenous folk plague, to wit, ergotism.

Sporadic Plague in Hamburg.

The occurrence of exotic diseases in great centers of civilization is always of extreme interest to the clinician because the maladies when submitted to all the technical resources of a metropolis often appear quite unlike the textbook descriptions which are naturally based on facts obtained under widely different circumstances. Thus for a long period cases of socalled yaws which drifted to the great medical centers were nothing but examples of syphilis to the metropolitan experts. Sannemann at a recent session of the Medical Society of Hamburg (*Münchener medizinische Wochenschrift*, November 5) stated that four cases of bubonic plague had appeared in that city since 1900, all from the River Plata ships (South America). Three of the four patients died. The onset was obscure and unlike that set down in textbooks. Early diagnosis was almost out of the question. Clinically the most striking facts were high temperatures and profound disturbance of the general economy. As for death, that was pyemic throughout, from secondary infection. Such cases could, therefore, simulate a pyemia from lymphadenitis. Rumpel, who had studied the plague at Oporto, laid great stress on the personal history. Given the case of a seaman or passenger just come from a plague country, with very high temperature, he must at once be regarded as a suspect. One should not make a diagnostic opening into a bubo until assured that pus is present.

News of the Week.

A Discussion on Vertigo will take place at the meeting of the Otological Section of the New York Academy of Medicine on December 13. Mr. Richard Lake, F.R.C.S., of London will read a paper entitled "Vertigo, a Clinical and Therapeutic Study," and the paper will be discussed by Drs. James F. McKernon, Charles L. Dana, E. B. Dench, Philip Hammond of Boston, Nathaniel Bowditch Potter, Percy Fridenberg, and others. The Chairman of the Section extends a cordial invitation to all who are interested in this subject.

Decrease in Death Rate.—The mortality in New York City for the week ending November 24 was 1,354 deaths, with a death rate of 13.65 per thousand of population, while in the same period of 1911 the deaths amounted to 1,378 and the rate was 14.43. The decrease occurred entirely in the number of adult deaths, and those of children under five years of age were slightly increased

The death rate for the city during the third quarter of the year, that is the months of July, August, and September, is given as 12.94, a decrease of 1.44 from the rate of the same months last year, or an absolute decrease of 1,187 deaths.

Requirements for Medical Licenses.—It is announced that after January 1, 1914, an applicant for license to practise medicine in the State of Pennsylvania must show that he has served as interne in a hospital for a period of at least one year after a four years' course of instruction in a medical school.

To Fight Cancer.—Carrying on the policy outlined at the Clinical Congress of Surgeons of North America in New York recently, the Chicago Medical Society has named a committee to further the campaign of publicity in the fight against cancer. The committee is composed of Dr. Franklin H. Martin, Chairman; Dr. C. Volini, Dr. C. C. O'Byrne, and Dr. Jacob Frank.

Licenses Granted.—The Missouri State Board of Health has issued licenses to practise to thirty-one medical graduates who successfully passed the examination given by the Board last October.

Railroad Casualties.—During the month of October, 1912, 3,771 persons were injured in accidents on the subway, elevated, and street railways of New York City, or 565 more than during the same month of last year. Twenty-five persons were killed and there were 208 cases of serious injury.

Earthquake and Pestilence.—Thousands of persons are said to have been killed in the rural districts of Mexico by the earthquake on November 22, and the survivors are threatened with serious epidemics of disease. Smallpox and typhoid fever have already appeared, and as the only water available is that in stagnant pools the infection is likely to spread with ease.

Personals.—Dr. J. J. O'Connell, Health Officer of the Port of New York, sailed on November 30 for Panama, where he will make a tour of inspection.

Dr. Ross H. Skillern has been appointed clinical professor of laryngology in the Medico-Chirurgical College of Philadelphia, in succession to Dr. Arthur H. Cleveland, resigned.

Dr. William Seaman Bainbridge of New York has been appointed consulting surgeon to the Tarrytown Hospital, Tarrytown, N. Y.

Dr. W. H. Luckett has removed to 18 West 87th street, New York.

Gifts to Charities.—By the will of the late Barbara McClure of Philadelphia, the sum of $100 is bequeathed to the Home for Consumptives at Chestnut Hill, Philadelphia.

The Stumpf Memorial Hospital Association of West Hudson, N. J., has received a gift of a house and land from Mr. Jacob Stumpf of Harrison. The house will be rebuilt into a modern hospital and the institution will be supported by the residents of West Hudson.

By the will of the late Dr. Richard H. Cleeman of Philadelphia, the sum of $50,000 is left to the University of Pennsylvania to be used for the erection of two dormitories which are to be known as Cleeman Halls.

University of Maryland.—At the celebration of Academic Day on November 12, the provost, Judge Henry Stockbridge, announced that checks and securities to the amount of $10,000 had been placed in his hands for the purpose of beginning the endowment of the chair for experimental physiology. This sum was the gift of Prof. John C. Hemmeter, who at present holds the chair of physiology at the University.

Nurses Graduate.—The graduating exercises of the German Hospital Training School for Nurses, New York, were held on November 28, when the president of the school handed diplomas to twenty-two young women who had completed the three years' course.

Surgical Clinics.—Dr. Parker Syms will hold a series of surgical clinics at the Lebanon Hospital, New York, on Wednesday afternoons at 3 o'clock, until March 1. The Lebanon Hospital is most conveniently reached by the West Farms Subway to the Jackson Avenue Station.

Tuberculosis Hospital.—The Supervisors of Westchester County, New York, whose request for permission to build a county tuberculosis hospital at Yorkville was recently denied by the State Commissioner of Health, are now considering the purchase of a farm of seventy-seven acres in the Pocantico Hills and adjoining the estate of Mr. John D. Rockefeller, near Tarrytown.

Hygiene and Public Health at McGill University.—Mr. John W. Scane, registrar of McGill University, writes: "I notice an article in the MEDICAL RECORD of November 16th, in which the statement is made that the University of Kansas School of Medicine announces a course of Public Health and Preventive Medicine which will be required for the degree of M.D., and that this is the first time that such a course has been made obligatory in a medical school. I should like to correct this statement and to say that the Medical Faculty of McGill University has required a course in Hygiene and Public Health for the degree since 1877 and that this course was first given in medicine in 1871 and in 1877 was made compulsory."

The German Medical Society of New York at a meeting held December 2, elected the following officers for 1913: *President*, Dr. G. Seeligmann; *Vice-President*, Dr. H. Fischer; *Secretary*, Dr. M. Rehling; *Treasurer*, Dr. S. Breitenfeld.

Associated Physicians of Montclair.—Dr. Joseph Collins, physician to the Neurological Institute, New York, will speak before the Associated Physicians of Montclair and vicinity on December 23, taking as his subject: "The Early Interpretation and Treatment of the Commoner Psychoses." Other lectures will be delivered before the Society by physicians of New York and Philadelphia each month until spring.

Rush Medical Society.—The Rush Medical Society of the University of Pennsylvania was organized in Philadelphia on November 24 for purposes similar to those of the Harvey Society of New York. Arrangements will be made for the delivery of public lectures for the diffusion of knowledge of the medical sciences.. The following officers have been elected: *President*, Dr. Richard M. Pearce; *Vice-President*, Dr. Alfred Stengel; *Secretary-Treasurer*, Dr. William Pepper; *Executive Committee*, Dr. H. Taylor, Dr. A. C. Abbott, and Dr. H. H. Donaldson.

For the Study of Alcoholism.—The forty-second annual meeting of the American Society for the Study of Alcohol and Other Narcotics will be held at the Hotel Raleigh, Washington, D. C., on December 10 and 11, 1912. The purpose of the meeting is the presentation and discussion of the latest and most authoritative studies on alcoholism,

inebriety, and drug taking. Particulars may be obtained from the secretary, Dr. T. D. Crothers of Hartford, Conn.

Third District (S. C.) Medical Association.—The following officers were elected at the annual meeting held in Greenwood on November 21: *President,* Dr. Thomas L. W. Bailey, Clinton; *Vice-President,* Dr. R. B. Epting, Greenwood; *Secretary-Treasurer,* Dr. G. P. Neel, Greenwood.

Crawford County (O.) Medical Society.—At the annual meeting held in Galion on November 21, the following officers were chosen for the ensuing year: *President,* Dr. William H. Guiss, Tiro; *Vice-President,* Dr. E. R. Schoolfield, Bucyrus; *Secretary-Treasurer,* Dr. Lucia Kemp, Bucyrus.

Eighth District (Cal.) Medical Society.—The annual convention was held at Chico on November 19, when the following officers were elected: *President,* Dr. Dan H. Moulton, Chico; *Vice-Presidents,* Dr. G. H. Fay, East Auburn; Dr. Charles B. Jones, Sacramento, and Dr. T. P. Peery, Yuba City; *Secretary,* Dr. Frederick F. Gundrum, Sacramento; *Treasurer,* Dr. Oscar Stansbury, Chico.

New York County Medical Society.—At the 107th annual meeting held on November 25 the following officers were elected: *President,* Dr. Brooks H. Wells; *Secretary,* Dr. John Van Doren Young; *Treasurer,* Dr. Charles H. Richardson; *Councillors,* Dr. David Bovaird, Jr., Dr. Joseph B. Russell, and Dr. John J. MacPhee.

The Late Dr. von Ramdohr.—The following resolution was passed at a recent meeting of the Medical Board of the Peoples Hospital: *Whereas,* Dr. Cæsar A. von Ramdohr had served the People's Hospital as Consulting Obstetrician since the foundation; and, *Whereas,* In his life he had acted to his professional brethren with rare kindness, courtesy, and consideration; and, *Whereas,* The members of the Medical Board and lay boards of the People's Hospital deeply deplore the loss of his knowledge, skill, and kindly aid; RESOLVED, That a copy of these resolutions be sent to the family of the late Dr. Cæsar A. von Ramdohr and to the medical journals, and that they be spread in full on the minutes of the Medical Board.

Obituary Notes.—Dr. ELIZABETH C. KELLER of Boston, Mass., one of the first women in the country to practise surgery, died at her home in Jamaica Plain on November 28, aged 75 years. She was graduated from the Women's Medical College of Pennsylvania, Philadelphia, in 1871, and soon after opened a free dispensary and hospital in that city. In 1875 she became resident physician at the New England Hospital for Women, and later established herself in private practise.

Dr. JOHN DALE MCGILL of Jersey City, N. J., for twenty-six years Surgeon-General of the New Jersey National Guard, died at his home on November 28, aged 65 years. Dr. McGill was graduated from Princeton University in 1867 and from the Medical Department of the University of Pennsylvania in 1870. He was for forty-one years a member of the staff of St. Francis Hospital, Jersey City, and of the consulting staff of the Jersey City Hospital, and had also served as police commissioner of Jersey City, president of the Board of Education, and president of the Board of Finance. He was a member of the American Medical Association and of the New Jersey State and Hudson County Medical Societies, and a former president of the last.

Dr. MARKAR G. DADIRRIAN of New York, a graduate of the New York University Medical College in 1871, a member of the New York State and County Medical Societies, the Physicians' Mutual Aid Association, and the Imperial American Society of Constantinople, died at his summer home in Hastings, N. Y., on November 24, aged 73 years.

Dr. JOHN E. BRUERE of New York, formerly of St. Charles, Mo., a graduate of the Medical Department of Washington University, St. Louis, in 1858, and a surgeon in the United States Army during the Civil War, died at his home on November 22, aged 76 years.

Dr. JAMES B. GASTON of Cripple Creek, Col., a graduate of the Rush Medical College, Chicago, in 1888, died suddenly of apoplexy on November 16, aged 61 years.

Dr. WILLIAM CAMPBELL of Equality, Ill., a member of the Illinois State and Gallatin County Medical Societies, died suddenly on November 21, aged 70 years.

Dr. JACOB HETRICK of Fort Wayne, Ind., a graduate of the Fort Wayne College of Medicine in 1881, and a member of the Indiana State and Allen County Medical Societies, died at his home after a long illness on November 19, aged 66 years.

Dr. SAMUEL DAWES BOWKER of Charlemont, Mass., a graduate of the University of Vermont College of Medicine, was struck and instantly killed by a railroad train near the Hoosac Tunnel, on November 15, in the 50th year of his age.

Dr. GEORGE EBENEZER FRANCIS of Worcester, Mass., a graduate of the Harvard University Medical College in 1863, surgeon in the United States Army during the Civil War, consulting surgeon to the Worcester City Hospital, the Memorial Hospital, and St. Vincent Hospital, a member of the Massachusetts State Medical Society, of which he was president from 1902 to 1004, and of the Worcester County Medical Society, died at his home from cystitis on November 20, aged 74 years.

Dr. PARKS REX of Wellsville, O., a graduate of Western Reserve University, Medical Department, in 1878, died at his home from Bright's disease on November 18, aged 64 years.

Dr. ROBERT E. LEE of Darlington, S. C., a graduate of the Medical College of the State of South Carolina, Charleston, in 1885, died at his home after a long illness on November 19.

Dr. NATHAN G. RIEFF of Albion, Ind., a graduate of the Hahnemann Medical College and Hospital, Philadelphia, in 1883, died at his home on November 27, aged 53 years.

Dr. THOMAS A. BOGGAN of Tupelo, Miss., a graduate of the Memphis Hospital Medical College, Tenn., in 1896, and a member of the Mississippi State and Lee County Medical Societies, died suddenly in Mooresville on November 20, aged 65 years.

Dr. ERNEST DUVAL of Rochester, N. H., a graduate of Laval University, Medical Department, Quebec, in 1884, died at his home on November 23, aged 52 years.

Dr. EDWARD PERRY BOWLES of Wolfville, N. S., a graduate of the College of Physicians and Surgeons, New York, in 1874, died suddenly on November 19.

The Rev. JONATHAN WINGATE WINKLEY of Boston, Mass., a graduate of the Harvard Divinity School and of the College of Physicians and Surgeons, Boston, in 1894, died at his home on November 19, aged 79 years.

Dr. EDWIN F. WARD of New York, a graduate

of the College of Physicians and Surgeons, New York, in 1861, a veteran of the Civil War, having served during the latter part as surgeon on the staff of General Phil Sheridan, and a member of the New York Academy of Medicine, the New York State and County Medical Societies, and the Greater New York Medical Association, died at his home on November 23, aged 76 years.

Dr. WALTER HENRY TOBEY of Boston, Mass., a graduate of the New York Homeopathic Medical College and Hospital in 1874, a former president of the Massachusetts Surgical and Gynecological Association, and a member of the Massachusetts Homeopathic Medical Society, died suddenly in his automobile on November 23, aged 65 years.

Dr. DANIEL MCDONALD of Glace Bay, N. S., a graduate of the Dalhousie Medical College, Halifax, in 1898, died in St. Joseph's Hospital, Glace Bay, after an operation for appendicitis, on November 16, aged 45 years.

Obituary.

EDWARD CURTIS, M.D.,

NEW YORK.

Dr. EDWARD CURTIS of New York, emeritus professor of materia medica and therapeutics in the College of Physicians and Surgeons, died at his home on November 28. Dr. Curtis was born in Providence, R. I., in 1838, and was graduated from Harvard College in 1859. He then began his medical studies at the College of Physicians and Surgeons, forsaking them to enlist in the United States Army on the outbreak of the war. He was finally graduated from the Medical Department of the University of Pennsylvania in 1864, and was appointed to the Army Medical Museum, where he developed the art of photomicrography. In 1870 he returned to New York and in 1878 was made professor of materia medica in the College of Physicians and Surgeons, an office which he relinquished in 1886 when he was made emeritus professor. From 1878 to 1904 he served as medical director of the Equitable Assurance Society of New York. He was the author of many scientific treatises and a member of the American Association for the Advancement of Science, and the New York State and County Medical Societies. Together with Dr. Woodward of the Surgeon-General's staff he performed the autopsy on President Lincoln in 1865.

Correspondence.

THE FUTURE OF THE DOCTOR.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The article by Dr. Dixon in a recent issue of the MEDICAL RECORD, and the prophetic address of Dr. Dana at the New York Academy of Medicine upon a kindred subject, are both timely reminders that the outlook of medicine as an agreeable and sufficient means of support is not inviting, and the writer is prompted to refer to what he thinks most medical men will accept as an explanation of the present demoralized condition of our calling. Most of this change in prosperity, it must be admitted, is due to ourselves alone, and the decline began at least two or three decades ago, for it has kept pace with the abuse of hospital and dispensary work, and the grinding out of a host of young medical men without much heed of the kind or extent of their education by second rate colleges. The profession, here as elsewhere, therefore, is overcrowded, and commercialism has resulted from this to a large extent.

As matters now stand, with the exception of those of us who are engaged in research work, teaching, or operative surgery and do not ordinarily practice, the rest are treated with scant courtesy or consideration by a half educated or credulous public who have gotten to prescribe for themselves, easily finding a panacea in the form of a patent medicine, or convenient tablets upon the shelves of the first accessible druggist. Some of this is due to the complete abandonement of prescription writing by the doctor of to-day and some to the lowering of his dignity and undue familiarity and unwise confidences.

Again the widespread paternalism which is closely connected with sensation or muck-raking, leads to the *superficial* education of the mob. More than one quackish individual with the literary style of the man on the end of the cart utters ridiculous warnings to the hypochondriac or interprets pseudoscience for an evidently substantial consideration. Congresses and semi-popular gatherings provide food for the idle curiosity of the morbid and introspective and upon one occasion lately the crowd amused itself by playing with psychological instruments of precision which should have been kept in the laboratory. Truly a little knowledge of a certain kind is worse than none at all.

Again through the abandonment of the family physician, whom Dr. Dana evidently believes to be extinct or about to become a thing of the past, the curious patient through the advice of meddlesome friends often without any medical advice whatever seeks the last new medical or surgical cureall. The writer has even known of a patient suffering from tabetic crises who has had four surgical operations performed by four eminent surgeons within a few years, the first being "for the removal of hemorrhoids;" the second entailing the enucleation of one testicle; the third the division of the sphincter ani and the levator ani muscles; the fourth, a reparative one by a competent and intelligent surgeon, was alone justified. A good family physician would have obviated all this blundering and cruelty. Equally useless and dangerous and expensive operations have been made by others under the same circumstances. In these days of progress and independence, amateur physicians dose each other with poisonous tablets, making their own diagnoses without medical help, and the broker's office, the club, or other places become convenient consulting rooms. There seems to be no trouble in buying tablets by the dozen or thousand, and it is rare that any entry is made in the pharmacists' poison record book.

Under these circumstances it is pleasant to hear the wise and venerable Doctor Jacobi uttering a small word of hope and deploring the existing situation. While the much abused family physician is now neglected, he will exist despite his present unpopularity; and the fight should be made by all of us against the vulgarization and popularization of the art of healing and the superficial propagation of false science. Perhaps the family physician who is so often forgotten by those he has brought into the world and carried through critical periods of suffering, will again take up his work as the valued counsellor and guide when special help is needed, for he certainly has a noble place that can-

not be usurped by quacks or charlatans, and the day of the extreme faddist or dilletanti cannot last forever.

AN OLD DOCTOR.

NEW YORK.

DR. WHITMAN'S REMARKS ON THE ABBOTT METHOD OF TREATING LATERAL CURVATURE OF THE SPINE.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—In the discussion of the Abbott treatment before the Clinical Congress of Surgeons, it was my purpose to present a record of actual experience. It was stated that this experience did not support Dr. Abbott's claims that fixed lateral curvature of the spine could be more easily cured than club-foot or bow-leg, nor that the correction of the deformity could be completed in three weeks. Many cases could not be cured, and correction or even improvement usually required months, rather than weeks, of treatment. There were also certain inevitable discomforts, inconveniences, and even dangers in the treatment which should be recognized by the surgeon and patient before the treatment was undertaken. Having enumerated the limitations in the scope and efficiency of the method, its advantages were presented in the following words: "Cases may now be improved or cured that formerly were not susceptible to improvement or cure, indicating not only the greater efficiency of the method, but that the changes incidental to deformity are less resistant than has been believed. It has been proved already, I think, that the underlying principle of the method is correct, namely, that, as lateral curvature is essentially a flexion deformity, rotation may be more easily reduced in flexion than in extension, and that deformity should be corrected before functional activity is permitted. When this principle is generally accepted, corrective treatment will be applied when it may be effective, and gymnastic exercises, now a futile routine, will find their proper place in the prevention of deformity and as a necessary adjunct in the after treatment."

In the report in the MEDICAL RECORD it is stated: "The corset has to be worn too long, and he felt sure that moderate lateral curvature could be reduced more easily by extension and gymnastic exercises." The reporter misunderstood me, for I did not say this, and as I believe that the Abbott method will eventually supersede such ineffective treatment, I should like to correct the misstatement and the impression made by the report, in which I seem to condemn a treatment of which I am heartily in favor.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

MEETINGS ON INSURANCE AT THE ROYAL COLLEGE OF PHYSICIANS AND IN VARIOUS TOWNS—STATEMENTS OF ADVISORY COMMITTEE AND OF NATIONAL MEDICAL UNION—AMBULANCE SERVICE—OBITUARY.

LONDON, November 15, 1912.

ON Wednesday a meeting was held at the Royal College of Physicians of London, of a joint committee of the English qualifying bodies. These are the two royal colleges, the Society of Apothecaries, and the medical faculties of the English universities. Resolutions were passed showing that in the opinion of the meeting (1) the conditions set up by the regulations of the insurance commissioners are of such a nature as to interfere injuriously with the rights and proper independence of the profession and with efficiency in the treatment of insured persons; (2) that practitioners ought not to be tried as to matters concerning professional matters by a non-professional tribunal; (3) that it would be unwise to submit to local committees so long as insured persons are in an overwhelming majority. A meeting of medical men in Dublin unanimously resolved that the latest concessions of the Chancellor are not such as to justify acceptance of service under the act as it now stands. The medical members of the Advisory Committee issued a circular in favor of trying to work the Act for three years after which revision might be sought in the light of the facts and figures accumulated. This appears to propose an easy method for Mr. Lloyd George to give way, but even if he could be trusted he may not be in office after three years. The National Medical Union, which has never wavered in its support of the cardinal points, has sent to every practitioner a criticism of the regulations pointing to the conclusion that they are "intolerable to any self-respecting medical man and would destroy forever the independence of the profession."

Resolutions to reject Mr. Lloyd George's last offer have been passed at meetings in Liverpool, Manchester, Birmingham, Oxford, Cambridge, Bristol, Plymouth, and many other places, every day seeming to bring new reports. Many are directions of divisions of the British Medical Asosciation to delegates how they are to vote at the representative meeting. As this meeting is convened for next Tuesday it is hardly worth while to speculate on what course that vote will direct to be taken.

The County Council have decided to seek parliamentary sanction to a scheme under which the Asylums' Board, the Port of London Authority, the Borough Councils, and the Boards of Guardians will unite to extend the ambulance service and render it more efficient.

The year of office of Sir T. Crosby, M.D., as Lord Mayor of London, has passed. Before retiring he gave a city banquet to a number of leaders of the profession. Sir Thomas and his daughter, Lady Mayoress, carry into their retirement the heartiest good wishes of the citizens, not a few of whom still express surprise that a man of eighty-two should have gone through the year of work with so little apparent fatigue.

The death of the well known ophthalmic surgeon, Arthur Henry Benson of London, took place on the sixth inst. He graduated in arts and medicine at the Dublin University, 1875-6, took F.R.C.S.I. in 1881. He was surgeon to the Eye and Ear Hospital and ophthalmic surgeon to the Royal City of Dublin Hospital. He was a son of the late Professor Benson and a brother of Sir Hawtry Benson. He contributed various papers to societies and was president of the pathological section of the Academy of Medicine, 1909-11.

Brigade Surgeon Frank Pout of the Army Medical Staff died suddenly on the 16th inst, aged 76.

Surgeon-General Alex. M. Dallas, C.I.E., has died in his eighty-third year. He entered the Indian Medical Service in 1856, was appointed superintendent of the central jail in 1859, Inspector-General of Prisons in 1863, and of Civil Hospitals in 1885. He was made a Companion of the Indian Empire in 1886.

OUR PARIS LETTER.

(From Our Regular Correspondent.)

CONGRESS OF UROLOGY—COMPARISON OF DIFFERENT METHODS OF TREATMENT OF RENAL TUBERCULOSIS—PROSTATECTOMY—IODIZED INSUFFLATIONS IN CHRONIC URETHRITIS — GALVANOCAUSTIC TREATMENT OF URETHRITIS—FOREIGN BODIES IN THE BLADDER—LITHOTRITY AND CYSTOSCOPY—NECROLOGY: PAUL LEGOND.

PARIS, October 15, 1912.

THE eighteenth reunion of the French Association of Urology was held in Paris from the ninth to the twelfth of October. The main subject for discussion was the "Comparison of the Different Forms of Treatment of Renal Tuberculosis." The symposium was opened by Léon Bernard and Heitz-Boyer. Following the labors of Albarran the majority of clinicians have resorted to nephrectomy in the treatment of renal tuberculosis. The opinion is almost unanimous that medical, including hygienic and medicinal, treatment is practically useless. Heliotherapy and radiotherapy have not demonstrated their value. There are certain physicians who would substitute for nephrectomy the use of antituberculous agents whose efficacy they extol. But the results of the purely medical or specific treatment are not entirely satisfactory. A few apparent cures are indeed to be noted, but the number of failures is large. Nephrectomy, on the other hand, produces results that are real and that justify the resort to this operation. The mortality of the latter is from one to six per cent. The value of this form of surgical intervention is as remarkable as is its benignity. Nephrectomy rescues from speedy death four-fifths of the individuals suffering from renal tuberculosis. Besides, those that survive remain completely and permanently cured. The conclusion of the speakers was that, excepting in cases in which the performance of nephrectomy is impossible, this becomes the operation of choice as soon as the diagnosis is made.

Opposed to this conclusion were the following: Castaigne of Paris, Le Fur of Paris, de Keersmaecker of Antwerp, Leclerc-Dandoy of Brussels, and Péchère of Brussels, who had obtained by means of medical treatment, chiefly by the use of tuberculin, extremely satisfactory results. But the large majority of urologists who took part in the discussion were in favor of nephrectomy. Léon Bernard, who closed the debate, stated that whereas the use of tuberculin caused an improvement in the tuberculous process in the kidney it did not lead to a complete cure. Proof of this statement was afforded by the observation that in many instances following tuberculin treatment the removal of the affected kidney revealed the presence of the tuberculous process which had never been influenced by the specific treatment.

The subject of prostatectomy gave rise to an interesting discussion. Castaigne and Lavenant have shown that prostatectomy has a beneficial influence upon concomitant chronic lesions of the kidneys. Marion favored the use of tamponade in suprapubic prostatectomy. The advantages of this procedure are first, the prevention of nervous hemorrhage, so that the patient is able to stand the operation better; secondly, it is possible to wait three or four days before dressing the wound, for there is no risk of a clot obstructing the tube. Occasionally the tampon causes an elevation of temperature.

Hamonié of Paris described an interesting procedure, namely, the treatment of chronic urethritis by means of iodized insufflations. The instrument consists of a sound containing a tube which carries the iodized vapors. These escape through windows in the wall of the sound. The return flow for the vapors is through the space between the sound and the inner tube.

The galvanocaustic treatment of chronic urethritis was favored by Georges Luys of Paris. The advantage of this method of treatment consists in the fact that it permits the complete destruction of the chronic foci. In an elaborate paper the speaker discussed the indications and contraindications of this method of treatment, the operative technique, the accidents that may occur, and the results of this procedure.

The subject of foreign bodies of the bladder was studied from the therapeutic viewpoint by Hasse of Liege. He reported the case of a woman forty-eight years of age, who, as the result of sexual perversion, had introduced into the bladder during the course of one year seventy-five foreign bodies, including the following: buttons of all kinds, hairpins, celluloid pins, safety pins, a nickel cross, coins, etc. These objects were removed quite easily through the greatly dilated ureter. Vincent, of Paris, reported the case of a girl, aged nine years, who had introduced into the bladder two hairpins, which, hooked together, were surrounded by a vesical calculus. The entire mass was easily removed by the hypogastric route.

Georges Luys of Paris emphasized the necessity of controlling by means of the cystoscope the complete evacuation of the fragments produced by the lithotrite. He insisted upon the close alliance between lithotrity and cystoscopy. Phosphatic calculi of the bladder may be removed with the aid of Luys' direct vision cystoscope. In fact, phosphatic calculi which give rise to a painful cystitis, are often soft and may be easily removed with the aid of a pair of forceps introduced through the cystoscope.

Paul Legond, clinical professor at the medical school of the University of Paris, has just died suddenly at the age of sixty-one years, in consequence of a severe attack of uremia. He was recognized in France as one of the foremost gynecologists. He had mastered the details of operating by the vaginal route and he had shown to the profession the advantages of Péan's operation. He had perfected the operation of morcellation of fibroid tumors and their complete extirpation by the vaginal route. His work on ectopic gestation is still fresh in the memory of all obstetricians and gynecologists. Paul Legond was one of the most brilliant professors in the medical faculty. Every one admired his countenance, at once energetic and soft, commanding and smiling. His tall stature and his powerful chest impressed one with the power that went hand in hand with the exuberance of his life. He was an eloquent speaker. This quality he demonstrated admirably when he presided last year at the surgical congress in Paris. Above all, he was kind to his pupils and to his patients. All who came in contact with him felt for him a peculiar veneration, for he had a sympathetic heart and knew how to find in the most painful moments the words that console and the smile that brings comfort.

2. Difficulties in Interpreting the Significance of Regional Muscle Rigidity and Degeneration about the Thorax.—J. L. Pomeroy points out that there is a complex mechanism in the causation of muscle rigidity and degeneration about the thorax, that there is the possibility of neuritis with localized conditions resulting from this lesion, a mechanical influence exerted upon the nerves of the mediastinum, and that segmental symptoms from the lungs are not specific for the lungs alone, but may be brought into play by aortic, cardiac and pericardial changes, and changes in other structures in the thorax. There is no doubt but that bronchial gland enlargement may give the same picture from a reflex standpoint as pulmonary tuberculosis. The conditions which obscure the diagnostic importance of muscle spasm and degeneration may arise from various lesions in the mediastinum, bronchial, adenopathy, aneurysm, pericarditis, new growth, cardiac disease, emphysema, asthma, etc. Again it may be a residual of former inflammatory condition of the pleura or lungs. It may occur from irritation of the pneumogastric, sympathetic, phrenic, or spinal nerves from lesions not in connection with lung tissue at all, but occurring at or near the nerve origin. Differences in development, occupation, posture, habits, deformities, age, nutrition, and certain diseases also obscure the picture. Rheumatic affections of the shoulder joint, particularly in the one known as arthritic neuritis with circumflex disturbance, result in marked changes in the tone and feeling of muscles in this region. Therefore, it must be concluded that muscle spasm and degeneration as a sign of pulmonary tuberculosis is to be interpreted only with extreme care and is of but suggestive value in a case of real doubt. From a diagnostic standpoint as to the presence of intrathoracic disease, muscle spasm and degeneration is as definite a sign of those processes as a similar phenomenon in the abdomen. In the hands of the expert clinician the muscle changes over the thorax give reliable information that inflammatory changes or pathological processes are to be found in the thorax, provided there is nothing in the peculiarities of the individual which could otherwise satisfactorily account for the signs. For accurately localizing the lesion in the lung or thorax these signs are of very variable significance.

9. The Value of Meteorism or Tympany in Peritonitis. Budd Van Sweringen.

2. The Relation of Pregnancy to Certain Conditions of the Digestive Organs.—A. L. Benedict thinks that the vague digestive disturbance known as morning sickness, in its most typical form, is probably a reflex motor phenomenon, due to the accumulation of saliva and mucus, there being no ischochymia, continuous secretion of true gastric juice containing hydrochloric acid by an empty stomach or evidence of fermentation. True hyperemesis gravidarum is obviously a gastric reflex rather than a genuine digestive disturbance. Yet lavage may be effective just as it sometimes is in obstinate singultus, by inducing local fatigue, mental impression, etc. The author discusses the mechanical features of pregnancy, especially with reference to enteroptosis, and says that none of the ptoses seems to depend materially upon uterine ptoses, including prolapse, procidentia, flexions, and versions. But this admission does not imply a disbelief in the harmful effects of pelvic displacements due to perineal defects or other conditions. The portal circulation is impeded, congestion tends to cause faults of secretion and absorption, hence fermentation and putrefaction tend to occur in excessive degree; colon bacillus virulence plays a large rôle in gallstones and pancreatic disease, while indol has been shown experimentally to cause hepatic sclerosis. While the relation of lacerated perineum to alimentary cancers, ulcers, achylias, etc., is far fetched, it may, nevertheless, be genuine. The author concludes with an appeal for immediate repair of the perineum whenever possible, and for secondary repair as soon as possible, certainly before marked atrophy has taken place.

7. The Use of Mixed Infection Vaccines in the Treatment of Myalgia and Arthritis.—R. E. Brenneman says that the term rheumatism has deservedly fallen into disfavor. The bacterial theory of the etiology of disease has led to a recognition of the true cause or causes of so-called rheumatism. The author emphasizes the desirability of a correct differentiation of the causes and seat of bodily pain, of making a correct diagnosis and then of using a definite and correct onomatology. A muscular pain should be called a myalgia and should be named so as to determine its location. If a joint is affected arthritis is the term to be employed. The term rheumatism is redundant, unnecessary, and unscientific. Schafer's theories appear probable, rational, and scientific. Of the value of serum therapy and vaccine therapy in proper cases there is little dispute. There are many different bacteria concerned in the causation of certain infective diseases and it therefore seems reasonable to use a vaccine composed of various strains of bacteria. He has, therefore, used such a vaccine in 11 cases—9 of arthritis, 1 of puerperal sepsis, and 1 of pneumonia. Great relief followed the vaccine treatment in all the cases of arthritis. The result in the case of puerperal sepsis was marked and very suggestive. In the case of pneumonia, it seemed from a study of the chart that after the first fall in the temperature, the subsequent injections held the disease in check and hastened the crises in the subsequently involved lobes.

7. Spinal Analgesia.—William Seaman Bainbridge

reviews the history of spinal analgesia and enumerates three general classes of solutions employed. First, the so-called "diffusible" solution employed by Babcock, in which alcohol is used to render the fluid lighter than the cerebrospinal fluid. To the second class belong the simple solutions of the analgesic agent with water, with water plus the cerebrospinal fluid, with cerebrospinal fluid alone, or with normal salt solution. To the third class belong the so-called "non-diffusible" solutions, which are rendered heavier than the cerebrospinal fluid by the addition of glucose, dextrine, or gum arabic. In 988 cases solutions of the second class were used, and in 500 of these cocaine was used. He now uses stovain or tropacocaine, but does not hesitate to employ cocaine. In the whole series there was one death probably due to "status lymphaticus." One case of temporary partial paralysis occurred, one of failure due to so-called dry spine, two cases with alypin in which there was considerable respiratory depression, and one where failure was apparently due to idiosyncrasy. The author reports illustrative cases in which the three different solutions were employed, and describes the apparatus, and the technique of administration. From the facts known it may be deduced in a general way that the indications for spinal analgesia are the contraindications for inhalation anasthesia. A person in marked shock or profoundly septic condition should not be subjected to this procedure. The real objections to the method are: (1) The operator is absolutely committed to the dose, whatever it may be. It can be increased by another injection, but it cannot be decreased. With the changes in the position of the patient, and with carefully graded dosage, control can be exercised. (2) In prolonged operations the analgesic effect may pass off before the operation is completed. In some cases, as in laparotomy, it is quite inconvenient to turn the patient over for another injection. This is not a procedure for the surgical novice and must continue to occupy a somewhat limited sphere until we know more of the physiological action of the agents employed and of the dosage required in order to obtain the desired results.

16. **The Reciprocal Influence of Morbid Conditions of the Mouth, Jaws, and General Economy.**—M. L. Shamberg emphasizes the influence of the unhygienic mouth as an etiological factor in systemic disease. The tongue has always served as a barometer of the physical condition of the patient but far too frequently the inspection of the mouth ends with the tongue. It is really unusual for physicians to make careful observations of the mouth as a whole, to determine the presence of lesions on the mucous surface of the cheeks, the floor of the mouth beneath the tongue, the palate, the gingival margins of the gums, or the roof and floor of the vestibule of the mouth. These parts give even greater information at times than do the tongue and lips. The influence of the mouth and jaws on the general economy and likewise the influence of the general economy on the condition of the mouth have not received the attention that they deserve. According to a list prepared by Edward H. Baker, 125 different affections have been traced by scientific men to dental and mouth disorders. The bearing that the mouth has on the general organism is governed by its ability to perform its normal function in preparing the food to be introduced into the system. A failure in any measure to live up to its contract in this particular is accompanied by disturbances further on in the process of digestion. Many reflex disturbances are also due to maxillary or dental abnormalities. The author promises to supplement this communication with one that will be more clinical in its nature.

17. **Temporary Toxic Amaurosis and Paralysis Following Injection of Ethyl Alcohol into a Chronic Empyema Sinus.**—Louis Friedman reports a rather unusual case of temporary paralysis and amaurosis following the injection of ethyl alcohol into an empyema sinus. The patient had received previous injections of 95 per cent. alcohol without untoward symptoms, but suddenly after one of the injections became limp and unconscious for a few seconds, both upper and lower extremities being paralyzed. Loss of vision was complete but cutaneous sensation was present. The patient's mind was clear, speech was normal, there was no cyanosis, the pupil reaction was normal to light, and the knee jerks were exaggerated. Motion slowly returned and the paralysis disappeared entirely in half an hour. The vision slowly improved and was perfect in about three days. Friedman has been unable to find any record of pure ethyl alcohol amaurosis.

2. **Motor and Speech Paralysis Due to Cerebral Angiospasm.**—William Russell calls attention to the fact that this spasm lead to a constriction of the lumen of the blood vessels and may be sufficiently pronounced to practically obliterate the lumen. The degree of spasm therefore determines the measure of the anemia of the affected area, and this again determines the intensity of clinical phenomena, whether it be complete or partial loss of motor power, or of sensibility; while the portion of the brain affected determines the character of the phenomena, whether motor, sensory, or mental. As the spasm tends to be temporary and evanescent so the phenomena resulting tend to be evanescent. It is the anemia which is the cause of the phenomena, not the vessel spasm *ipso facto*. The causes of the spasm may be heat, cold, or nerve influences. In addition there seems to be no doubt clinically that waste substances retained in the blood act thus upon the blood vessel wall, causing paralyzing action on the muscle tissue of the wall. The two factors to be kept in mind in dealing with the individual case are: (1) the probable condition of the blood vessels, and (2) the driving power of the left ventricle. The anemia may be determined by atheroma or obliterative endarteritis associated with a feeble heart. Russell cites an illustrative case and shows how important it is to understand the condition and to treat it by stimulation rather than to regard it as a case of high blood pressure with threatening hemorrhage and to use relaxing and depressant treatment. He calls attention to the association of migraine and temporary paralysis which has been credited to a temporary anemia. The association of motor paralysis and aphasia is the commonest type and forms the largest groups of cases. The group illustrates angiospasm in cerebral vessels affected by either angiospasm or obliterative endarteritis. He then considers transitory hemoparesis, citing several illustrative cases which support his contention that these temporary paralyses have an evanescent cause and that the only reasonable explanation is the one he has offered. The site of the angiospasm is very frequently in the great motor pathway, in or above the internal capsule. A historical sketch of the subject is given which the writer thinks supports his contentions by showing that others offered the same explanation of the phenomena as he has offered. He expresses the hope that the practical importance of the subject will be recognized and that at some future time he may deal with its more speculative aspects.

3. **On the Respiratory Neuroses.**—Samuel West points out the difference between ordinary quiet breathing and deep or forced breathing. When told to take a deep breath the movements are entirely altered, cease to be abdominal, and become entirely costal; in other words, the automatic center is inhibited and the control taken over for the time being by the voluntary centers. The neuroses of the respiratory organs fall into two groups, according as they are, or are not, associated with, or lead to, dyspnea and its consequences, viz., cyanosis and suffocation. In the first group those with dyspnea and cyanosis are found asthma, laryngismus stridulus and other laryngeal spasms, and whooping cough. In the second group, in which there is no interference with the aeration of the blood and consequently no cyanosis or suffocation, are found paroxysmal tachypnea, the air hunger of diabetes mellitus and the allied condition in uremia, and in the third are found grouped respiration and Cheyne-Stokes breathing. A consideration of the respiratory neuroses in each of these conditions leads to the same conclusion, namely, that it is not the respiratory center in the medulla that is at fault, but some higher coördinating centers possibly in close relation with the other centers of volitional action, and therefore, presumably, in the cortex of the brain. In this connection the physiological considerations set forth in the article are of importance. It is obvious that a view of this kind is likely to modify considerably the lines of treatment to be adopted.

1. An Address on the Duties of the State in Regard to Tuberculosis. Arthur Ransome.
2. Tuberculosis in General Practice. J. A. Gibb.
3. Reflections on the Importance of Toxin Saturation of Tissues. Edward E. Prest.

1. **Duties of the State in Regard to Tuberculosis.**—Arthur Ransome does not think that the State should undertake the treatment of disease. It should rather turn its attention in the direction of prevention. The result of other enterprises undertaken by the State do not hold out any promise that State officials could succeed in the treatment of tuberculosis as well as do at present the several voluntary agencies. A report of the Poor Law Commission, which concludes with the statement that "from first to last the outdoor medical service of the Poor Law has no conception of the public health point of view," is evidence of this statement. Much the same conclusions are reached when the indoor treatment of paupers by the State is considered. The case is entirely different with regard to the public health service. No fault can be found with the work of its officials and this is because the State here is attending to its legitimate business, not the cure, but the prevention of disease. He then proceeds to show that the plans set forth under the Insurance Act for the care of tuberculosis are equally destined to fail, and that it is important that the subject be seriously dealt with by medical critics before the funds assigned for the purpose are in the process of being squandered. The duties of the State in regard to prevention are three: 1. It can take practical measures to abolish the bacillus. 2. It can improve the physical condition of the people so as to diminish their susceptibility to the disease. 3. Most important of all, it can so amend the favorite haunts of the disease as to destroy its power for evil. As to the first, many measures have been suggested, such as compulsory notification, penalizing spitting, gratuitous examination of sputum, disinfection of dwellings, clothing, etc. All of these measures may be more or less useful, but at best can only remove some of the sources of infection, leaving others still untouched. The problem of lessening the susceptibility to infection can be solved by solving the third proposition, by abolishing the haunts of the bacillus. This can be done by the provision of healthy homes, by proper drainage and water supply, by better provision for ventilation, doing away with courts and blind alleys, by limiting the height of buildings, by mitigating the pollution of the air as far as possible. Attention must be directed not only to the ventilation of schools, but to that of all public resorts. The State would also be within the scope of its legitimate action, Ransome maintains, if it provided for the dangerous cases of open tuberculosis, if it subsidized homes for the dying and tuberculosis dispensaries, and if it assisted in the formation of herds of cattle free from disease.

3. **Importance of Toxic Saturation of Tissues Considered in Relation to the Treatment of Pulmonary Tuberculosis.**—Edward E. Prest says that where a tuberculous infection shows such a degree of activity, or the body tissues as a whole yield an insufficient amount of antibody, then the healthy tissues arrive at a condition which he calls toxin saturation; no antibody can be produced, and the toxin circulating the system will assist the activity of the bacilli, the disease will spread rapidly, and death speedily follow, unless means are at once taken to counteract this condition, and produce once more a condition of hyposaturation. Such a state of affairs does not occur in tuberculosis attacking relatively immobile tissue. From this it follows that means of determining the condition of the tissues with reference to saturation by toxin will be of enormous importance. The most important method is an accurate record of the temperature taken in the rectum; the patient should be kept in bed for this purpose. If it is found that the temperature taken before rising in the morning is above 97.7° F. the tissues are approaching a condition of toxic saturation; or, if the temperature during the day, when the patient is at rest in bed, rises higher than 99.4° F., the same conclusion may be arrived at. In cases where the disease is only slightly active, where almost all the toxin is neutralized by the tissues at the seat of the disease, although the temperature may almost constantly deviate from the normal, yet the remaining tissues of the body may be considerably removed from saturation by toxin. The symptoms of saturation are the classical symptoms of pulmonary tuberculosis. A temperature such as the above indicates that the balance has been restored, but gives no indication of the capacity of the tissues to deal with the toxin. If a little exercise on the previous day causes a rise in the morning temperature the tissues are nearly saturated; if considerable exercise does not affect the temperature, it follows that there is no approximation to tissue saturation. The degree of saturation may also be determined by the administration of tuberculin. If a small dose causes a rise in temperature in a case where the temperature was previously normal, it may be assumed that tissue saturation is nearly complete. If the patient be near toxin saturation, the activated tuberculin, even if the dose be small, may stir up tuberculous foci. In the treatment of pulmonary tuberculosis by tuberculin, one may begin with small doses if the rectal temperature is as stated above, and exercise does not cause a rise in temperature; in cases commencing with hemoptysis without previous symptoms; in the so-called early cases which are slightly febrile, after rest in bed and sanatorium treatment until the temperatures become normal; in cases of considerable duration where, owing to fibrosis and highly resistant tissues, toxic saturation is not complete; in cases with extensive disease where a considerable degree of toxic tolerance had been produced. In cases exhibiting a large amount of caseous disease small doses may be given and repeated at intervals of at least a week in order to avoid ulceration of large masses of diseased tissue. The prevention of toxic saturation in early cases, Prest says, is of paramount importance.

The Great Epidemic of Typhus in Napoleon's Russian Campaign.—The outbreak of typhus in the present Balkan-Turkish campaign naturally arouses interest as to the possibility of duplicating some of the great epidemics of past wars. At a recent session of the Berlin Society for Social Medicine, Hygiene and Statistics Prinzing gave a brief retrospect of the epidemic of 1813 in which Napoleon's defeated troops and allies scattered the pestilence through Western Europe. The Russian army alone lost 62,000 men and of the 30,000 or more French prisoners nearly all but ten per cent. died of typhus or exposure. The Jews of Wilna and vicinity lost by death over sixty thousand. The disease soon reached Prussia, destroyed eight thousand in Danzig, and nearly as many in and around the metropolis. As the war continued about Leipzig and Dresden the pestilence followed and the French losses are placed at 80,000 (whether those of the Russian campaign are herein included does not appear). The continuance of the campaign into 1814 was responsible for further ravages of the German states, so that when all was over Prussia alone had lost 200,000 inhabitants in the two years. The malady was at that time but little known, as its autonomy was first recognized in 1810. It was not even known whether isolation would be of service or the reverse. As comment on the preceding one might mention the possible effects of typhus in thwarting the ambitions of Napoleon were it not for the fact that his antagonists suffered equally in this respect. In the Franco-Prussian war the poorly vaccinated French lost 200,000 people from smallpox, while the well-vaccinated Germans largely escaped. The influence of a pestilence in a war will depend entirely on whether one, both or neither army has the ability and willingness to profit by the latest discoveries in sanitary science.

Metastatic Cancer of the Skin.—Askanazy discusses especially the relationship of these growths to the cutaneous nerves. The problem is a new one, for the author knows of no antecedent finds. The primary cancer was seated in the breast and was not highly malignant, being an example clinically of so-called Reclus's disease. Not until affected by some severe constitutional symptoms did patient seek medical aid. The breast was amputated, but patient survived but a few months, dying of cachexia. From the outset she had presented some cutaneous nodules which appeared in crops with disturbance of sensation. These lesions were well disseminated over the entire surface with exception of the extremities. The average size was that of a pea. In certain regions the lesions were grouped and there was no bilateral symmetry. The patient could predict through the sensory disturbances when and where a new nodule was to come, this declaration being frequently corroborated by the author. The diagnosis lay between cancer metastases and a primary cancerous dermatosis. Trial excision left no doubt as to the cancerous nature of the formations. Autopsy showed local recurrence of cancer in the breast and innumerable visceral metastases. The case being therefore one of extreme carcinosis, the other feature of interest was the peculiar implication of the sensory nerves. Elaborate histologic study left no doubt that the skin metatasis was not of the common kind but had actually occurred in the cutaneous nerves.

Severe Cerebral Symptoms in Consumptives Without Anatomical Finds.—Querner describes two such cases. The first was in a male aged 20 without familial taint who had recently begun to cough and emaciate. He was an alcoholic. The chest showed movements of normal excursion limits, but there were evidences of apical and laryngeal disease and tubercle bacilli in the sputum. The other viscera were intact. Temperature rose at times to 39° or 40° C. The cerebral symptoms began with frightful dreams followed by confusion. Kernig's sign appeared and persisted, but all other evidences of meningitis, including results of lumbal punction, were negative. Mental state attended off and on by confusion and hallucinations. Death evidently resulted from exhaustion. Up to the last tuberculous meningitis could be excluded, although a meningeal syndrome had been suggested. Autopsy revealed, in addition to the ordinary local tuberculous finds, degeneration of the myocardium. The author saw another case with meningitic-paralytic symptoms, which upon autopsy presented no serious endocranial lesions. There had been a doubtfully positive Wassermann reaction. The author finds cases parallel to his own in recent French literature, ascribed to the action of tuberculous toxins and termed "encephalopathie tuberculineuse."

Cinchona Alkaloids and Corneal Anesthesia.—Morgenroth and Ginsberg describe the anesthesia of the cornea produced by quinine, hydroquinine, and ethylhydrocuprein. All of these cause total anesthesia of the rabbit's cornea. The solvent was water and also for the last named synthetic olive oil. The salts used were chiefly the chlorides. While quinine is but slightly soluble in water, the other two are so freely soluble that highly concentrated solutions are readily prepared. Twenty per cent. solutions produce an extremely protracted anesthetic effect perceptible for more than a week. But these substances will hardly come into practical use because of the discovery that solutions stronger than 2.5 per cent. have been seen to cause corneal opacities. In some cases this is transitory. High concentration also causes chemosis and in general the irritant action will make these salts so unsafe that they will hardly be thought of seriously as corneal anesthetics.

Münchener medizinische Wochenschrift.

November 12, 1912.

Acute Alcoholic Amblyopia.—Kaiser reports a case of this rare affection which from its very nature must always at first cause a suspicion of accidental wood alcohol poisoning. Patient, who was aged 53, had consumed enough spirits to produce delirium and hallucinations, with tremor. His visual hallucinations were, however, peculiar in that they showed some defect of perception. White, blinding snow appeared dark and dirty, and when looking on plain white paper he saw colors and objects. When he had slept off his cerebral symptoms he developed polyneuritis, while his visual perceptions still remained abnormal. Neuritis optica could readily be excluded. The patient had drunk up nearly four marks' worth of spirits, so that all his symptoms had been acute; however, he contradicted himself several times as to his consumption of liquor and probably did not know himself what he had taken. He remembered than everything had grown dark to his vision save for flashes of light, like fireworks. The visual field was now tested and found to be strongly contracted concentrically without central scotoma. It gradually improved and attained a limit for white, but was still improving for colors. At this juncture for some unexplained reason the delirium and hallucinations returned to some extent, but again subsided. The condition was markedly unlike chronic alcoholic amblyopia in which central scotoma is present. Some of the grain spirits which the patient consumed was tested for wood alcohol with negative result. The author regards the condition as due to sudden damage of the opticus fibers by drinking a very large amount of spirits within a short time. Visual acuity was not permanently affected and the prognosis for ultimate recovery for color perception is good.

Rare Cutaneous Manifestation in Renal Insufficiency.—Portig relates the case of a woman aged 41 who had begun to show a syndrome comprising nausea and vomit-

ing, diarrhea, anorexia, and violent headache with later anxious states and confusion, and eventually apathy. Physical examination revealed very little outside of the vascular system and urine. There was some angiosclerosis and cardiac enlargement and albuminuria with cylinders. The urine was also reduced in bulk. Venesection was practised for impending uremia. The cutaneous phenomenon which bore directly upon the defective excretion of urine consisted of a sort of sudamina on the face associated with hyperidrosis. The skin looked as if sprinkled with snowflakes. This appearance was evidently due to the formation of crystals, a so-called crystalline desquamation. This was found to be urea. There could be no doubt that the latter had actually escaped by means of the perspiration. The case illustrates the wisdom and necessity of stimulating the flow of the latter in threatened uremia.

Deutsche medizinische Wochenschrift.

November 12, 1912.

A Combination Therapy of Pernicious Anemia.—Brieger states that in association with Trebing he had made the discovery that in many cases of cancer, both operated and non-operated, he, by giving pancreatin inwardly, had brought down the previously high antitryptic index to normal, while there was a corresponding improvement in appetite, general condition and weight. But in some cancerous patients pancreatin had the opposite results and increased the index. At that time it was suggested that for tuberculosis one might combine a pancreatin cure with a tuberculin cure. During the past three years the author has also sought to treat pernicious anemia with a combination of pancreatin and arsenic, and A. Pinkuss has recently mentioned Brieger's work in this direction. The arsenic is given as Fowler's solution, two drops thrice daily, to be increased and then diminished in the usual fashion. The pancreatin was given three times daily before meals, as much as could be taken up on a knife blade. The author cites in detail three cases of pernicious anemia thus treated; all improved notably. One patient has been under the treatment three full years and is still alive. Cures for this malignant affection are not claimed, but the lives of the two other patients were undoubtedly prolonged. The author believes that pancreatin is a catalysator which should enjoy a larger field in internal therapeutics.

Döhle's Leucocyte Inclusions in Scarlatina.—Kretschmer publishes the following conclusions concerning these formations: They are present in all recent cases of scarlatina, and are to be found but seldom in other affections with exception of diphtheria and sepsis in which they occur with some frequency. Their presence possesses considerable diagnostic significance in scarlatina because they do not occur to any extent in the conditions which resemble the latter. They are in no sense causes or inciters of the disease, and since they are not specific doubtlass represent only a reaction-product of the leucocytes to the disease toxins.

Dissemination of Diphtheria and Lepra by Means of the Feces.—Delbanco cites a number of recent publications involving the transmissibility of certain diseases. It has recently been stated that the urine in diphtheria usually contains virulent bacteria and should always be disinfected. The author, with Haas, published recently an article on anal diphtheria, which localization, with the known entrance of bacteria from the throat, etc., into the feces, makes it imperative to disinfect these excreta as well. In this connection should be mentioned the numerous finds of lepra bacilli in the feces of lepers and to a less extent in the urine. Arning, Babes, Boeck and other leprologists have seen them in the feces. Boeck thinks the immunity of large cities to lepra may be in part due to the fact that in such centers the feces are practically destroyed. He is not certain that the future will not recognize the fecal route as the principal one in the spread of lepra. If the so-called rat leprosy should prove to be the actual disease it would doubtless be connected with the consumption by these animals of human excrement.

The Blood in Pulmonary Tuberculosis.—P. Masenti and M. Borgogno note that the cellular elements of the blood do not furnish any diagnostic criteria in tuberculosis. On the other hand, from the prognostic viewpoint, one may attach a favorable significance to a relative neutrophile polynucleosis and to a marked diminution in the number of eosinophiles and lymphocytes.—*La Riforma Medica.*

The Irritability of the Sympathetic Nervous System.—F. Boschan states that Loewi has shown that one may obtain an idea of the condition of the sympathetic nervous system in a human being by introducing a drop of a one per cent. solution of adrenalin into the conjunctival sac. In normal individuals there does not result any dilatation of the pupil. This, however, does take place in certain cases of diabetes and Graves' disease. The adrenalin mydriasis occurs only when the irritability of the sympathetic is abnormally raised. Boschan investigated this reaction in 170 cases, including healthy and sick infants. The reaction was negative in the healthy newborn, in healthy infants of various ages, in the premature, in cases of chronic nutritional disturbances, in chronic infection, in acute digestive disturbances that are not accompanied by constitutional symptoms, and in acute infections without toxic symptoms. The reaction was positive in moribund infants, in cases of enteritis accompanied by toxic symptoms, in all acute infections with toxic manifestations, and in a few chronic diseases. There is apparently a close relationship between toxic ailments on the one hand and the presence of Loewi's reaction on the other, and since in these cases there is an increased susceptibility to cocain, it is concluded that the pupillary reaction indicates an increased irritability of the sympathetic nervous system as the result of toxic conditions. The adrenalin mydriasis has no diagnostic significance. Its presence indicates always that a toxic condition is getting worse, while the disappearance of this reaction corresponds to an improvement in the clinical picture.—*Monatsschrift für Kinderheilkunde.*

Physiological Influence of Ovarian Secretion.—A. L. McIlroy states that the ovary controls the nutrition of the uterus and other reproductive organs, since removal of both ovaries causes atrophy of the muscular and glandular elements of the uterus, etc., the degree of atrophy being in direct proportion to the length of time which has elapsed since the operation. There is also a diminution in the uterine blood-vessels, and a tendency to atheroma—a condition very closely allied to fibrosis of the uterus in the human subject. Menstruation and œstrus do not occur after complete removal of both ovaries. In young animals after oöphorectomy the infantile type is maintained. Removal of the uterus, or retention of uterine secretion, does not affect the functional development of the ovaries, seeing that the elements of the ovary are well preserved after hysterectomy and ligation of the uterine horns. Retained uterine fluid does not counteract the atrophy of the uterus which takes place after removal of both ovaries. There is thinning out of the uterine wall at the point of greatest distension, and no compensatory hypertrophy has been observed. Removal of one ovary causes compensatory hypertrophy of the other in the ancestrous state. That the interstitial cells perform the chief rôle in the maintenance of the nutrition of the uterus is evidenced by (*a*) the survival of these cells in grafted ovaries, (*b*) the follicles becoming absorbed or cystic, and (*c*) the fact that no atrophy of the uterus occurs when these cells are present. The interstitial cells become functionally active during pro-œstrum, as shown by their being enlarged and their cytoplasm becoming infiltrated with a lipoid substance (in female dog). That the corpus luteum is the part of the ovary which exerts the most active influence upon the body as a whole is shown by the fact that corpus luteum extract when injected causes rise of the general blood-pressure. From the result of one experiment it was found that the ovaries do not play such an important part in the elimination of calcium as is supposed, since after castration the calcium output was increased, whereas it was diminished as the result of administration of corpus luteum extract. Removal of the ovaries in rabbits causes an increased deposit of fat in the tissues of the body.—*Proceedings of the Royal Society of Medicine.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

FRAUDULENT PRACTICES.

The possibility of fraud and deception should be constantly kept in mind, as it is not uncommon to meet with some of the following practices:

Fraud Practised by the Applicant.—The fraudulent practices discussed in the following paragraphs are those usually originating with the applicant:

Age.—The age is understated at times by applicants in order to derive the benefit of a lower premium. Insuring a considerable number of risks for premiums computed for younger ages will involve an unwarranted loss to a life insurance company, as the premium for each life is based on the Experience Table of Mortality. If the examiner doubts the accuracy of the given age he should communicate this fact to the home office. It must not be forgotten, however, that if several men were commissioned to judge the age of a certain individual, there would almost always be a difference of several years between the highest and the lowest estimates. An examiner might, therefore, do an injustice to an applicant were he to report a discrepancy between the given and the apparent ages unless it amounts to at least five years.

Suppression and Distortion of Facts.—Suppression, as well as distortion, of facts constitutes misrepresentation, as every application for life insurance calls for a declaration in some form from the applicant that he has disclosed full and accurate information in regard to his personal and family history. According to law an undue concealment or nondisclosure of facts and circumstances which one party is under legal or equitable obligation to communicate, and which the other party has a right to know, establishes a misrepresentation or breach of warranty and will give sufficient grounds to a company to cancel the policy provided the delinquency is important enough and is discovered within a reasonable length of time after the date of issuance, a period which may be generally stated as two years. When, then, there is the slightest doubt as to the veracity of an applicant, the examiner will do a good deed to him as well as the company by intimating the extent of the possible penalty in diplomatic but unmistakable terms.

Concealment of Physical Defects.—Dishonest applicants, assisted at times by corrupt agents, display considerable inventive skill in preventing the discovery of physical impairments by the examiners. Examples of these attempts are innumerable in the history of life insurance. Space forbids a description of all of them even if it were possible. A few of the instances which have come to the writer's notice may serve as illustrations of the importance of close scrutiny in every examination.

An application was recently received in which the applicant had persisted in remaining in a sitting position during the examination, his excuse being a badly fitting shoe hurting his foot. The suspicions of the home office officials were aroused by a report from another source, and the examiner, being requested to re-investigate, had to admit with chagrin that he had been fooled by a subject with spinal disease. If this examiner had taken the precaution of without exception observing the gait, as he should do in every case, he would have saved himself considerable mortification.

In another recent case, a well-trained examiner had occasion to confess himself tricked by an applicant who vigorously chewed gum to hide the evidence of facial paralysis.

A chronic axillary abscess, which had not been acknowledged during the questioning, nearly escaped detection. The applicant was a clergyman and his statements would have been accepted without hesitation by the majority of examiners. Unfortunately for him, however, the examiner who had charge was a very cautious and inquisitive individual who insisted on making the examination with a completely bared chest, and this led to the discovery of the abscess.

Fraud Practised by the Applicant and Agent.—The agent and applicant have been discovered in league, the former having coached the latter to conceal certain facts or set them forth in a misleading way.

In other cases, the agent succeeds in getting possession of an adverse report from an examiner which should have been sent to the home office. The agent then takes the applicant to another examiner with the hope that he will not discover the defect or will be complacent enough to overlook it. If such a report is surrendered to the agent, notwithstanding the fact that such a procedure is both ill-advised and dangerous, the examiner should at once immediately notify the home office of the name and date of birth of the applicant and the impairment, so that the fraud may be prevented.

Substitution is difficult but is attempted at times. It is especially easy for this practice to be followed among the many undesirable aliens who are swarming into the United States. Two conspiracies of considerable magnitude have come into the writer's experience and both happened among that class of people. The practice of substitution is not, however, always confined to members of this low grade of society. It, therefore, behooves the examiner to keep his eyes open and report any suspicious circumstances to the home office.

Fraud Practised by the Agent.—The agent may attempt to exert an evil influence on the examiner by requesting or even demanding him to modify or omit some adverse statement from the report. At other times, the agent will try to prevent the carrying out a part of or even the entire physical examination. No examiner worthy of the name would submit to such overtures, but it is wise to remember these injunctions, as some of the unscrupulous agents are most plausible and persistent in their arguments.

The agent or any other person should never be permitted to procure the urine from the applicant, no matter how much trust and confidence the examiner has in those individuals.

An agent will sometimes change the report after it has left the hands of the examiner. It is a good rule, even when the agent is trusted and honest, to invariably send the report directly to the local manager or home office.

Fraud Practised by the Examiner.—To the credit of the profession it may be asserted that bribery and collusion are rare occurrences among medical examiners. Such practices have happened, however, sufficiently often to bring about the enactment of laws in some of the states for shielding the companies against fraudulent conduct on the

part of the examining physicians, whereby the wilful making of a fraudulent statement in an application for life insurance is made a misdemeanor punishable by fine or imprisonment.

Fraud Practised by Policyholders.—This does not concern the medical examiner directly, and reference to the crimes perpetrated by policyholders for defrauding life insurance companies is made only as a matter of interest. Suicide by persons who wish to provide for their families at once is practically prevented by the insertion of a clause in the application, which provides that suicide within a certain time after the issuance of the policy shall not make the policy a claim against the company, whether the suicide was sane or insane. Murder of a person insured in favor of the murderer is another means of fraud. Mysterious disappearance, usually arranged to present the probability of suicide, is the most successful and common form of crime adopted for this purpose, but as the companies must be on their guard under suspicious circumstances, such schemes are usually foiled.

The Insurability of Women.—T. Hewson Bradford embodies in this article some of the facts contained in a paper on this subject read before the American Association of Medical Examiners with the addition of the effects of major operations viewed in the light of the experience of some well-known surgeons and gynecologists, as well as of several medical directors of insurance companies. With experience and a more thorough knowledge of statistics many of the objections to insuring women have been modified and others entirely eradicated. Statistics have proved that the majority of sudden deaths from internal or pathological causes occur in men, and the greater tenacity of life in women makes it seem remarkable that companies should ever have refrained from accepting women as risks. Thrift, forethought, economy, and prudence in the management of details have been characteristics of women and the introduction of them as risks in insurance companies conduces to confirm and strengthen these qualities and fosters true motherhood in securing to their progeny the means to avoid care and trials. Environment as a factor in life insurance is for most women more healthful, comfortable, and sanitary than for men; as a class womankind is less exposed to dangers and accidents, is more sheltered, and less exposed to the temptations of life. Should woman be physically affected by a life of dissipation she never has enough money to keep her policy up. Pneumonia is much more prevalent and fatal among men than among women, and the same is true of typhoid fever. It is a fact, especially after the age of fifty years, that nephritic and vesical diseases are more prevalent among men. Pregnancy and parturition are no longer looked upon as pathological conditions, but are recognized as physiological events. One per cent. is the mortality in parturition in cases well cared for. Puberty and the menopause are only serious periods because the fundamental laws of Nature are not strictly observed. Education as to the avoidance of the ills incident to these periods is being rapidly disseminated. In the examination of women for life insurance the interrogations should be most explicit. Great stress should be laid on the possible existence of any pelvic disorder, characterized by pain over the fundus or ovarian regions, the existence of leucorrhea, or tendency to amenorrhea, dysmenorrhea, and metrorrhagia. All clothing which interferes with careful auscultation and percussion of the chest should be removed and a thorough examination of the apices should be made. Likewise over the abdomen the examination must not be made through a gauze undershirt. Many a case of latent appendicitis can be detected by the existence of tenderness and induration over McBurney's point, and by external palpation, the presence of uterine fibroids may be detected. It is absolutely necessary that a vaginal examination be made. In risks when conditions are detected by interrogations, such an examination should be insisted upon, for only thus can a salpingitis, pyosalpinx, fibroids, or a beginning malignant growth be diagnosticated. The day is not far distant when the examination blanks of insurance companies will contain a clause requiring this vaginal examination. A fruitful source of many ills so prevalent in the female sex are the methods and practices employed to prevent conception; these practices may be responsible for melancholia, chronic invalidism, chronic oophoritis, and salpingitis. With a history of miscarriage or abortion a risk should not be accepted until a living child is born at term. A widow whose husband has died of tuberculosis should not be accepted until two years after his death. Cancer as a hereditary factor must be closely investigated in women risks as this disease is far more transmissible in women than in men. Care should be exercised to guard against fraud in the substitution of urine. In the book of instructions issued by the Philadelphia Life Insurance Company it is stated that the company does not desire to insure women recently married, engaged to be married, pregnant, or approaching the change of life. In regard to the major operations on the pelvic organs the experience of prominent surgeons has been asked regarding the prognosis of hysterectomy in cases of fibroids, pyosalpinx, hydrosalpinx, and other causes with the exception of malignancy. Replies had been received from Howard Kelly, Barton Cooke Hirst, John Montgomery Baldy, E. E. Montgomery, W. Esterly Ashton, George M. Boyd, John B. Deaver, John G. Clark, Harry Toulmin, and Charles H. Willitts. These replies are printed and show a unanimity of opinion to the effect that major operations, if there is no history of tuberculosis or suspicion of malignancy, can have no effect upon the assurability, if sufficient time is allowed to elapse after the operation; in cases of appendectomy, salpingectomy, and ovariotomy, six months; for supravaginal hysterectomy, two years. By allowing two years to elapse the artificia menopause has been thoroughly established. If a rigid physical examination and a careful investigation on the line of moral hazard and insurable interest are made in all cases of female applicants, insurance companies cannot err in accepting women as risks.—*New York Medical Journal*, November 23, 1912.

Medical Officers of the State Mutual Life Assurance Company of Worcester.—At a meeting of the Board of Directors held on Tuesday, November 12, 1912, the following officers were unanimously elected: *Medical Director*, Dr. Homer Gage; *Assistant Medical Directors*, Dr. Charles D. Wheeler and Dr. Merrick Lincoln.

Association of Life Insurance Presidents.—The sixth annual meeting of this Association was held on Thursday and Friday of this week at the Hotel Astor, New York City.

Book Reviews.

Gonococcal Infections. By Major C. E. Pollock, Royal Army Medical Corps, and Major L. W. Harrison, Royal Army Medical Corps. London: Henry Frowde, Oxford University Press; Hodder & Stoughton, 1912.

In this compact manual of 222 pages there is given a concise account of the present knowledge of gonococcal infections. The subject is dealt with under the following headings: Introduction; pathology; vaccine and serum therapy; primary infections; treatment of gonorrhea in the male; complications in the male; gonococcal infections in the adult female; gonococcal ophthalmia; gonococcal vulvovaginitis of little girls, and gonococcal septicemia. The authors do not altogether concur in the teaching of the Vienna school that "every attack of gonorrhea is curable except the first." Nevertheless they find that the treatment of gonococcal infections is still far from satisfactory, and that no one knows yet how to cure a chronic gonorrhea. As regards the use of injections they state that these may be employed with benefit, even in acute cases, provided the solutions are not too strong or irritating. A full discussion is given to the subject of the vaccine treatment of gonorrhea. This method is not adapted for the acute stages of the disease but is eminently successful in the treatment of the complications, and particularly of gonorrheal arthritis. The critical valuation and comparison of the various methods of treatment of gonococcal infections serve to make this volume a most valuable addition to the literature of the subject.

Consumption in General Practice. By H. Hyslop Thomson, M.D., D.P.H. Price $5.50. London: Hodder & Stoughton, 1912.

This volume of 335 pages, while not containing anything new, is a fairly complete resumé of our present knowledge of diagnosis, prognosis and treatment of tuberculosis and its complications. The book is written by a man of large experience and intended for the general practitioner. In his chapter on diagnosis, the author takes into consideration the often neglected family and personal history, and the symptoms following acute illness and exposure to infection. In chapter IV entitled "Confirming Diagnosis," he emphasizes the importance of tuberculin tests. It is gratifying, however, to see that he rejects the ophthalmic test which should be replaced by what he calls the safer and more delicate cutireactions. In the same chapter he also recommends the tuberculoopsonic index as a means of diagnosis, which is much more in vogue in England than in this country. Lastly he pleads for the animal inoculation test. Of the *x*-rays he very justly says that, except in the hands of expert observers *x*-ray examination has a limited field in the diagnosis of pulmonary tuberculosis. His chapter on differential diagnosis is perhaps rather deficient. He does not say a word of the bronchial and pulmonary type of influenza which causes even the expert diagnostician so much difficulty to differentiate.

The chapter on prognosis deals with the well-known features. In it the author considers age, nationality, and occupation, but fails to mention the important item of temperament. In speaking of nationalities and their relation to prognosis of tuberculous diseases, he comes to the same conclusion regarding the alleged immunity of the Hebrews at which many American observers have arrived, namely, that there is none, or at least there is none any longer. He says, "The Jews have always been regarded as comparatively immune to tuberculosis, but the racial immunity is certainly becoming less evident among the Jewish population in England."

In the chapter on treatment, which Dr. Thomson divides into preventive, modern sanatorium, tuberculin, and symptomatic treatment, the portion on autoinoculation is perhaps the most interesting and is well worth a careful perusal. Paterson and Inman are quoted as authorities for the value of autoinoculation by manual labor controlled by the opsonic index. The concluding chapter on after-care, home-treatment, and sanatorium construction is also well worth perusing, having important bearings on the social aspect of tuberculosis.

The Therapy of Syphilis, Its Development and Present Position. By Dr. Paul Mulzer, of Berlin, with a preface by Prof. P. Uhlenhuth, Privy Councillor. Translated by A. Newbold. Price net $1.50. New York: Rebman Company, 1912.

After a short, scholarly preface by Prof. Uhlenhuth, the author describes the modern arsenical preparations, Atoxyl, Arsacetin (Ehrlich), Atoxylate of Mercury (Uhlenhuth), Hectine, Soamin, Arsenophenylglycin, and Salvarsan, which have been used in the treatment of spyhilis. The major portion of the book is devoted to Salvarsan, the technique of its preparation and administration, its effect upon the organism in general and upon syphilis in its different stages. His results and experiences are practically the same as those hitherto published by many other writers. With regard to the Wassermann reaction, he believes that its practical value is principally in differential diagnosis and that only repeatedly negative reactions extending over a fairly prolonged period can be accepted as evidence of cure. Poor and awkward translations mar the literary smoothness; for example, the careless translation of "Erreger" into "exciter." On page 111 appears the history of an unfortunate patient who "had to be fed with pharyngeal probes and nutrient enema." In describing a cutaneous eruption on page 175 the infiltrations were described as "varying in size from a crown to a five-crown piece." Forty of the two hundred and forty-eight pages are given over to index and literary references.

Pharmacology and Therapeutics for Students and Practitioners of Medicine. By Horatio C. Wood, Jr., M.D., Professor of Pharmacology and Therapeutics in the Medico-Chirurgical College, Physician to the Medico-Chirurgical Hospital, Second Vice-Chairman of the Committee of Revision of the U. S. Pharmacopeia. Philadelphia and London: J. B. Lippincott Company.

This is a new work. The title Pharmacology is used in place of the old Materia Medica, and includes the study of the physical and chemical properties of drugs, the changes produced in the normal functions by them, and their principal use in the treatment of disease. It is evident that instruction in Materia Medica is the main object of the book; the sections on Therapeutics are much briefer, and, with four exceptions, the various diseases which require treatment are not even mentioned in the index. Hence, as a work on Therapeutics for the busy practitioner the present book is of little or no use. The four conditions which form the exception referred to above are: Acute bronchitis, cough, heart disease, and malaria. Why these four are selected for such exception we do not know. Certainly very few physicians limit their practice to bronchitis, heart disease, and malaria. The chief use of the volume would seem to be that of a class book on Materia Medica for medical students, and it is quite possible that the author's classification will appeal to some teachers. The subjects treated in the volume are: Drugs used to affect secretion (diuretics, diaphoretics, expectorants, and drugs which diminish secretion); Drugs used to affect the nervous system (somnifacients, anesthetics, analgesics, spinal depressants, motor nerve paralyzants, and sensory nerve paralyzants); Drugs used to affect circulation (cardiac stimulants, vasomotor stimulants, and drugs which reduce blood-pressure); Drugs used to affect the alimentary tract (stomachics, emetics, and cathartics); Drugs affecting metabolic processes: Drugs acting on causes of disease (anthelmintics, antimalarials, and disinfectants); Extraneous remedies (digestants, alkalies, demulcents, emollients, counter-irritants, and escharotics); and drugs of minor importance.

Ueber die Behandlung der Gonorrhöe des Mannes. Von Prof. Dr. V. Klingmüller in Kiel. Preis 1 mark. Halle a. s.: Carl Marhold Verlagsbuchhandlung, 1912.

This brochure of six thousand words is replete with sound teaching. He regards internal medication as worthless, relies upon urethral germicides, and emphasizes proofs of cure before giving marriage consent.

Clinical Bacteriology and Hematology for Practitioners. By W. D'Este Emery, M.D., B.Sc., London Director of the Laboratories and Lecturer on Pathology and Bacteriology King's College Hospital, and Lecturer on General Pathology, London School of Medicine for Women; Formerly Hunterian Professor, Royal College of Surgeons. Fourth edition. Philadelphia: P. Blakiston's Son & Co., 1912.

The fourth edition of this well-known book differs but little from its predecessors. The chief point of difference is the addition of a description of the author's modification of the technique for the performance of the Wassermann reaction. The book is prepared especially for the practitioner who has had little or no training in bacteriology and hematology and who has no laboratory near him on which he may rely for aid. To this end it is admirably arranged and the matter well chosen. The fact that the present student receives better training along these lines does not detract from the value of this volume and it is evidently destined for a long and successful life.

Society Reports.

THE NEW YORK ACADEMY OF MEDICINE.

Regular Meeting, Held November 7, 1912.

Dr. L. Emmett Holt, Vice-President, in the Chair.

Dr. Jacobi Resigns as Trustee.—Dr. Jacobi said that he had resigned his trusteeship several times when it had not been accepted because there were a number of good men younger than he who should be broken into the work. He believed that he had done his work and that it was time to select a younger man.

Dr. Arthur M. Jacobus presented the following resolution, which was unanimously carried:

Resolved: That the resignation of Dr. Jacobi as Trustee of the New York Academy of Medicine, an office which he had filled as President of the Academy ex-officio and as trustee by election together since 1885, nearly twenty-eight years, with great ability and fidelity and with invaluable benefit to the Academy, be accepted with sincere regrets and the heartiest wishes for his good health and happiness in the future.

The Prevention of Trachoma in New York School Children.—Dr. Anna W. Williams read this paper. She stated that the investigations of the workers who had been studying trachoma and allied conditions in the Division of Laboratories of the New York Department of Health had been going on for about two years. When they began the work they found a great deal of vagueness in the literature in regard to the whole subject of trachoma. The most that could be said for their knowledge today was that their studies had opened up new and interesting aspects. A great deal of the confusion had arisen from the fact that no large series of cases had been under close observation for a long time. Such a series they had immediately started, keeping continuous charts by the folder system, and they had now under observation somewhere in the neighborhood of 2,000 cases. They soon found a few most interesting facts which were: 1. The finding of hemoglobiniphilic bacilli and the trachoma inclusions coincidently so frequently in their papillary trachoma cases. 2. The morphological similarity between these bacilli and the trachoma inclusions. 3. The inability to differentiate these bacilli from those found in acute conjunctivitis and in many subacute borderline cases. These facts led to the old conclusion that acute contagious conjunctivitis was merely the first stage of the chronic condition of hyperplastic inflammation known as trachoma; that in chronic cases on the one hand the bacilli were altered in virulence and, on the other hand, the patient, through neglect or other causes, had acquired a hypersusceptibility to this altered virulance. When they reached this conclusion they decided that the chief means of preventing trachoma was to treat more carefully than they had the acute cases as well as those diagnosed as trachoma and borderline cases. This they had proceeded to do as well as they could with their limited facilities. They focused their attention on the lower East Side district, where most of these cases were found. Here the children affected had to be reached more directly through the schools and so the consent and assistance of the Board of Education was obtained. Two school clinics were started and special mixed classes were formed for the selected cases. Thus far there were two of these classes, one for the smaller and one for the larger children. A nurse was constantly in attendance at these classes and the children were instructed in general hygiene and in the hygiene of the eye, nose, and mouth. They were made to wash on entrance and just before going home. They were treated twice daily with the special drug needed, leaving boric acid treatment to be given at home. In addition to talks and demonstrations given to the children in the schools, talks were given to mothers in a model flat kindly lent for the purpose. The importance of this instruction in hygiene had always been known, as it was agreed that trachoma on the whole was a dirt disease; it occurred most frequently and intensely among the careless poor. They had found whole families with marked trachoma. By repeated insistance upon personal hygiene, by treating more closely, and by following up their cases of acute as well as of subacute conjunctivitis they had obtained certain results which were shown in tabulated form. Many of the cases which were now considered cured might have to be changed later. This table brought out the following points: 1. The large number of cases. 2. The relation of folliculosis to trachoma. 3. The relation of acute conjunctivitis to trachoma. 4. The number of cases cured. 5. The number of fresh cases of acute papillary conjunctivitis. Whether they helped to bring about the present lack of trachoma by their teaching of hygiene, their treatment and the following up closely of cases of acute conjunctivitis, it was too early to say, but they hoped that by continuous observation of these cases they might have more exact knowledge in another year.

Dr. Stewart L. Craig spoke of the importance of isolating these patients suffering from trachoma, which, he said, was a very difficult thing to do in New York City. This was a condition which was a source of danger to every child. The classes that had been established were a step in the right direction.

Observations on the Clinical Use of Immune and Normal Sera.—Dr. Matthias Nicoll, Jr., presented this communication. He said that the addition of a clinical staff to the force of the Research Laboratory had been a factor in stimulating an interest in the theory and practice of specific therapy among medical men of this city and the surrounding territory. This had been accomplished by the distribution of literature on the subject of serums and vaccines, by consultations with hospital and outside physicians, and by the fact that the laboratory force stood ready, as far as possible, to personally administer specific treatment when requested to do so. Sera had been supplied freely to physicians of this city who asked for them on the sole condition that, at the termination of the case, they should forward to the laboratory a short clinical history of the case with such data as would be valuable in determining the value of the serum. Such records were not for publication except by the permission of the physician and interfered in no way with any use he might wish to make of them. Notwithstanding this request and numerous follow up letters, not more than one-tenth of the physicians and institutions supplied had complied with its requirement. Series of cases had been treated, however, by some of the staff of the laboratory in their own services and in the hospitals of the Department of Health. By this means and by visiting other institutions where they had supplied the sera a certain amount of information had had been accumulated. There could be no doubt but the large dose, 100 to 200 c.c., which was generally regarded as necessary to produce results with the immune sera had militated against their more general use. When such a dose was used subcutaneously an apparatus such as was exhibited was almost essential and was not readily obtainable. An intravenous administration required a certain amount of practice and was unquestionably looked upon with more or less dread by the average physician. Until some means was found of concentrating the active principle it was difficult to see how such drawbacks could be overcome, and the sera would be used as it was now, very largely only in such cases as were regarded as desperate. Of the pneumococcus serum which had been kept in stock only a short time during which there was but little pneumonia, the results obtained in the small number of cases in which it was used had not been sufficiently marked to enable one to draw any definite conclusions as to its value. In some instances it seemed to have shortened the course of the disease and caused a drop in the temperature; in others no effect was produced. It had usually been given intravenously in doses of 100 c.c. It was truly polyvalent, the horse having been immunized with a dozen or more strains, first of pneumococcus killed by heat, later autolysates, and, finally, living virulent pneumococci. Anti-streptococcus serum, as at present supplied, was a polyvalent preparation obtained from horses. It included a dozen or more strains obtained from scarlet fever cases, from cases of puerperal sepsis, empyema, erysipelas, etc. A special serum for use in malignant endocarditis was also made. This serum had until recently been used but little in this country, but they were now gradually getting records at the Research Laboratory of cases which enabled them to draw conclusions as to its value. Its use was increasing very rapidly. Of all the conditions in which it had been used perhaps it had proved most successful in scarlet fever. Abroad it had been given in a large series of cases as a routine measure and at an early stage of the disease. With the lower mortality in this country such a proceeding was scarcely justifiable and its use here had been limited to the so-called septic cases. For this reason it was not possible to compare results. In a series of cases treated at the Willard Parker Hospital the effect on the pulse and temperature was very noticeable and the discharges from the nose and mouth very rapidly subsided together with the swelling of the lymphatic glands about the neck. Dr. Nicoll reported a case in which the serum was given intravenously in doses much larger than they had been accustomed to using and the results were so startling that he felt convinced of the value of the serum. In puerperal sepsis the subcutaneous

and intravenous use of the serum left much to be desired. A number of cases apparently were much benefited and a much larger number were not influenced. It had to be stated, however, that in many instances the patients had been *in extremis* when the treatment was undertaken. In erysipelas, in a number of instances, the temperature had fallen by rapid crisis following the use of the serum and the skin lesion had subsided within two or three days. In other cases the effect of the serum was not distinctly marked. The value of this serum locally as a packing for discharging wounds, cellulitis, etc., was not sufficiently appreciated. Under its use sluggish granulations rapidly became active and healthy, the discharge ceased and the wounds healed with great rapidity. As a local application to throats, especially in scarlet fever, it was extremely valuable. It should be applied freely every two hours. As a packing for an infected uterus it had also proved very valuable. Normal horse serum had proved of decided value in subcutaneous doses of 10 to 20 c.c., repeated if necessary, in intestinal hemorrhage, notably in that of typhoid fever, epistaxis, stubborn purpura hemorrhagica, and to a certain extent hemopytisis and ulcer of the stomach. It had proved of less value in hemorrhage of the newly born, and it would seem that in this condition direct transfusion or the use of human serum was preferable. The serum had been used, principally in England, as an application to chronic ulcers with excellent results. In considering the bad results which might follow the use of the serum, he mentioned, rashes of an urticarial character which might be accompanied by a moderate rise in temperature, and occasionally joint pains, chills which occasionally followed an intravenous injection of a large amount of serum, and in one case he had seen delirium None of these symptoms had lasted more than a short time and added little more than discomfort to the patient. The laboratories were responsible for the bugaboo of anaphylactic shock. This was a phenomena which could be readily produced experimentally in certain lower animals by properly spacing the administration of a foreign protein and with fatal results. Fortunately this rarely occurred in human beings. He had seen anaphylactic shock but once and that was in the case of an almost moribund child. In very asthmatic individuals and those of marked lymphatic diathesis the use of sera should, if possible, be avoided

The Differential Diagnosis and Treatment of Cerebrospinal Meningitis.—Dr. Phebe L. DuBois presented this paper in which she recalled that in 1906 the New York Board of Health had supplied the antimeningitis serum but that it had been found to be of slight avail and its preparation had been discontinued. After its value when administered interspinously had been proved the Rockefeller Institute had given the Health Department two horses immunized against the meningococcus and a generous supply of the serum, so it had been offered, together with the services of a consultant, to every physician reporting a case. In this way they had seen 247 cases, at least half of which were reported as epidemic cerebrospinal meningitis. The essayist showed a table which made it evident that there was a large percentage of errors in the diagnosis and that there were few cases of cerebrospinal meningitis in New York. The streptococcus, pneumococcus and influenzal cases could not have been differentiated except by lumbar puncture. The cases of infantile paralysis that they had seen had been of the encephalitic rather than the myelitic type. Rigidity of the neck often led to other conditions being mistaken for meningitis. The meningisimus coming early, before there were any signs of pneumonia, was the most difficult of all conditions to distinguish from true meningitis. In epidemic cerebrospinal meningitis and infantile paralysis the onset was usually sudden in comparison with a slower onset in tuberculous meningitis. In meningococcus meningitis the patient's mental condition was usually good excepting in the fulminating type. In tuberculous meningitis there was often a history of irritability followed by increasing stupor; in infantile paralysis the patient could be aroused. Cases of epidemic meningitis showed marked rigidity of the neck while in the tuberculous cases this symptom was apt to be slight or only a moderate anterior posterior rigidity. They had found Brudzinski's and Macewen's signs much more marked than Kernig's. The fever was higher in infantile paralysis and epidemic cerebrospinal meningitis than in tuberculous. Convulsions occurred in all three conditions. Projectile vomiting was not uncommon in tuberculous meningitis. The surest means of diagnosis, however, was by examination of the spinal fluid, and that was not always certain. Cerebrospinal meningitis nearly always gave a cloudy fluid while the other conditions yielded a clear fluid under increased pressure. They usually trusted to guinea pig inoculation for the final diagnosis when they did not find the bacilli. In regard to treatment Dr. DuBois said that for prophylaxis they relied on quarantine and looking after carriers. They now made cultures from the throats of those coming in contact with the patient, but thus far had not learned the most effective means of ridding the carriers of bacilli. Dr. Sophian had found that the injection of antimeningococcus vaccine was effective. Hatchel and Hayward had used a spray of antimeningococcic serum effectively. They had found that argyrol in 15 to 20 per cent. strength was the most effective in killing the meningococci *in vitro*. The specific treatment consisted in the interspinal injection of antimeningitis serum. They have injected the serum if they found a cloudy fluid on puncture. The amount of serum injected was usually a little less than that of the fluid withdrawn. Blood pressure was used as the guide for dosage. The number of injections depended upon the condition of the patient. The rigidity of the neck was usually late in disappearing and if the patient was improving in every other way this did not disturb them. They had used the autogenous vaccine in two cases that threatened to become chronic. The cases that developed basic meningitis where communication between the meninges of the brain and cord were cut off had never recovered in their experience. For general treatment they recommended the administration of urotropin because it had been shown that after its ingestion formalin was found in the cerebrospinal fluid. They also advocated the use of sedatives where the patient was restless. The diet should not be too limited as the duration of the disease might be prolonged. Meningococci were sometimes found in the urine and this should be remembered in ordering the hygiene of the sick room. Before using the serum the mortality had averaged 75 per cent.; now it averaged 50 per cent. Dr. Sophian in his experience in Texas had a mortality of 28 per cent. in the hospital. The prognosis was better for children than for adults.

Dr. L. Emmett Holt reported a case in which a very discouraging result followed the injection of the serum. The baby was seven months old and after the third injection stopped breathing for several minutes; artificial respiration had to be used before the baby again breathed maturally. He had seen a similar case in the hospital.

Dr. DuBois said that she had seen six or eight cases of that kind.

The Dosage of Diphtheria and Tetanus Antitoxin as Determined by Animal Experimentation.—Dr. William H. Park said that in Boston they were in the habit of giving large doses of diphtheria antitoxin, while in Philadelphia they gave about one-half as much. Dr. George Patten Biggs had made a series of laboratory experiments in animals in the endeavor to throw some light on this subject. It was to be remembered that the toxins were elaborated in the tissues involved and that a certain quantity was used in attacking the cells and a certain quantity got into the lymph and blood; a smaller quantity went through the capillaries. This liquid passing through the body fluids poisoned the general cells which were almost beyond reach and the question arose, how much poison was there? They tested the blood of patients coming to the hospital before they were injected. Charts were exhibited which showed the comparative amount of antitoxin in the blood at one, six, and twenty-four hours, when 10,000 units were given subcutaneously and intravenously. The time element was an important factor and the subcutaneous injection was a slow method of getting the antitoxin in the blood and general tissues. The antitoxin should be administered intravenously. Two, three, or four doses were not necessary: a single dose should be sufficient. The intravenous injection should be employed in the advanced and malignant cases. The patient would be saved by small amounts of antitoxin if it was given early in the disease. In the very severe cases one should give large doses intravenously for the purpose of hurrying it to the tissues. The time element was also important in tetanus and here the antitoxin should always be given intravenously. Large doses should be employed, such as 20,000, and repeated if necessary.

Parasitic Thyroiditis.—C. Basile states that this is an acute or chronic disease which affects chiefly infants and which manifests itself with fever, enlargement of the thyroid, hyperthyroidism, and phenomena of myxedema. There are certain associated symptoms referable to the nervous, cardiac, and hemopoietic systems. The etiological factor is a trypanosome, the *Schizotripanum cruzi*.—*Il Policlinico.*

SOUTHERN MEDICAL ASSOCIATION.

Sixth Annual Meeting, Held at Jacksonville, Fla., November 12, 13, and 14, 1912.

THE PRESIDENT, DR. J. M. JACKSON, MIAMI, FLORIDA, IN THE CHAIR.

The Diagnosis of Malaria.—Dr. GRAHAM E. E. HENSON, Jacksonville, Florida, stated that examination of the blood in cases of suspected malaria should be rigidly conducted for the detection of the parasites. Care should be taken to so time the taking of the smear as to insure the most likely time to find the parasites in the peripheral circulation. It should be the aim of the physician to make honest efforts to secure laboratory confirmation of the clinical findings before placing the patient on specific treatment, provided there were no symptoms suggesting the more pernicious type of the disease. In the event that quinine had been administered before the patient came under observation, a tentative diagnosis of malaria, even in the absence of the detection of the parasites, was justifiable under the following circumstances: 1. That the clinical history of malaria was obtainable. 2. That the patient had enlarged spleen. 3. That a leucopenia was present. 4. That the red-cell count was below normal. 5. That the hemoglobin was reduced, and that the differential count showed an increased percentage of large mononuclears. If these rules were adhered to, which might within certain limits be elastic, the many incorrect diagnoses of malaria that to-day covered a multiude of sins, and constituted the greatest blot in tropical and subtropical medicine, would be removed, and many of the unfortunates who to-day considered themselves the victims of chronic malaria, might be told what their condition really was, and possibly be relieved from further suffering.

Dr. E. C. THRASH, Atlanta, Georgia, spoke of a case that came under his observation three or four weeks ago in which a diagnosis of tuberculosis had been made by a local physician. For six or eight weeks the diagnosis lay between malaria and typhoid fever. He found the spleen of the patient very much enlarged, ruled out tuberculosis, and told the patient he thought he had either typhoid fever or malaria, and that he would soon decide between the two. He had been taking quinine systematically and regularly in all sorts of ways. He gave him treatment for ten days, watched him, found he ran a temperature continuously, and would occasionally have a chill. At the end of the eighth or ninth day he began to make examinations of the blood every six hours, and in the fourth examination he found estivoautumnal parasites. This man could have been saved a great deal of annoyance and a long attack of illness if the instructions outlined in Dr. Henson's paper had been carried out. He put the patient on four grains of cacodylate of sodium hypodermically daily and on large doses of quinine hypodermically, to which he responded promptly, and had had no trouble since.

Dr. CHARLES F. CRAIG, U. S. Army, mentioned two cases showing the importance of blood examination in malaria. One man became unconscious on the street one day and was picked up and taken to the emergency hospital. He died in a short time. The speaker had the opportunity of examining the brain and spleen in the case and found them both loaded with estivoautumnal parasites. Another case was at the Washington Hospital for a week before a blood examination was made. This patient died, and postmortem examination revealed the spleen filled with these parasites. It was the general impression that pernicious malaria did not occur in the city of Washington, yet within a month two cases occurred which were not recognized.

Dr. JOHN T. HALSEY, New Orleans, said that in the month of October he had two cases of pernicious cerebral malaria at the Charity Hospital, New Orleans, in neither one of which did physical examination give a hint of malaria. These cases would recover if the disease was recognized promptly and quinine given hypodermically in a very energetic manner.

Dr. JAMES H. RANDOLPH, Jacksonville, reported three cases of the cerebral form of malaria which recently came under his observation, and which illustrated in a very striking manner the importance of blood examinations. These cases were characterized by delirium.

Dr. WILLIAM ROSS, Jacksonville, related the case of a child who had six convulsions in five hours, was unconscious, had absolutely all the symptoms of acute epidemic cerebrospinal meningitis, with a temperature of 102°. His diagnosis was cerebrospinal meningitis. He was about to make a lumbar puncture. He took a blood smear, and found malarial parasites of both the estivoautumnal and tertian type. The child was unconscious for six days before it responded to quinine treatment.

Dr. CHARLES T. DRENNAN, Hot Springs, Arkansas, said it was just as imperative to make blood examinations in suspected cases of rheumatism as it was to make uranalyses in conditions which would lead us to suspect interstitial nephritis.

Dr. L. A. GREEN, Jacksonville, stated that the records of the State hospital showed that a number of patients admitted as insane were instances of pernicious malaria. These patients reacted promptly to quinine medication and recovered, but left the institution with the stigma that they had been insane, when, as a matter of fact, they had been suffering from malaria.

Dr. GREEN, New Orleans, said that in the Fall of 1898 a patient was brought into the Charity Hospital with a diagnosis of chronic interstitial nephritis with uremia. An examination of the blood and urine was insisted upon, and disclosed the case to be one of pernicious malaria. The patient was treated promptly with quinine and recovered.

Dr. JOSEPH GOLDBERGER, Washington, D. C., said there could be no doubt that in hospitals in these days a routine examination of the blood was absolutely essential, but the general practitioner did not, as a general rule, avail himself of this means of diagnosis in a great many cases, believing that it was unnecessary.

Dr. C. C. BASS, New Orleans, referred to the time of taking blood from the patient, and said that if we were dealing with the estivoautumnal type, the parasite might not be present in the blood for six or eight hours. It was worth while to direct attention to the fact that the estivoautumnal case in which the clinical course was more or less tertian, with chills and intermittent fever, with perhaps normal temperature, was due to the fact that the parasites segmented almost all together in groups as they did in the tertian and quartan type. In such cases the number of parasites present in the blood after six or eight hours would be smaller than at any other time. There never occurred a time when the parasites in the blood of the patient who was having malarial chills and fever were not numerous enough to be easily found. The proper time to take a blood examination for malaria was whenever one saw the patient.

Preliminary Study of Malaria in Alabama.—Dr. R. H. VON ESDORF, U. S. Public Health Service, Mobile, Alabama, drew the following conclusions: 1. All forms of malarial fevers prevail in the State of Alabama. 2. The types of infection in the order of prevalence are tertian, estivoautumnal, sub-tertian, quotidian and quartan. 3. The colored race is a large factor in the spread of infection, in whom the chronic type of malarial infection is proportionately greater than in the white. 4. To obtain an index of infection in the community, a blood examination should be made of adults as well as children of those who are permanent residents in such locality. 5. Latent or non-chronic cases should be treated vigorously for at least a month, and then with prophylactic doses of quinine for a period of from April to November. 6. Prophylactic doses of quinine should be taken by all persons in Alabama living in the localities known to be infected, between the period of April 1 to November 1. The prophylactic dose advised and used by me is ten grains of quinine sulphate, given in five grain doses, morning and evening. 7. The microscope should be more generally used for making or confirming the diagnosis of malaria, or, if practicable, advantage should be taken of the State laboratory, where examinations of blood will be made.

The Incidence of Malaria in the Puerperium.—Dr. J. V. FREEMAN, Jacksonville, Florida, took the position that when a woman had elevation of temperature in the puerperium, whom the physician confined previously, and during that time she gave a great deal of anxiety and trouble, and he discovered malarial infection, if he delivered her a second time he was justified in giving prophylactic doses of quinine, but he was not justified in giving it to every case he saw.

Dr. GRAHAM E. E. HENSON, Jacksonville, said that owing to the fact that any rise of temperature in the puerperium caused great alarm not only to the attending physician, but also to the members of the family, it had been his custom for the last five years, as soon as a patient was delivered, to put her on ten grains of quinine a day. He did not think there was anyone who practised medicine who would more strongly oppose measures to mask infection than himself; at the same time, owing not only to the anxiety caused by fever in the puerperium, but also to the fact that malarial infection did develop, the mother was put on large doses of quinine to control the infection after it had once manifested itself. By following this

line of procedure, and delivering 100 or more women, he had never seen malarial fever develop in the puerperium, and on that account he would strongly urge that these patients be given ten grain doses of quinine. He generally gave five grains in the morning and five grains at night.

Dr. Stevens T. Harris, Highlands, North Carolina, said with regard to fever returning periodically being classed as malaria, it was not true. It was absolutely erroneous to make a diagnosis of malaria from this standpoint. He had seen fever, chills, sweats, typically malarial in character recur without the presence of malaria. One might also have chills occurring periodically and with regularity in tuberculosis, and possibly in other septic conditions. He would strongly urge that the use of the microscope was the only way to diagnose malaria.

Dr. B. B. Simms, Talladega, Alabama, said we could have chills and fever, and even if we found the plasmodia we could not call the case malaria every time, because we frequently had plasmodia in our blood. In Alabama it had been found that 11 per cent. of the people had malarial parasites in the blood without manifesting symptoms of malaria.

Dr. W. A. Boyd, Columbia, South Carolina, believed that a woman who went through the trials and troubles of childbirth had suffered enough, and the physician should not, as a routine, impose upon her the necessity of caring for ten or fifteen grains of quinine because of a possible malaria. If we had a puerperal woman who showed a febrile condition, and we were not sure of the actual condition present, he did not believe as obstetricians we were justified in putting that woman upon the routine treatment of quinine until we had proven to ourselves and for our patient's benefit, as the result of bacteriological examination, that she was infected with malaria.

The Production of Beriberiform Polyneuritis in Fowls with Substances Other than Rice.—Dr. Creighton Wellman, New Orleans, stated that before he took up the problem experimentally, Prof. Bass, in a series of experiments during 1911, showed that the characteristic polyneuritis of fowls could be produced by feeding them an exclusive diet of milled Louisiana white rice. During Prof. Bass' subsequent absence in Central America, he carried on another series of experiments and observed that not only milled Louisiana rice would produce this condition, but also that a single diet of other carbohydrates would accomplish precisely the same result. For instance, he was able to produce this characteristic condition in fowls more rapidly and completely with cane sugar than with milled rice. Pure corn starch would produce the condition rather more slowly, but fully as completely as milled rice. He also found that a mixed diet plus small doses of oxalic acid would produce a condition indistinguishable from that caused by milled rice. Finally, like other observers, he produced the condition by semi-starvation. These experiments were in each instance checked by controls. The production of a beriberiform neuritis in fowls by other substances than milled rice was a new observation and suggested a revision of the accepted views regarding rice as a sole cause of beriberi in man.

President's Address.—Dr. J. M. Jackson, Miami, Florida, said the Association of Medical Colleges of the South could do much to solve the problem of medical education, as the intimate acquaintance of each with the other would make it possible to deal personally and individually with each school. Great would be the day when the weaker and unequipped schools gave way and we should have centralized upon a few schools whose equipment and advantages in both didactic and clinical instruction would be equal to any school anywhere. He was astonished to learn how few professors entered medical schools with fitness as teachers of obstetrics, and he supposed it was quite so in other branches. When schools were run for the good of the profession and humanity, then would we have this improved condition. The medical profession was a quasi-public profession and it should have in connection with it capable teachers and proper equipment of hospitals in localities of sufficient size to furnish ample clinical material, which was to-day considered so important a part of medical education, and these should be run for the benefit of the well as well as for the sick occupying their beds.

Public health was a nation's greatest asset and the conservation of it the greatest need of the day. This conservation could only be done by an educated people and a highly educated medical profession as directors.

The Thyroid and Hyperthyroidism—Address in Surgery.—Dr. Stuart McGuire, Richmond, Virginia, said that when a patient with exophthalmic goiter came to a surgeon, the case ought to be kept under observation and carefully studied for some days before deciding on the character of the operation best suited to the individual and the safest time to perform it. In the hands of experts the mortality of operations for hyperthyroidism was now from 2 to 5 per cent., and 85 per cent. of those who recovered might be said to be symptomatic cures. It was neither honest nor expedient to make light of the operation or to belittle its difficulties and dangers. The figures quoted were from the statistics of master surgeons and by no means represented the results of the average operator. After a successful operation for hyperthyroidism the improvement in the patient was immediate and marked. No operation in surgery produced such quick and brilliant results. Tremor disappeared, the pulse fell to normal, the eyes became less and less wild, and restlessness and irritability were replaced by quiet and composure. The wound, as a rule, healed rapidly, and the patient was able to leave the hospital in from ten to fourteen days. Because the patient was well from the operation, and because the acute symptoms were relieved, was no ground for immediate return to the ordinary activities of life. Crile very properly stated that it required approximately the same time to recover from exophthalmic goiter as from a nervous breakdown from other causes. A successful operation should be followed by an adequate period of rest.

Vaccine Therapy.—Dr. Irwin E. Colgin, Waco, Texas, said the most uniform results obtained from the use of vaccines were in cases of pyogenic infection, especially those caused by staphylococci, such as furunculosis and carbuncles. This was due to two factors, the chronicity of the infection and the uniformity of the causative organism. Success had also been the rule in treating cases of acne vulgaris. A combined vaccine of staphylococci and bacillus acne of Gilchrist was used, based on the theory that the original nodule was due to bacillus acne, and the pustule to secondary infection of staphylococci. He advised giving fifty million staphylococci and ten million bacillus acne as the initial dose. One should give increasing doses at intervals of from a week to ten days. In vaccine therapy success depended upon 1. choosing cases applicable to the use of bacterial vaccines. 2. Determining the causative factor. One should not depend upon mixed vaccines, as usually if he got rid of the main factor nature could take care of the balance of the infection. 3. Select the dose according to individual patients and do not follow set rules. 4. Make the interval long enough between injections to let the body respond to the stimulation.

Dr. J. B. Elliott, Jr., New Orleans, said that last year he reported several cases of typhoid fever treated by vaccines. Since that time he had had four cases of typhoid fever treated in the same way by the use of typhoid vaccines. The results had been uniformly successful. The cases had all terminated about the 20th or 22d day, and after three doses of vaccine there was generally a fall of the temperature to normal. He had failed to see any harm done in any case by the use of typhoid vaccines.

Dr. E. C. Thrash, Atlanta, had been observing the use of these vaccines during the last few years and had been much chagrined at the profession treating them so indifferently. If we could cure 5 per cent. or 10 per cent. of the cases of specific disease, we had made a long stride in our therapy, because, when we ruled out syphilis and malaria, they were about all the diseases we could cure with drugs. There was nothing more valuable in our therapeutic work than careful studies of the action of these vaccines and administering them intelligently.

Hydrothorax in Its Relation to Cardio-Renal Lesions.—Dr. Frank A. Jones, Memphis, Tennessee, drew the following conclusions: 1. Hydrothorax is often an acute condition instead of a part of a general dropsy. That acute nephritis is often ushered in by an attack of acute edema of the lungs, followed rapidly by acute fulminating hydrothorax. 2. That, in all probability, the attack of edema of the lung followed rapidly by hydrothorax is due to the same toxic agencies which, at the same time, produce the renal changes. 3. That in these cases passive congestion, venous stasis, etc., have nothing to do with the production of the edema; that the large black lung is analogous to the large red kidney. 4. When dyspnea is marked, either in cardiac or renal lesions, examine the patient just as critically for hydrothorax. 5. Hydrothorax, massive in nature, is often latent. 6. Saline cathartics and digitalis, when hydrothorax is present to any appreciable degree, are dangerous. They invite edema of the lungs and paralysis of the heart.

Relation of Gas Embolism to the Production of Artificial Pneumothorax.—Dr. Stevens T. Harris, Highlands, North Carolina, said from all sides came reports

of the employment and success of artificial pneumothorax as a treatment of tuberculosis of the lung. It was safe to say that the results of no other method ever employed could compare with the wonderful results obtained by this procedure. It was the only real curative treatment for phthisis which had ever been devised. Surgical procedure had again scored a victory. Artificial pneumothorax, like other surgical methods, had its dangers, and chief among them, was gas embolism. Nearly all of the deaths due to the treatment had been caused by this condition. The chances for gas embolism were remote after one had definitely proven a free pleura and more or less of an activity had been formed. He had never seen it occur when this was the case, except where there were thickened pleura and some adhesions, and where too high a pressure was suddenly produced.

The Present Status of Our Knowledge Regarding the Parasitic Amebas.—Dr. CHARLES F. CRAIG, U. S. Army, said we were still ignorant regarding the exact method of the transmission of these parasites from host to host, and we knew nothing whatever about the relation the species found in the lower animals bore to those found in man, so that researches along these lines might result in valuable knowledge regarding the epidemiology of amebic dysentery. The point of greatest practical importance to the physician was the demonstration of a harmless entameba in so large a proportion of healthy persons, and those suffering from diseases other than dysentery, and the vital necessity of differentiating between this species and those causing disease, before making the diagnosis of amebic dysentery in patients who did not present typical clinical symptoms of the disease. He would, therefore, urge the greater use of the microscope on the diagnosis of the diseases of the intestinal tract, especially in regions where amebic dysentery and other parasitic infections of the intestine were endemic, believing that this one measure would be of more service in arriving at a correct diagnosis than any other command.

(*To be continued.*)

AMERICAN GASTROENTEROLOGICAL ASSOCIATION.

Fifteenth Annual Meeting, Held at Atlantic City, N. J., June 3 and 4, 1912.

DR. WALTER B. CANNON OF BOSTON, MASS., PRESIDENT, IN THE CHAIR.

Agar Tubes for the Estimation of the Pancreatic Ferments.—Dr. MAX EINHORN of New York City presented a method of testing the ferments with agar tubes, which seemed to him to be simple and worthy of recommendation, although some of the details would have to be worked out further. The agar tubes were mixed with albumin, starch, and fat; and the ferment action was allowed to take place in them by osmois. If the test substances added were colored with indicators, which underwent a change when acted upon, it was easy to ascertain the presence of the ferment and also to estimate their approximate amounts by the volume of tube changed.

Dr. J. C. HEMMETER said that although he had never tried this method, it impressed him very favorably. He asked whether the use of agar complicated the deductions; because, whether testing for fat, for carbohydrate, or for proteid, proteid would be present, since agar itself was a proteid.

Dr. EINHORN replied that the reason he had taken agar was that if produced in some kind of concentration and allowed to pass the digestive tract, it would not disappear. If used in a one per cent. soultion, it would disappear; but if used in a three per cent. solution, it would not do so. He also said that agar was not changed by the ferments, but that the other things added could be acted upon by them.

Some Unsolved Problems in Gastroenterology.—This was the title of the president's address delivered by Dr. WALTER B. CANNON of Boston. Among these unsolved problems he mentioned the reflex of swallowing, the "myenteric" reflex, by which a stimulant at any point in the digestive canal provoked contraction above and relaxation below that point. In connection with this reflex there arose, he said, the question as to the relation between the diastalsis of the ileum and the anastalsis, or reversed waves, in the proximal colon. The relation of the myenteric reflex to defecation had also not yet been studied. Another possible relation of this reflex to the activities of the canal lay in the function of the ileocolic sphincter, the cardiac and pyloric phincters likewise being operated through the myenteric reflex. Another problem on which Dr. Cannon thought that a great deal more work needed to be done was on absorption; but he considered the problem that he had touched upon in his address at the previous annual meeting more significant than any other. In that address he had submitted evidence as to the fundamental importance of tonus in the movements of the alimentary canal. In the intimate connection of the digestive processes with other activities of the body lay the most significant and the most profoundly interesting problems, not only of gastroenterology and of internal medicine as a whole, but also of physiology as a special science. It was because of this interlacing of interests, Dr. Cannon said, that surgeons, and physicians, and specialists, and workers in the medical sciences gathered together each year, in order to focus such light as each of them might be able to throw on these more or less obscure features of the subject.

The Diagnostic Worth of the Glycyltryptophan and the Tryptophan Tests in Diseases of the Stomach.—Dr. FRANK SMITHIES of Rochester, Minn., stated that in this series more than one-third of the proved cases of cancer of the stomach gave positive glycyltryptophan reactions. More than one-fourth were lactic-acid positive, and about one-thirteenth of the number exhibited the tryptophan test. While gastric conditions other than cancer exhibited positive glycyltryptophan reactions, in no single case of disease of the stomach was this test obtained so frequently as in cancer. The work done did not show that the tryptophan test was, as had been claimed, pathognomic of cancer. Low free hydrochloric or total acidity was frequently determined in gastric contents exhibiting positive glycyltryptophan, lactic acid, and tryptophan reactions. Many cases of low acidity were negative to the above-mentioned tests. Approximately one-half of the positive glycyltrptophan and tryptophan reactions were in gastric extracts containing bile and blood elements. Approximately one-fourth of the negative extracts contained blood and bile elements.

Dr. G. A. FRIEDMAN stated that he had been working with the glycyltrytophan test in about twenty cases, and that his experiments had shown that in cancer the reaction was sometimes obtained, although in other conditions he had never obtained a positive reaction. He had never come across a positive case of cancer, as shown by this test, when other symptoms were not present. Usually lactic acid and all the signs of cancer would be found. He believed that the tryptophan test for this disease was of no value whatever.

Dr. JOHN A. LICHTY said that he had given up using that test a year ago. It seemed to him that the points that interfered with the test were those usually present in carcinoma of the stomach.

Dr. JACOB KAUFMANN said that one should make use of every available method that would enable one to make an early diagnosis of carcinoma. A most reliable test was the presence of blood in the stool. In a recent comparison of tests for carcinoma, in 98 per cent., or 104 cases out of 110, blood was found. In the test for blood in the stool, one must eliminate all possibility of error by arranging a careful diet of green vegetables, and by avoiding the putting of instruments into the stomach. The moment one used a tube, there would be the possibility of a lesion.

Dr. SEYMOUR BASCH had also found the test unreliable in gastric carcinoma diagnosis. Another test, which he offered on theory, consisted in the presence of undissolved albumin. The basis of the test was that the gastric contents, if they contained the cancer secretion, would contain more albumin than the ordinary test of gastric secretion. The ferments digested more albumin, and the higher the body of albumin the greater was the amount of pepsin. Dr. Basch considered the test simpler than either of the other two tests, and easier to carry out.

Dr. JAMES TAFT PILCHER said that he had had an opportunity to examine four or five hundred patients with cancer of the stomach on whom operation had been performed and the diagnosis confirmed. In all of these it was fourd that these tests did not give any basis on which to apply diagnosis. The clinical history was much more definite and of much more diagnostic value, he thought, than any of the tests that had been put forth. One procedure that seemed to bear more directly on positive diagnosis was that of giving bismuth and taking a radiograph of the actions of the stomach through the fluoroscope.

Dr. J. C. HEMMETER remarked that it must be remembered that Dr. Smithies was aiming to recognize the disease at a very early stage. The results were not, as yet,

clear cut. He considered Dr. Kaufmann's idea of showing the presence of blood in the feces important.

Dr. SMITHIES stated that in a great many cases carcinoma could be diagnosed accurately by the history, but that in his cases he had proved that the albumin test, the stain test, and the like, were all of vital value in the diagnosis of carcinoma of the stomach.

Indicanuria.—Dr. WILLIAM GERRY MORGAN of Washington, D. C., presented a paper based on the analysis of one hundred and thirty-eight cases treated during 1911. He said that the indicanuria might be accidental (transitory), or might be a definite part of the clinical picture, although still associated with other pathological processes. In a very few cases it was an indication of true intestinal autointoxication. Particular stress should be laid upon loss of nerve-tone as the cause of the underlying putrefaction, it having been found that in Washington the end of the busy season was the time that most cases were seen. The symptoms were those of an intoxication with a poison having especial affinity for the nervous system. The symptom found present in the greatest number of cases was gas-formation in the bowel, indicative of the putrefaction. Others of the most promient symptoms were early fatigue, loss of ambition, malaise, headache, dizziness, and muscle pains. A myriad of other nervous manifestations were present. He thought that the cure must consist in measures preventing the formation of toxins and eliminating those already formed. Other associated conditions must be treated. Treatment of the condition itself should consist in general hygienic measures, diet, exercise, irrigations, and occasional medication. Purgatives had been found to do harm. In the majority of cases cure was easy, but progress in the occasional true autointoxication was slow.

Dr. JACOB KAUFMANN remarked that many conditions were being described as being caused by autointoxication, but that not a single fact had been shown that could prove that there was intestinal autointoxication. The problem remained unsolved, he thought. No substance had been demonstrated as acting as a toxin, indican itself not being considered toxic. In such cases he had sometimes found albumin. A certain amount of intestinal putrefaction was present, producing an output of indican, although increased intestinal putrefaction might be present without the indican. While admitting the possibility that such things as intestinal autointoxication existed, he did not think that the increased amount of indican could be used as an indication of the increased intoxication.

Dr. MAX EINHORN said that these troubles of autointoxication had been greatly exalted by the profession, many patients being told that they had poisoned their systems, being put on a rigid diet, and not allowed to do this or that. The result was that these patients became nervous and frightened. He had had some such patients, and had relieved their condition by allowing them to live like other people, not bothering about constipation, diet, exercise, and so on. He considered the whole idea of autointoxication as still being theoretical, and not practical, and said that the chief thing to teach such patients was that they must live rationally.

Dr. DUDLEY D. ROBERTS, while admitting that indicanuria had been something of a failure, said that the subject pointed out a half hope; although, before its relation to intestinal toxemia could be proved, much work remained to be done on this subject. Although he had one hundred and fifty cases under observation, he did not feel that he knew much more than when he had started.

Dr. JAMES P. TUTTLE had had many cases of so-called autointoxication, and in that type of disease had observed that in the worst cases of chronic constipation it had no relation to indicanuria, many cases loaded with mucus, casts, etc., having no traces of indican. He found that indicanuria was almost always associated with some type of staphylococcus or streptococcus infection, and was inclined to think that in cases with a large amount of indicanuria there was some slight lesion, possibly around the lower end of the cecum. He said that these cases did not need to be washed out with a barrel of water. It was not necessary for a man to have two bowel movements a day. He had seen patients having one movement every two or three days, and they were just as well as though they had more. His advice was not to scare the patients.

Dr. MORGAN, from his experience with indicanuria, thought it unimportant whether the urine was examined for indican or not. He considered it a definite picture, increase of indican being found along with the other conditions. There was an absorption in the canal that he thought rather important, but he did not believe that diet was good for autointoxication, and considered a rational way of living best. A part of the cure should consist in taking the patient away from business, because it was the condition of the nervous system, or lack of nerve-power, which had been exhausted from use in other directions, that did not permit of the patient's functionating properly.

Surgical Measures for the Relief of Abdominal Symptoms Due to Ptosis of the Stomach and Colon.—Dr. JOSEPH C. BLOODGOOD of Baltimore, Md., said that in the twenty cases operated on since January, 1911, the indications for operation were stasis in the stomach or colon, or in both. All the cases had received medical treatment without relief. In formulating the operative procedure, he had been governed by the symptoms, *x*-ray findings, and conditions exposed on opening the abdomen. In most of the cases the *x*-ray findings were least helpful. He believed that he had demonstrated for the first time the relation of chronic dilatation of the duodenum to ptosis of the colon. The dilatation of the duodenum was the end result of ptosis of the colon. The stomach trouble came on later, and the surgeon did not usually see the patients until they were in a very bad condition. The most satisfactory results had been obtained in the group of cases associated either with pyloric kink or with dilatation of the duodenum. The dilatation of the duodenum showed the simplicity of the relief of cases often diagnosed as chronic neurasthenia and many other conditions. The symptoms found by him included pancreatic juice and bile in the stomach. The patients were usually very much depressed. To relieve the condition, one should resect the right half of the colon, and suture the ileum to the transverse colon. The removal of the right half of the colon would not always relieve the patients of constipation and stasis in the colon. He had never resected the entire colon, but he believed that if one wished to restore the patient to a normal condition one must do this. In some cases two operations might be necessary.

Dr. MAX EINHORN said that he had in mind a condition somewhat similar to one that Dr. Bloodgood had mentioned—a group of patients who had slight stagnation of the colon, in combination with bile and pancreatic juice in the stomach. On examining the stomach, he said, one would always find more residue of fat. In his cases there was an obstruction of the duodenum below the papilla of Vater. The main symptoms were severe pain and vomiting. The usual operation for this had formerly been gastroenterostomy below Vater's papilla. No ptosis, as such, he thought, should be attacked by operation. If there were symptoms an operation might be performed for their relief. There might, he thought, be instances in which operations on the colon were of benefit, but he considered it an unnecessary procedure to subject a patient who was simply constipated to an operation for prolapse of the colon, or any point of the intestines. There must be something else present, in order to render such an operation justifiable.

Dr. JAMES TAFT PILCHER said that another method that was applicable in these cases consisted in raising the stomach into the epigastrium and also raising the colon, putting a row of six or eight sutures in the mesentery of the transverse colon, and suturing it across the abdomen, two inches above the umbilicus. At the same time the drag and the stasis that the condition occasioned should be removed. In repeated cases Dr. Pilcher's results from this method of procedure had been satisfactory.

Dr. JACOB KAUFMANN remarked that a very important question was: What is the primary factor that develops these conditions? Dr. Bloodgood's cases had shown none of the conditions mentioned by Dr. Einhorn, and Dr. Kaufmann had seen few cases of the type presented by Dr. Bloodgood. He thought, however, that surgical intervention might be warranted in certain cases. One should consider the cause of the development of such pronounced types of atomy and dilatation.

Dr. WALTER B. CANNON pointed out the fact that most of the structures in the abdominal cavity were readily movable, and said that if they had approximately the specific gravity of water he had some difficutly in seeing how there could be any great drag of one structure on another.

Dr. ALLEN ARTHUR JONES asked whether Dr. Bloodgood had observed relief from symptoms such as he had described in cases operated on for floating kidney. Dr. Jones had seen two cases in which there had been very signal relief from symptoms produced by a nephrorrhaphy, and described a considerable part of their success to the fact that the transverse colon and cecum had been lifted.

Dr. CHARLES G. STOCKTON thought that in these cases the physician should consider the state of the abdominal

walls. If there were marked tire and relaxation, it would be difficult to obtain that standard of intra-abdominal pressure to which Dr. Cannon had referred.

Dr. G. A. FRIEDMANN stated that gastroptosis and enteroptosis were constitutional diseases. Many patients, besides these gastric and intestinal symptoms, had many general symptoms, and most of them were anemic. He could not see, therefore, how an operation could improve such a condition, general treatment for the anemia being necessary. A patient with a gastroptosis might acquire an organic disease, and this might be remedied surgically, but in the pure cases of gastroptosis he did not believe that one should advise surgical interference.

Dr. HENRY W. BETTMANN said that nothing could be clearer than that a merely anatomic relation of the organs could not be a matter of great importance. The point of drag was one that had worried him for a number of years. It was inconceivable to him that the lower abdominal organis could drag on the upper. If that were the cause of the symptoms the placing of the patient on his back for a number of days or weeks would overcome the symptoms. He thought that the idea of the drag was erroneous and would have to be abandoned. None of the patients whom he had seen and who had had the colon raised and attached to the abdominal wall, the pylorus also being raised, had been materially benefited, and some had been made considerably worse by that procedure. He believed that the use of the *x*-ray had led to an increase in the number of operations performed by persons who did not thoroughly understand gastroenterological problems, without a corresponding benefit, and thought that surgeons should go slowly in this department. One patient would be benefited by the operation, while twenty would be either not benefited or made worse.

Dr. A. L. BENEDICT drew attention to the fact that there was a difference between a stomach that was in a state of ptosis and one that was normal in its relations, but dilated. In many case reports, he said, the word ptosis referred merely to a slight dilatation of the stomach and a sagging of its greater curvature.

Dr. LUDWIG W. KAST said that the greater curvature might be five or ten centimeters below the level of the umbilicus and yet the stomach might still perform all its work. It might take a little longer to do this, but the stomach would still be within the physiological limits. A stomach with a less lowered greater curvature might not perform the work required. One should differentiate between the position of the stomach and the function of the stomach. Dr. Kast asked whether Dr. Bloodgood advocated operation for change in position or for change in function.

Dr. BLOODGOOD, in closing, said that when there was an ulcer or a cancer of the colon, one could resect the diseased part and restore continuity. If there existed a volvulus of the signoid one could untwist it and relieve the symptoms. It was a perfectly feasible operation to resect the stomach. In nine of the twenty cases that he had before referred to, there had been definite gastric symptoms. The stomach did not empty itself, and the patients could not eat. After resection of the stomach and after duodenal dilation, the patients were able to eat. In his study of this subject Dr. Bloodgood had tried to find an anatomical basis, so as to relieve the symptoms. So far as the stomach was concerned, it was settled; but so far as the colon was concerned, it was not.

Hyper- and Hypotonicity of the Vagus and Sympathetic Nerves as Causes of Disease of the Digestive Tract.—Dr. J. C. HEMMETER of Baltimore, Md., stated that just as there existed a myogenic and neurogenic tonus, so there was also a secretory tonus, which had not been so thoroughly studied. The latent period of secretion after stimulating the sympathetic or the chora tympani nerve supplying the submaxillary gland was greater after the nerve control over this gland had been abolished for several hours by freezing either nerve or by cutting it. This preparedness for giving a ready secretion upon adequate stimuli might be defined as secretory tonus. The threshold of stimulation also rose in experiments in which the gland had been cut off from the nerve-supply for several hours. The entire neuromuscular apparatus, both voluntary and involuntary, was in a condition of tonic activity. Dr. Hemmeter explained, due to the continual inflow of sensory impulses to the motor neurones of either spinal cord or brain, or both. The doctrine of "vagotonia" and "sympathicotonia" assumes that the disturbances of peristalsis, innervation, and secretion in the digestive tract were due to permanently altered tonicity of the vagus and sympathetic; that is, either an exaggerated, augmented, or a diminished tonicity of these nerves existed.

Dr. JACOB KAUFMANN believed that a study of the physiology of the digestive tract and its disturbances would help a great deal more in understanding stagronitestinal disorders and the treatment of these conditions than would the mere consideration of anatomical or pathologico-anatomical facts. Cases of irregular growth might be attributed, he thought, to an interference with the activity of the liver by lack of thyroid secretion. By studying more specifically the disturbances either of the pneumogastric nerve or the sympathetic nervous system in connection with the internal secretion, one would be helped very much in solving these problems.

Dr. LUDWIG W. KAST remarked that there was an application of the neurological and secretory facts to the clinical problems. The antagonism between the two nervous systems created a condition of equilibrium in different directions in the musculature of the secretory apparatus. One frequently saw conditions in which the patient had increased hyperacidity, and in which the motility was very intense. Without having duodenal ulceration, these patients had hunger-pains, the contraction having reached such a degree as to become painful. After the test-breakfast was evacuated, the secretion still went on without having any stomach-contents to act upon. That was the time when the opportunity was given for the development of duodenal ulceration. Atropin benefited this class of cases very much symptomatically.

Dr. S. J. MELTZER said that in such a vague field as gastroenterology, so long as the investigators had confined themselves to anatomy and chemistry, they had had some facts to go on, but when they commenced to take up the functional aspect of the matter, they were making wild hypotheses. The alleged facts that they had to go on had not been verified.

Dr. WALTER B. CANNON pointed out the possibility that lack of tonus or diminution in it might be due to failure of the vagus to deliver the impulse producing tonus, or to the action of the thoracico-lumbar in delivering the impulse that reduced the tonus.

Dr. HEMMETER, in closing, stated that atropin would relieve cases caused by high tension of the vagus system. It was clear, also, he said, how overstimulation of the vagus could produce gastric ulcer, because if one stimulated around the nucleus of the vagus and kept it up, this would lead to conditions that destroyed the epithelium of the stomach.

The History of Radiology of the Digestive Tract for the Diagnosis of Ulcer and Carcinoma.—Dr. J. C. HEMMETER of Baltimore, Md., said that he had published some experiments of his aiming at photography of the human stomach by means of the Roentgen ray in the *Boston Medical and Surgical Journal* for June 18, 1896. Investigations showing the possibility of photographing conditions accompanying cancer, and ulcer by the *x*-rays have been confirmed in this country and in Europe. Mathematical, or technical, and personal, or functional, errors had to be avoided, he said, in the execution of the method Failures to accomplish results by it had been due to one or other of these errors.

A Few Important Points in X-Ray Examination of the Digestive Tract.—Dr. FRANKLIN W. WHITE of Boston, Mass., treated this subject from the clinician's standpoint. He said that examination of the mechanical factors of digestion was of the greatest importance in diagnosis. He considered the *x*-ray a brilliant method of examination. Comparisons with other methods of testing the motility of the stomach in ptosis, spasm, ulcer, and cancer showed a great variability in the results; and there was need for great caution in interpreting them. There was a great necessity for a standard bismuth meal. A study of peristalsis was possible, he stated, only with the *x*-ray. *X*-ray tests of secretion were of small value. The duodenum was very difficult to examine, and its examination might be assisted by artificial distension. Delayed motility was of great importance. The colon might be successfully examined by giving a bismuth meal and administering an enema; but great care must be exercised, or the value of the results would be impaired by various sources of error. The *x*-ray should be combined with other methods of examination in making the diagnosis.

Dr. JOHN A. LICHTY asked how much and what kind of bismuth should be used for the meal. He had not been able to get an entire filling up of the stomach. In his opinion, the *x*-ray would never replace the stomach tube, even though it gave more definite outlines, because he considered the stomach-tube superior in some respects. He had had a case that appeared from the *x*-ray to be cancer of the stomach, but that turned out to be cancer of the colon. He wondered whether the bismuth itself did not interfere with the normal emptying of the stomach by

neutralizing the hyperacidity that existed in many cases.

Dr. JOHN C. HEMMETER said that quite a number of cases of bismuth poisoning had been reported after these examinations and that he had directed his attention to seeing whether something else could not be substituted for the bismuth. He believed that bismuth, when used for the relief of ulcer, must interfere with the impulses from the stomach, and thought that the delayed peristalsis might be due to that. He had tried, in place of the bismuth, aluminum silicate, calcium carbonate, and calcium phosphate; and had succeeded in obtaining good shadows with them. None of this material was absorbed. He said that there were two errors that hindered progress, the mathematical and the functional. The former was in the apparatus; and the latter in the person. The exposures had been made to occupy only a few seconds.

Dr. SEYMOUR BASCH mentioned the fact that for the last few years barium had been used abroad with good results. It was, he said, cheaper than bismuth, and no poisoning had resulted from its use. There had been no bad symptoms in the thousands of reported cases in which it had been used, and he thought that Americans should take it up.

Dr. WALTER B. CANNON had used barium several years ago, in order to determine its effect on peristalsis, and had obtained the same results with it as with bismuth. He thought that if everyone would retain for record the *x*-rays, and if the surgeon would record what he had found at operation and have *x*-rays taken of every specimen removed, the *x*-ray would be proved to be an important instrument of precision. He felt confident that a combination of the *x*-ray with bismuth above and below would absolutely demonstrate the position of the carcinoma.

Dr. WHITE said that he used two ounces of bismuth to one pint of buttermilk, as a vehicle. The tube he considered also of value as a control. Poisoning by bismuth, he thought, to be a thing of the past, it having occurred at the time when nitrate of bismuth was used.

The Lactose Test Meal in the Establishment of Alimentary Hypersection in the Diagnosis of Ulcer.—Dr. DUDLEY D. ROBERTS of Brooklyn, N. Y., gave at some length the results of studies carried on with the lactose test-meal since the time of its presentation to the Association, the previous year, when used in normal cases, in enteroptotic cases with different conditions of secretion and motility, in the various surgical conditions that cause gastric complaints, and in ulcer. Under normal circumstances there remained, one hour after the ingestion of the test-meal, not more than 50 c.c. With this, there was found from 50 to 100 c.c. of gastric juice. There was then a normal ration of more than 1:1.5 between the residue of test-meal and the gastric juice still in the stomach. From his experience he thought that it might be assumed that when the gastric-juice residue was three times that of the test-meal residue, there was hypersecretion of marked degree. In all cases there was alimentary hypersecretion. In some instances this was even up to the ratio of 1:9. In one case of chronic appendicitis there was a hypersecretion with a ratio of 1:3.1. This occurred in only one instance. On the ulcer cases the degree of hypersecretion was low.

The Healing of Gastric and Duodenal Ulcer with Bismuth.—Dr. CHARLES D. AARON of Detroit, Mich., stated that bismuth had been used as a medicinal agent since its introduction by Oidier, of Geneva, in 1786, although it was Kussmaul who had systematized its use. The anodyne effect of this drug was univesally conceded, and research work on this subject had furnished evidence that the protection afforded by bismuth subnitrate in gastric and duodenal ulcer was both physical and chemical. Experiments on dogs showed that bismuth, a few hours after its administration, was finely distributed over the gastric wall. This acted as a protective layer, and might remain undisturbed for several days. The chemical effect of bismuth subnitrate, he said, was due to the liberation of nitric acid during its decomposition. The treatment with bismuth could never be regarded as a substitute for the rest cure in the treatment of ulcer. Its general purpose was to support the rest treatment, especially when the latter failed, or when the ulcer took a chronic course, tended to relapse, or gave rise to considerable pain; and, furthermore, in the treatment of outdoor patients.

The Gastrointestinal Disturbances Observed in Pernicious Anemia.—Dr. JULIUS FRIEDENWALD of Baltimore, Md., gave the results of observations of his extending over a series of fifty-eight cases of pernicious anemia, in all of which gastrointestinal symptoms had been noted. From a study of these cases, it was evident to him that a large proportion were attended with gastrointestinal disturbances, as well as with an absence of gastric secretion. There was present an achylia gastrica in about seventy per cent. of the cases, and even in the stage of apparent recovery the gastric secretion did not return. In a smaller proportion of cases (twenty per cent.), there was a marked diminution in the secretion, and in a few instances (about ten per cent.) it remained normal. He thought it quite probable that the poison that produced the hemolysis was the same that was also responsible for the alteration in the gastric secretion.

A Contribution to the Etiology of Pernicious Anemia.—Dr. JAMES TAFT PILCHER of Brooklyn, N. Y., had observed 433 cases of abdominal complaints in which the symptom of achlorhydria hemorrhagica gastrica was present and wished to offer for consideration the following facts: (1) Achlorhydria is merely a symptom denoting chronic gastritis; (2) it is usually evoked through extragastric irritative factors, which are often susceptible of correlation; (3) there are present in such stomachs great numbers of bacteria, among which streptococci are especially to be noted; (4) practically all recorded cases of authenticated pernicious anemia present the symptom of achlorhydria and the presence of occult blood in the stomach extract; (5) thirty-four instances of pernicious anemia were noted in patients presenting the symptom of achlorhydria hemorrhagica gastrica; (6) lack of hydrochloric acid and the presence of occult blood were shown to exist for a year before any blood changes were noted in a few cases, paresthesia was evidenced some time previous to blood impairment in some, and the patients had suffered for years from chronic gastrointestinal complaints in others; (7) eighty per cent. of the cases of pernicious anemia have increased temperature at some time during the course of the disease; (9) pure cultures of streptococci have been found in patients with pernicious anemia who were running a fever; (10) bacterial hemolysins and other toxic substances are known to produce anemia resembling the pernicious type; (11) efforts to control the bacterial growth in the gastrointestinal tract have caused complete remissions in this disease in some instances; (12) the phenomena of the blood-picture characteristic of pernicious anemia may be explained by the action of toxins, which impair the formation of antibodies until a bacteremia is produced; (13) the toxins being eliminated by the profuse flora in the gastrointestinal tract, the impairment of bodily resistance is accomplished through their absorption; (14) the reactive and combative ability of patients suffering from achlorhydria differs in different cases, and on this ground might be explained the relative rare occurrence of pernicious anemia. The author thought that these facts would suggest that there might be some direct correlation between the profuse growth of bacteria and the onset of a dyscrasia of the blood known as pernicious anemia.

Pernicious Anemia.—Dr. G. W. MCCASKEY of Fort Wayne, Ind., said that the investigations of the last few years had placed pernicious anemia in a clearer light and indicated the direction in which a final solution of the problem should be looked for. He considered the classification of the different anemias as being unsatisfactory, as yet, the facts that formed the groundwork of the clinical and pathological conception of pernicious anemia having reference to the blood-picture, the data in regard to hematogenesis, and certain points in the clinical history and therapeutic results. There were several facts that appeared to him to make the exclusive theory of toxic irritation of the bone-marrow untenable. In the experimental anemia produced in animals by ricin poisoning, the curious fact has been established that relatively large doses, producing a rapidly progressive anemia, were associated with a normoblastic bone-marrow regeneration; while repeated small doses, acting more slowly, produced mealoblastic degeneration. Undoubtedly, he thought, something besides the specific action of a toxin or group of toxins was necessary, and he believed that in embryological faults or tendencies a plausible explanation, at least, might be sought. The existence of such special tendencies was strictly in accord with well-known biological laws and squared with clinical observations.

Dr. J. A. LICHTY said that all seemed to agree that the underlying basis of anemia was some toxin, but that no one knew what produced the toxin. Gastric disorders, nervous affections, etc., formerly thought to be etiological factors, were recognized now as symptoms. It had been his experience that all these casese had chronic gastritis associated with them, and he wished to ask Dr. Pilcher whether he had meant that all his cases of anemia had had chronic gastritis. Dr. Lichty had found a gastric condition in certain cases in which pernicious anemia was present; for example, in the course of typhoid fever. He

added that of seventy or eighty patients that he had treated for this condition, all had died but one, and that one probably would do so. This latter case was the only one in which there was no fault with the blood.

Dr. A. L. Benedict said that while pernicious anemia was usually associated with achlorhydria hemorrhagica gastrica, this was not always so. In his opinion, pernicious anemia was simply a bad case of anemia, in which it was hard to trace the exact cause.

Dr. Jacob Kaufmann thought that Dr. McCaskey had ably expressed the fact in saying that pernicious anemia was produced by toxins in the blood. The question, however, was where the toxins came from. Taking the view of Dr. McCaskey, one could readily understand that there was a certain group of cases in which the toxin originated in the gastrointestinal canal, chronic gastrointestinal disorders being usually considered to produce the picture of pernicious anemia. Dr. Kaufmann, however, called attention to the fact that the gastrointestinal canal was not only secretory, but also excretory, and said that it was worth while to look into these questions, because the treatment depended on what one considered as the cause in each specific instance. He had seen excellent results in certain cases of pernicious anemia in which gastrointestinal disorders were not the cause of the disease, derived from blood-cultures.

Dr. Willy Meyer said that he had done transfusion of blood in two cases of pernicious anemia during the previous year. In both cases the immediate result was excellent, but later one of the patients died, although the other remained improved.

Dr. Pilcher did not think that every case into which the alkaloid substance had been introduced would develop symptoms of pernicious anemia, as some persons reacted to the same substances differently from others. This was explained by idiosyncrasy. In regard to Dr. Lichty's not finding any chronic gastritis in some of his cases of pernicious anemia, Dr. Pilcher said that, while he did not know what pathological data Dr. Lichty had on that subject, he wished to state that those examining hundreds of cases found that all had pathological evidence of marked atrophy and chronic gastritis of the stomach mucosa.

Dr. McCaskey said that he thought that they got into the gastrointestinal tract incidentally or accidentally. He considered them important in the etiology of the disease, but said that it was hard to determine how large was the part of the bacteria in pernicious anemia. A negative finding was usually the result of the blood-culture. The reason for the existence of achlorhydria was that there was not enough secretion to saturate the proteins. It was a condition of lowered quantity of secretion, and this might come from many causes.

Carcinoma of the Esophagus from the Standpoint of Intrathoracic Surgery.—Dr. Willy Meyer, of New York City thought that if progress was to be made in the radical surgical treatment of carcinoma of the esophagus, the patients must come for operation earlier than at present, and their general health must be sufficiently preserved to warrant resection of the growth. He said that the diagnosis was usually not difficult, even in the early stages. The diagnosis having been made, the cancer must be excised without regard to its location in the course of the esophagus. It commonly covered too large a portion of the tube to render possible the ideal operation, but this resection was often necessary to enable one to make a resection within healthy tissue later on. The feasibility of the latter procedure, with good functional results, had been proved. His experience had shown that the condition in which patients were received did not permit of an operation of such magnitude as was required at one sitting. A two-stage operation was necessary, the details of which he was working out.

Dr. Jesse S. Myer of St. Louis, Mo., remarked that there was no question in his mind but that the operation on carcinoma of the esophagus was a coming one. Everything, he thought, depended on getting hold of the patient early. There was no way of making a diagnosis of carcinoma of the esophagus without the esophagoscope. The use of this instrument was so simple and the suffering of the patients from their disturbances was so intense that they were ready to permit it to be employed. Dr. Myer urged the use of the esophagoscope by every physician doing extraintestinal work. If there was an element of doubt as to the exact condition, a section should be taken out and examined.

Dr. Walter B. Cannon of Boston, Mass., from a physiological point of view, did not know of any reason why one should not cocainize above the vagus nerve, so that the innervation of the heart would not be disturbed on account of mechanical manipulation of the nerve. In a variety of animal observations, he had found that if the laryngeal nerves were cut on both sides, there would be a slight rapidity of the heart, but lower respiration. There would be a temporary loss of tone, in the absence of the vagus stimuli in the stomach and intestines.

Dr. Seymour Basch had been impressed with the apparent simplicity of performing these operations, if they were done early. Of course, it would be impossible to tell patients at this early period that they had a case of carcinoma. If the use of the esophagoscope were as easy as Dr. Meyer had said, there would be no difficulty, Dr. Basch thought, in employing it; but his experience had been that this operation was not such a simple matter. He considered it barbarous, and said that all knew it to be dangerous.

Dr. Willy Meyer stated that Dr. Sharp, of Berlin, had devised a sound that had a rubber balloon, which was to be blown up with water. This instrument was for use in early diagnosis, and its inventor claimed that in no case could he do his diagnosing so early with the esophagoscope as with this sound, which Dr. Meyer said was used by him at the German Hospital. If both pneumagastrics were involved, both could not be divided. If, in exceptional cases, this could be done and the patient would not die from paralysis of the heart or lungs, it would mean a great step forward. He thought that all those working inadequately for certain ends should combine their forces, so that, no matter what their specialties might be, one goal might be before them all.

Dr. Walter B. Cannon said that he did not mean to have the inference drawn from his remarks that it was perfectly feasible to cut both pneumogastrics without producing any harmful effects. He did not think that there would be definite effects on the heart and lungs produced by cutting them, if the laryngeal were left. It was in relation to the alimentary canal, he said, that the trouble arose, there being disturbance of movement and secretion. By carefully washing out the stomach and avoiding the production of epithelioma, a patient would live for a year with both pneumogastrics cut; but it required the greatest care to bring about such a result.

Dr. Willy Meyer explained that, in view of the extreme thinness of the esophagus, the nerves became intimately adherent to the tumor; so that the greatest delicacy of manipulation was necessary. In some cases, it was impossible to operate. If there was support, the operation could be done.

Crypts and Columns of Morgagni: Their Relationship to Rectal Diseases.—Dr. James P. Tuttle of New York City, stated that the semilunar, or anal, valves (called, also, the pockets, or crypts, of Morgagni) dipped down between the mucocutaneous lining of the anal canal and extended more or less deeply into its caliber. The rectal columns attached their base at the upper margin, between the valves, and furnished an exit for the veins of the rectum to anastomose with those of the anus. To these two structures, the crypts and columns of Morgagni, especially the latter, he wished to call attention as influencing rectal diseases such as pruritus ani, hemorrhoids, chronic spasmodic sphincter, obscure fissure, invisible ulceration of the anal canal, and skin tabs. In operating for any of these conditions, he said, one often failed to cure them unless these structures were properly attended to.

Dr. Seymour Basch said that there were three symptoms that were almost constant in these cases—pain, bleeding and itching; but that there were intervals of cessation of one, two or all of these symptoms. There existed many anal canals that one could not thoroughly inspect without a general anesthetic. In probably half of his cases, he could readily locate these points with the use of the speculum. The points to look at were in the right and left posterior quadrants and the anterior median line. Occasionally they were found elsewhere. There might be only one of these that was pathological. The symptoms that these produced were often referable to the remote parts of the body. He attributed his failures to relieve entirely anal pruritus in some cases to the fact that he had attempted to do it under local anesthesia. Pruritis, he said, was not a disease, but a symptom. In some cases, there were no visible external manifestations; while in others, there were distinct skin changes.

Dr. Willy Meyer asked whether Dr. Tuttle considered every crypt into which he could enter his probe pathological.

Dr. Tuttle said that he did not consider every crypt diseased. It depended on how deep the probe would go in. If it went no farther than the subcutaneous tissues, he did not consider the crypt diseased; but when a probe drew

blood in one of the crypts or excited itching or pain, then he considered that there existed a pathological condition. He stated that there was no organ of the body too remote to be affected reflexly by one of these painful and concealed ulcers, and this applied to the reflex action of the crypts. In constipation or obstipation, stretching of the sphincter might relieve the patient for awhile; but the condition would return, if one of the crypts was diseased. Cutting got at the bottom of the trouble, which stretching did not do. The so-called watery urethral discharge was due, in a good many cases, to obscure fissure or inflammation in the front sinus. He had successfully treated, within the last six months, seven of these cases.

The following officers were elected for the ensuing year: *President*, Jacob Kaufmann, of New York City; *First Vice-President*, Joseph C. Bloodgood, of Baltimore, Md.; *Second Vice-President*, William Gerry Morgan, of Washington, D. C.; *Secretary and Treasurer*, Franklin W. White, of Boston, Mass. The date and place of the next annual meeting have not been decided upon.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Arizona State Board of Medical Examiners.

ANATOMY.

1. What arteries supply the heart with blood, and where do they originate?
2. Describe the thoracic duct.
3. Describe the thyroid gland, including blood and nerve supply.
4. Where is the fissure of Sylvius, and what artery does it contain?
5. What muscles assist in (*a*) mastication; (*b*) deglutition?
6. Describe the diaphragm, its principal openings, and nerve supply.
7. Name the bones of the head.
8. Name the ligaments of the hip joint.
9. State (*a*) the nerve supply of the rectum and (*b*) the blood supply of the rectum.
10. Describe the inguinal canal.

PHYSIOLOGY.

1. What part of the nervous system is involved in stammering speech?
2. Describe the pneumogastric nerve and its functions.
3. Describe lymph and how it is formed.
4. Classify foods and give a general description of each.
5. What is the pulse and what do its varieties signify within physiological limits?
6. Describe the physiology of menstruation.
7. Briefly describe visual accommodations.

HYGIENE.

1. What means should be taken to prevent spreading of smallpox?
2. What means should be taken to prevent spreading of diseases in schools?
3. What regimen should be enforced in the sick room of tuberculous patients?
4. Why should we abolish the common drinking cup?
5. Describe the proper care of foods in stores and markets, and why?
6. What are the dangers from drinking water from an unprotected watershed?
7. Why are plumbing fixtures ventilated?

MATERIA MEDICA.

1. Define materia medica and therapeutics.
2. Define tincture, extract, and ointment.
3. By what process and from what source is sugar of milk principally obtained?
4. State the source of ichthyol and give its uses in medicine.
5. Give the Latin title of paregoric; name all its constituents, and give the amount of the principal drug in one ounce of the mixture.
6. Give the composition of the official compound cathartic pill.
7. Name the alkaloids of nux vomica.
8. What is incompatibility in medicine, and what are the different kinds of incompatibility? Give an example of each.
9. Describe four diuretics and give dose of each.
10. What class of acids would you use to acidify alkaline urine? Name one and give dose.

CHEMISTRY AND TOXICOLOGY.

1. What element occurs most abundantly in Nature and what are three of its more common combinations?
2. Atmospheric air is composed of what elements and in what proportion by volume?
3. Give definition of acids and formulæ of six acids commonly used in medicine.
4. Define a salt and explain the difference between normal and basic salts.
5. What are hydrocarbons? Mention three.
6. Give difference between alcohols and ethers.
7. What chemical elements occur in all proteids? Name three common proteins.
8. What are the common sources of acetic acid?
9. Name the normal constituents of human milk and their approximate proportions.
10. Give treatment of arsenic poisoning.
11. What is the chemical antidote for carbolic acid poisoning? What would you use for physiological antidote?
12. What is best treatment for poisoning by strong mineral acids?

PATHOLOGY.

1. Define hyperemia and give varieties and causes.
2. Define transudate and exudate with examples of both.
3. Define (*a*) embolism, (*b*) thrombosis; examples.
4. Inflammation—define and give symptoms.
5. Describe the pathological findings in typhoid fever.

ANSWERS.

ANATOMY.

1. The arteries which supply the heart with blood are the right and left coronary arteries, which arise from the ascending aorta.

2. The *thoracic duct* extends from the second lumbar vertebra, where it commences by a dilatation, the *receptaculum chyli*, to junction of left internal jugular with left subclavian vein. The abdominal part is placed on the front of the body of the second lumbar vertebra, behind and to the right side of the aorta and on the inner side of the right crus; it then enters the thorax through aortic opening, on the right side of aorta, lying between it and the vena azygos major, and passes upward to right of aorta on right intercostal vessels. Opposite the fourth dorsal vertebra it passes to the left behind arch, and runs along the left side of the esophagus, behind the left common carotid artery. At the level of the seventh cervical vertebra it turns outward, and, passing behind left internal jugular and crossing first part of left subclavian artery, arches over the apex of the left pleura to open at the angle of union of the left internal jugular and left subclavian veins. (From *Aids to Anatomy.*)

The *portions of the body drained by it* are: Both lower limbs; abdomen, except upper surface of the liver; left half of thorax; left side of head and neck, and left upper extremity.

3. The *thyroid gland* consists of two lateral lobes and an isthmus; it is situated at the front and sides of the neck. The lobes extend from about the middle of the thyroid cartilage to the fifth or sixth tracheal ring; the isthmus generally covers the second and third tracheal rings. The lobes measure about 2x1¼x¾ inches; the gland usually weighs about one ounce. *Blood supply:* Superior, and inferior thyroid arteries, with thyroidea ima; and superior, middle, and inferior thyroid veins. *Nerve supply:* Branches from the inferior laryngeal nerve, and from the middle and inferior cervical ganglia of the sympathetic.

4. The *fissure of Sylvius* begins at the base of the brain at the outer part of the anterior perforated space, passes outward, backward, and upward, and ends in the parietal lobe. This is the horizontal limb of the fissure. From the anterior part of the horizontal limb a short fissure extends forward and upward into the frontal lobe. This is the vertical or ascending limb of the fissure. The fissure separates the frontal and parietal lobes of the brain from the temporal lobe. It lodges the middle cerebral artery.

5. *Muscles of mastication:* Masseter, temporal, external pterygoid, internal pterygoid, and buccinator. *Muscles of deglutition:* Buccinator, hyoglossus, styloglossus, palatoglossus, palatopharyngeus, azygos uvulæ, tensor palati, levator palati, stylopharyngeus, stylohyoid, geniohyoid, mylohyoid, thyrohyoid, digastric, constrictors of pharynx, and the intrinsic muscles of the tongue.

6. The *diaphragm* is a musculofibrous septum which divides the thoracic from the abdominal cavity; it is fan-shaped; the broad, elliptical portion is horizontal, and the crura are vertical. It is attached to the ensiform, to the internal surfaces of the lower six costal cartilages, to bodies and intervertebral substances of first, second, and third lumbar vertebræ. Its *openings* are: (1) The aortic, transmitting the aorta, vena azygos major, and the thor-

acic duct; (2) the esophageal, transmitting the esophagus, pneumogastric nerves, and some small esophageal arteries; (3) the opening for the vena cava, transmitting the inferior vena cava, and small branches of the right phrenic nerve; (4) the right crural, transmitting the right splanchnic nerves; (5) the left crural, transmitting the left splanchnic nerves and the vena azygos minor. *Nerve supply:* The phrenics, lower intercostals, and the phrenic plexus of the sympathetic.

7. The *bones of the head* are: Occipital, two parietal, frontal, two temporal, sphenoid, ethmoid, two nasal, two superior maxillary, two lacrymal, two malar, two palate, two inferior turbinated, inferior maxillary, and vomer.

8. The *ligaments of the hip joint* are: Capsular, ilio-femoral, teres, cotyloid, and transverse.

9. RECTUM. *Nerve supply:* From sacral plexus, fourth sacral, and inferior hemorrhoidal nerves, and from inferior mesenteric and hypogastric plexuses. *Blood supply:* Superior hemorrhoidal, middle hemorrhoidal, and inferior hemorrhoidal arteries and veins.

10. The *inguinal canal* is an oblique canal situated a little above and running parallel with Poupart's ligament. It is from an inch and a half to two inches in length, runs downward and inward, and extends from the internal abdominal ring to the external abdominal ring.

Its *boundaries are: In front:* the skin, superficial fascia, aponeurosis of the external oblique, and (for its outer third) the internal oblique. *Behind:* the conjoined tendon, the triangular fascia, the transversalis fascia, subperitoneal fat, and peritoneum. *Above:* the fibers of the internal oblique and transversalis. *Below:* Poupart's ligament and the transversalis fascia.

Contents: the spermatic cord in the male, and the round ligament in the female.

PHYSIOLOGY.

1. The hypoglossal nerve and the motor centers for speech in Broca's convolution (in the left cerebral hemisphere) are concerned.

2. PNEUMOGASTRIC NERVE. *Superficial origin:* Groove between restiform and olivary bodies. *Deep origin:* Nuclei in floor of fourth ventricle. *Distribution* is shown by the names of the branches: Meningeal, auricular, pharyngeal, superior and inferior laryngeal, cardiac, pulmonary, esophageal, and gastric. *Function:* It supplies (1) *motor* influence to the pharynx and esophagus, stomach, and intestines, to the larynx, trachea, bronchi, and lungs; (2) *sensory* and, in part (3) *vasomotor* influence, to the same regions; (4) *inhibitory* influence to the *heart;* (5) *inhibitory* afferent impulses to the *vasomotor center;* (6) *excito-secretory* to the salivary glands; (7) *excito-motor* in coughing, vomiting, etc.

3. LYMPH. *Origin:* There are two theories as to the formation of lymph: (1) That it is formed from the blood plasma by the processes of filtration, diffusion, and osmosis. (2) That in addition to these, the endothelial cells of the capillaries exercise some influence. *Description:* Lymph is a colorless, albuminous fluid, alkaline in reaction, with specific gravity of about 1015, containing lymph corpuscles, and coagulating when drawn from its vessels. *Composition:* Proteins (serum albumin, fibrinogen), sugar, sodium chloride and carbonate, water, urea fat. *Function:* To provide cells and tissues with materials necessary for their growth, repair, and functional activities; and to receive and carry away their waste products.

4. *Foods are classified* as:

- Organic
  - Nitrogenous—Proteid
  - Non-nitrogenous
    - Carbohydrates
    - Fats
- Inorganic
  - Salts.
  - Water.

FOOD.	FUNCTIONS.
Proteids.	
1. All substances containing nitrogen, of a composition identical with, or nearly that of albumin; proportion of N to C being nearly as 2 to 7.	Formation and repair of tissues and fluids of body. Regulation of absorption and utilization of oxygen. May also form fat and carbohydrate, and yield energy sometimes. In most foods the above, both animal and vegetable, are largely converted into albumoses and peptones during digestion. These perform the above functions less perfectly, or only under particular circumstances.
2. Substances containing a larger proportion of N are apparently less nutritious; proportion of N to C about 2 to 5½.	These substances appear essentially as regulators of digestion and assimilation, especially with reference to the gelatin group.
3. Extractive matters, such as are contained in the juice of the flesh.	
Carbohydrates.	
Substances containing no N, but made up of C, H and O; the O being exactly sufficient to convert all the H into H_2O.	Production of energy and animal heat by oxidation. Form fats and possibly some proteids.
Fats.	
Substances containing no N, but made up of C, H and O; the proportion of O being *less* than sufficient to convert all the H into H_2O.	Supply of fatty tissues, nutrition of nervous system; supply of energy, and animal heat by oxidation.
Salts.	Support of bony skeleton, supply of HCl for digestion, regulation of energy and nutrition.

(Notter and Firth's *Hygiene.*)

5. The *pulse* is a wave of expansion which travels along the arteries, and is due to the discharge from the left ventricle of a volume of blood, during systole, into the already full arterial system. The points to be observed are: (1) Its *frequency;* this gives the rate of the heart beats. (2) Its *compressibility:* this denotes the force with which the heart is beating. (3) Its *tension;* this denotes the peripheral resistance, and also the state of the arterial walls. (4) Its *regularity* or *rhythm:* this denotes the regularity (or otherwise) of the heart's action in force or rhythm. The average rate during infancy is about 120 per minute; during youth, about 80; and during old age, about 60. The normal ratio of pulse to respiration is about 4:1.

6. *Menstruation* is a periodic disturbance in the female characterized by a bloody discharge from the uterine cavity; it occurs periodically during the time of the woman's sexual activity, but is temporarily suspended during pregnancy and early lactation. The relation existing between ovulation and menstruation is not known. The two processes are usually coexistent, but they may be independent of each other. The following theories have been held: (1) Menstruation is dependent upon ovulation; (2) ovulation is dependent upon menstruation; (3) they are independent of each other; (4) they both depend upon some other (at present unknown) cause.

7. "*Mechanism of Accommodation.*—The lens is an elastic structure, and when released from the flattening influence of its suspensory ligament tends to assume a spherical shape. During accommodation the ciliary muscle (especially the circular fibers) contracts, drawing forward the choroid and relaxing the suspensory ligament; this diminishes the tension of the lens capsule and allows the inherent elasticity of the lens to increase its convexity. The change in curvature affects chiefly the anterior surface of the lens. This is Helmholtz's theory and the one usually accepted. Lately Tscherning has advanced a different theory; he maintains that the ciliary muscle increases the tension of the suspensory ligament during contraction and that this causes peripheral flattening of the lens with bulging anteriorly at its center. The act of accommodation is accompanied by contraction of the pupil, and (in binocular vision) by convergence of the visual lines." (May's *Diseases of the Eye.*)

HYGIENE.

1. *To prevent spread of smallpox:* Vaccinate every one during an epidemic; isolate and quarantine the patient; no one but the physician and nurse must enter the room; the physician should put on a large washable gown when he goes in, and remove it on leaving, at the same time washing his hands in a disinfectant; the nurse, when she leaves the sick room, should also remove her clothes and put on others, at the same time disinfecting herself. Flies and vermin must be kept out of the room, doors and windows should be screened. At the termination of the disease everything should be disinfected; toys, and books, etc., are better burned; the room or rooms should be fumigated with sulphur or formaldehyde.

2. *The principal means of preventing the spread of contagious diseases in schools* are: Regular and efficient inspection by physicians; prompt exclusion and isolation of any one suffering from a contagious disease, or coming from a house where such disease is; compulsory notification of all infectious and contagious diseases; individual towels, drinking vessels, and other implements; children who have had a contagious or infectious disease or who have come from a house where such disease prevailed should not be readmitted to school until sufficient time has elapsed since the occurrence of the last case to insure safety.

3. *Hygienic precautions to be taken in treating a case of tuberculosis:* "The patient's quarters should be free from dust, and admit of spending many hours daily in the open air in all weathers, properly sheltered, and, if very ill, lying wrapped in a hammock or reclining chair. His bedroom should be well aired at night, draughts being avoided. The room should be uncarpeted and free from hangings. It should be often cleaned and periodically disinfected. All sputum should be collected in paper spit-cups, which should be burned daily. Smoking should be forbidden. Harm is done by any exercise which results in fatigue, and while fever exists it should not be attempted at all. Patients should be taught the necessity of practising lung gymnastics and breathing only through the nose, which should be kept clear and free from occlusion by secretions, or an hypertrophied catarrhal mucosa. . . . The clothing should be woolen, but not too heavy, or sweating is increased; and a flannel nightgown and loosely knit leggings should be worn at night in cool weather. The skin should be cleansed by daily sponge-baths of lukewarm alcohol and water." (Thompson's *Practical Medicine.*)

4. The common drinking cup should be abolished because its use is both dirty and dangerous; diseases are conveyed in this way.

5. The stores and markets should be constructed so as to allow abundant light and ventilation; the walls should be solid, impervious, and non-absorbent; the floors should be non-absorbent, graded, drained, and capable of being properly flushed. Animals and insects should be kept out; windows should be screened; the temperature should be regulated. Animals often impart diseases (such as intestinal parasites) to vegetables; insects and parasites transmit diseases; flies are notorious offenders in this way. The food should be pure when it is admitted to the market or store. Food should be covered when practicable. Everything in connection with food, store, market, baskets, implements, etc., should be kept clean. Implements used for one kind of food should not be used for another kind of food. All remnants of food should be promptly removed and covered up.

6. Water from an unprotected watershed is liable to pollution by sewage and waste products.

7. Plumbing fixtures are ventilated to prevent undue pressure of air or gases being exerted upon the house fixings and later on entering the house.

MATERIA MEDICA.

1. *Materia medica* is that branch of science which treats of the substances and agents used as medicines.

Therapeutics is the art of healing.

2. A *Tincture* is an alcoholic solution of a medicinal substance.

An *Extract* is a solid or semi-solid preparation produced by the evaporation of a solution of some vegetable substance.

An *Ointment* is a fatty preparation, of a softer consistence than a cerate, and intended to be applied to the skin by inunction.

3. *Sugar of milk* is obtained from the whey of cow's milk by the process of evaporation: it is then purified by re-crystallization.

4. Ichthyol is obtained from ichthyosulphuric acid, which comes from a crude oil obtained by destructive distillation of fossil fish found in the earth in the mountains of Tyrol. It is used in inflammatory conditions generally, erysipelas, rheumatism, and certain chronic skin diseases.

5. The *Latin title of paregoric* is Tinctura opii camphorata. Its constituents are: Powdered opium, benzoic acid, camphor, oil of anise, glycerin, and diluted alcohol. One ounce of the mixture contains nearly two grains of opium.

6. The *official compound cathartic pill* contains: Compound extract of coloeynth, calomel, resin of jalap, and gamboge.

7. The *alkaloids of nux vomica* are: Strychnine and brucine.

8. *Incompatibility* is that relation between medicines which renders their admixture unsuitable. Incompatibility may be chemical, pharmaceutical, or therapeutic. *Chemical incompatibility* is seen in compounding an acid with a base, and forming a salt. *Pharmaceutical incompatibility* is seen in compounding a resinous tincture with an aqueous solution. *Therapeutic incompatibility* is seen when two agents are administered together which have an opposite action, such as belladonna and physostigma.

9. *Four diuretics, with doses:* Potassium acetate, 30 grains; Potassium citrate, 15 grains; Infusion of digitalis, 2 drams; and spirit of nitrous ether, 30 minims.

10. Organic (aromatic carboxylic) acids, such as benzoic acid, or salicylic acid. Dose of benzoic acid, 7½ grains.

CHEMISTRY AND TOXICOLOGY.

1. The element occurring most abundantly in nature is oxygen. It is in combination in water, quicklime, litharge.

2. Atmospheric air is composed of 21 parts, by volume, of oxygen; and 79 parts, by volume, of nitrogen.

3. An *acid* is a compound of an electronegative element or residue with hydrogen, which hydrogen it can part with in exchange for an electropositive element, without the formation of a base. *Six acids used in medicine:* Hydrochloric acid, HCl; sulphuric acid, H_2SO_4; nitric acid, HNO_3; acetic acid, CH_3COOH; phosphoric acid, H_3PO_4; and salicylic acid, $C_6H_4OH.COOH$.

4. A *salt* is a substance formed by the substitution of an electropositive or basylous element for part or all of the replaceable hydrogen of an acid. When all of the replaceable hydrogen of the acid has been replaced, the salt is called a *normal salt*. A *basic salt* results when part of the OH groups of a base are replaced by an acid group.

5. *Hydrocarbons* are substances containing carbon and hydrogen only; as methane, ethane, propane.

6. *Alcohols* are the hydroxides of hydrocarbon radicals; whereas *ethers* are the oxides of hydrocarbon radicals.

7. All proteids contain carbon, hydrogen, nitrogen, and oxygen. *Three common proteins:* Serum albumin, lactalbumin, and keratin.

8. *Common sources of acetic acid:* Starch, sugar, gelatin, fibrin, cellulose, tartaric and citric acids.

9. *Human milk* contains: Water, about 87 per cent.; proteid, about 2 per cent.; fats, about 3 to 4 per cent.; and milk-sugar, about 6 to 7 per cent.

10. The official antidote for arsenical poisoning is freshly prepared solution of ferric hydroxide. Mix 40 parts of soluton of ferric sulphate with 125 parts of water and keep it in a large well-stoppered bottle. Rub ten parts of magnesium oxide with some cold water to a thin smooth mixture, transfer it to a bottle holding about a liter, and then fill with water to about 750 c.c. When required for use, shake the magnesium mixture, add it gradually to the ferric sulphate solution, and shake them together till the mixture is uniform.

11. The *chemical antidote* for carbolic acid poisoning is sodium sulphate; the *physiological antidote* is alcohol.

12. In poisoning by strong mineral acids, give magnesia suspended in a small quantity of water, or a strong solution of soap.

PATHOLOGY.

1. *Hyperemia* is excess of blood in the dilated vessels of a part. It is: (1) *Active* or *arterial*, when there is excess of arterial blood in a part, and (generally) an acceleration of flow. (2) *Passive* or *venous*, or *mechanical*, in which the excess of blood is in the veins and capillaries, and the flow is retarded.

Causes of arterial hyperemia: Diminished arterial resistance (fatigue, injuries, sudden removal of pressure, inhibition of the vasotonic action of the sympathetic system, and stimulation of the vasodilator nerves. *Causes of venous hyperemia:* Diminished cardiac power; dilated or obstructed or rigid arteries; absence of muscular contractions on the veins, incompetence of valves in the veins.

2. A *transudate* is a fluid within the tissues not the result of inflammation. An *exudate* is the fluid present in inflammatory conditions. Example of the former, edema, dropsy; of the latter, in inflammations.

3. A THROMBUS is a blood clot formed in the blood-vessels during life. The process is called thrombosis. *Causes:* Changes in the blood current; changes in the vessel wall; anything within the blood current not covered with endothelium. Generally more than one of these conditions are present. *Results:* Formation of emboli; infarction; heart clot, and sudden death; cerebral softening; the thrombi may become organized, liquefy, soften, become calcified, putrefy, become discolored, or may resolve.

An EMBOLUS is a plug in the circulation. The process is called embolism. *Causes:* Thrombi, detached pieces from the heart valves, microorganisms, oil, fat, parasites, pieces of new growths. *Results:* Obstruction to the circulation;

infarction, inflammation of blood-vessel; dilatation of blood-vessel.

4. *Inflammation* is the name given to the series of changes occurring in a part as the result of injury, provided that the injury does not destroy the vitality of the part. *Symptoms:* Redness, swelling, pain, heat, and disordered functions.

5. *Pathology of typhoid fever.*—"Principally inflammation of the lymphoid tissue of the lower portion of the ileum, with more or less catarrh throughout the bowels. Peyer's Patches—1st week.—Are swollen through infiltration of leucocytes, the surfaces raised and fawn-colored—the infiltration involves the submucous coat. The lesions are most numerous at the lower end of the ileum. 2nd week.—The surface becomes abraded; sloughs form, which are often bile-stained. 3rd week.—Sloughs come away, leaving ulcerating surfaces. Typical typhoid ulcers are thus formed. A few solitary glands undergo the same process. At the end of the week the ulcers begin to granulate, but healing is usually slow. Mesenteric glands may undergo the same changes, but more often become swollen, red, and tender only, or break down into cheesy masses. Other organs—Spleen and liver are enlarged; heart is soft and flabby. The voluntary muscles undergo granular degeneration; in fact, similar changes to those found after death from high temperature." (Wheeler and Jack.)

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. 14
Arizona*	J. W. Thomas, Phoenix	Phoenix	Jan 6
Arkansas	F. T. Murphy, Brinkley	Little Rock	..
California*	Chas. L. Tisdale, 929 Butler Building, San Francisco		..
Colorado	David A. Strickler, Empire Building, Denver	Denver	Jan. 7
Connecticut*	Chas. A. Tuttle, New Haven	New Haven	Mar. 11
Delaware	J. H. Wilson, Dover	Dover	Dec. 17
Dist. of Col'ba	Geo. C. Ober, Washington	Washington	Jan. 14
Florida*	I. D. Fernandez, Jacksonville	Jacksonville	May 12
Georgia	C. T. Nolan, Marietta	Atlanta	May ..
Idaho*	O. J. Allen, Bellevue	Boise	Apr. 1
Illinois	J. A. Egan, Springfield	Chicago	Jan. ..
Indiana	W. T. Gott, Crawfordsville	Indianapolis	Jan. 14
Iowa	G. H. Sumner, Des Moines	Des Moines	.. ..
Kansas	H. A. Dykes, Lebanon	Topeka	Feb. 11
Kentucky	J. N. McCormack, Bowling Green	Louisville	Dec. 12
Louisiana	A. B. Brown, Cusach's Bldg., New Orleans	New Orleans	June 5
Maine	F. W. Searle, Portland	Portland	.. ..
Maryland	J. McP. Scott, Hagerstown	Baltimore	Dec. 10
Massachusetts*	E. B. Harvey, State House, Boston	Boston	.. ..
Michigan	B. D. Harison, 205 Whitney Building, Detroit	Ann Arbor	June 10
Minnesota	W. S. Fullerton, St. Paul	Minneapolis	Jan. 7
Mississippi	S. H. McLean, Jackson	Jackson	.. ..
Missouri	Frank B. Hiller, Jefferson City		.. ..
Montana*	Wm. C. Riddell, Helena	Helena	Apr. 1

W. Virginia	H. A. Barbee, Point Pleasant	Wheeling	.. ..
Wisconsin	J. M. Beffel, Milwaukee	Milwaukee	Jan. 14
Wyoming	A. B. Tonkin, Riverton	Riverton	.. ..

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Care of Motor Tires.—For the motorist who wishes to economize in the matter of tires, the points to be observed are: (1) Manipulate the clutch and apply the brakes carefully. (2) Concentrate the weight as much as possible over the back axle. (3) Test the wheels carefully for parallelism and alignment both when the car is empty and loaded. (4) Fill up or vulcanize cuts in the protective rubber tread as soon as they appear. (5) Examine the tires periodically for nails embedded in the tread. (6) Run the tires in alternate directions from time to time.—*Automobile Topics.*

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

DER JETZIGE STAND DER KREBSFORSCHUNG. By Prof. Dr. GEORG KLEMPERER. 74 pages; paper; price 2 M. August Hirschwald, Publisher, Berlin.

ON THE OXYDATIONS AND CLEAVAGES OF GLUCOSE. YEAST GLUCASE, A NEW GLUCOLYTIC FERMENT. By VICTOR BIRCKNER. 183 pages; paper; price .75. University of California, Publishers, Berkeley.

COMMENTS ON SOME PLANS OF HOSPITAL CONSTRUCTION. By HERMAN M. BIGGS, M.D. 61 pages; illustrated; paper. Department of Health of the City of New York, Publishers.

TYPHOID FEVER IN NEW YORK CITY. By CHARLES F. BOLDUAN, M.D. 52 pages; paper. Department of Health of the City of New York, Publishers.

THE DIVISION OF CHILD HYGIENE OF THE DEPARTMENT OF HEALTH OF THE CITY OF NEW YORK. By S. JOSEPHINE BAKER, M.D. 103 pages; illustrated; paper. Department of Health of the City of New York, Publishers.

THE TUBERCULOSIS CLINICS AND DAY CAMPS OF THE DEPARTMENT OF HEALTH. By JOHN S. BILLINGS, Jr., M.D. 123 pages; illustrated; paper. Department of Health of the City of New York, Publishers.

WHEELER'S HANDBOOK OF MEDICINE. By WILLIAM R. JACK, B.Sc., F.R.F.P.S.G. Fourth Edition. 532 pages; flexible leather; price $3.25; cloth; $3.00 net. William Wood & Company, Publishers, New York.

PUBLIC HEALTH CHEMISTRY AND BACTERIOLOGY. By DAVID MCKAIL, M.D., D.P.H., F.R.F.P.S.G. 409 pages; cloth; price $2.50 net. William Wood & Company, Publishers, New York.

LEHRBUCH DER HAUT UND GESCHLECHTSLEIDEN. By Dr. S. JESSNER. Vol. I. No. 1. 96 pages; illustrated; paper. Curt Kabitzsch, Publisher, Würzburg.

HANDBUCH DER SPEZIELLEN CHIRURGIE DES OHRES UND DER OBEREN LUFTWEGE. Vol. II. No. 1. By Dr. L. KATZ, H. PREYSING and F. BLUMENFELD. 56 pages; illustrated; paper; price 6.50 M. Curt Kabitzsch, Publisher, Würzburg.

DIE SCHUSSVERLETZUNGEN DES SCHADELS IM KRIEGE. By OTTO HOLBECK. 479 pages; illustrated; paper; price 12 M. August Hirschwald, Publisher, Berlin.

A MANUAL OF SURGICAL TREATMENT. By Sir W. WATSON CHEYNE, Bart., C.B., and F. F. BURGHARD, M.S., F.R.C.S. Vol. III. 575 pages; illustrated; cloth. Lea & Febiger, Publishers, Philadelphia and New York.

THE ANATOMY OF THE HUMAN EYE AS ILLUSTRATED BY ENLARGED STEREOSCOPIC PHOTOGRAPHS. By ARTHUR THOMSON, M.A., M.B., F.R.C.S. Oxford University Press, Publishers, New York.

Miscellany.

Human Life as a National Asset.—At the meeting of the National Conservation Congress, held in Indianapolis on October 2 and 3, Mr. E. E. Rittenhouse, Conservation Commissioner of the Equitable Assurance Society, read a paper with this title. He asked that the Congress should consider the following suggestions: 1. To encourage business institutions, civic, social, and religious organizations which have influence over any considerable number of people to join in, at least, some of the many phases of the life conservation campaign. 2. To encourage the education of the individual to adopt healthful habits of life, to avoid the intemperate life, which means excess in eating, drinking, working, and playing, and unhealthful indulgence in indolence as well. 3. To encourage communities to establish and maintain ample public health organizations consistent with the magnitude of the work in hand. 4. To advocate the organization of local health leagues as a stimulus to public interest and to give aid and support to the public health service. 5. To encourage the slowly growing sentiment for a rigid supervision, and isolation, if necessary, of victims of tuberculosis, which is the only way in which this devastating plague can be stamped out. 6. To advocate the employment of civic nurses in the health service, who may also act as health inspectors and aid in educational work. 7. To advocate the issuance and distribution by the states or municipalities of an official prevention manual to teach the public how to avoid preventable disease. 8. To urge every individual to go to his or her doctor for periodical health inspections to detect disease in time to arrest or cure it. 9. To urge employers of labor to give their employees these examinations free as a part of their efficiency and welfare program. 10. To encourage philanthropy, now so generously contributing for the care of the sick, to also enter the field of disease prevention which it has so far quite generally neglected.

The Waste of Medical Experience.—When an old practitioner passes away his experience dies with him. Books there are in abundance and the reports of cases generally contribute something to the sum knowledge. Without such records progress would be impossible, and every case honestly reported adds a stone to the slowly rising temple of truth. But men like Jenner or Gull are represented in catalogues by only a few papers and addresses. What would one not give for the experience of a man who had been in general practice for half a century, who had seen many whom he had brought into the world grow up and in their turn become parents and then pass away, all the time under his observation! Such men seldom have time to write down what they see and what their practice has taught them. Often, too, they have not the faculty of exposition. Generally, however, such experience is so personal to the man, consisting as it does of the accumulated impressions of all the senses gathered by long observation, that by its very nature it is not transmissible to another. It was in this that the old system of pupilage had an advantage which modern scientific training, with all the apparatus of the clinical laboratory, fails adequately to supply. There is the physiognomy of disease, the interpretation of which has, owing to the large use of instruments of precision, become almost a lost art. There is the knowledge of that subtle something, called for convenience "constitution," which so often makes all the difference between success and failure in treatment, and other still more intangible things, which together make up the knowledge a man acquires in practice. The young man writes because he thinks he has something new to tell; the old man does not write because he finds age has made him indolent and he is perhaps unwilling to put his experience on paper. Yet if old practitioners could and would set down faithfully what they had seen and done in their professional career, a mine of information not to be found in textbooks or scientific monographs would be available.—*British Medical Journal*, October 26, 1912.

Molière and Medicine.—B. M. Randolph states that no one has ridiculed physicians more effectively and amusingly than has Molière, who directed the shafts of his satire without compunction against the abuses and absurdities of his time, but who seemed to have an especial antipathy for doctors. Various reasons have been assigned for this: his landlord was a physician, and there was a constant feud between the wives of the two; Molière himself was a consumptive and was embittered by personal experience of the futility of remedies employed in treating him; he attributed to malpractice the death of his only son, and also that of an intimate friend who received a triple dose of antimony; a medical friend, a physician, was ostracized by the faculty for approving a quack remedy. While these facts doubtless influenced Molière, it is not necessary to attribute his attitude to mere prejudice. The absurdities, pretensions, and avarice of the practitioners of the time, and their pedantry, assumption of dignity, affected dress, and professional jargon could not fail to appeal to the satirist's pen.—*Old Dominion Journal of Medicine and Surgery.*

Damning Carbureters.—Time was when ignition troubles got to be a sort of habit with the motorist; his obsession was that whenever anything went wrong the spark was at fault. Now the ignition is about the last thing to be inspected when the motor fails to move, and instead of the old obsession a new one has taken possession of the man behind the wheel. It is that no matter what goes wrong the carbureter needs attention. Often the idea takes possession of the motorist's soul that no amount of fixing will remedy the difficulty—that a new carbureter of a different sort is absolutely necessary. Such a one was apprehended by an expert of the maker of that particular carbureter, hurriedly tucking up his sleeves and declaring with sputtering anathemas that he was going to knock the blamed thing off his engine—he wouldn't stand for it any longer, so he wouldn't. And only after much persuasion would he agree to stand aside and let the expert have a look around before the axe was swung. This is what he found: Two intake valves riding on the push-rods, one spark-plug porcelain cracked, another plug with the points touching, one magneto brush burned up, two leaky valves, all the cylinders loaded with carbon and water in the gasoline. "These things all together make a 'bum' carbureter," concluded the agent sapiently at the end of the examination. Unquestionably carbureters are giving more trouble today than ever before. The fact is brought to notice only because carhureter difficulties have increased a very little while others have decreased a good deal. The only reason is that the quality of gasoline now served to the motorist is poorer than ever before and more variable. For its higher price the "trust" is blamed in terms of outraged innocence, but the effects of its low and variable gravity, its decreased volatility and its high percentage of impurities, instead of being attributed to the proper source, are laid at the door of the carbureter maker. The injustice probably will result in an early improvement of the breed of "mixers," while leaving the public intelligence absolutely dulled to the vital question of fuel supply—*Automobile Topics.*

THE SANITARY CONTROL OF LOCAL MILK SUPPLIES THROUGH LOCAL OFFICIAL AGENCIES.*

BY ERNST J. LEDERLE, PH.D.,

COMMISSIONER OF HEALTH, CITY OF NEW YORK.

IT will perhaps be generally recognized by those interested in the administrative control of the production and sale of milk that New York City offers a most conspicuous example of a municipality undertaking practically the entire supervision of its own milk supply all the way from the cow to the consumer. Most large cities doubtless exercise more or less jurisdiction over the sale of milk within their limits, but no other city that I know of has developed such an extensive system of inspection of dairies and creameries as is practised by the City of New York, notwithstanding that nearly all of the 45,000 farms on which our milk supply is produced are located outside the city limits and more than 6000 of them outside the State of New York.

The Board of Health has power to adopt a sanitary code without the concurring vote of any other municipal authority, and this code has the full force and effect of law in New York City so long as its provisions are consistent with general State laws. The existing system of public control of New York's milk supply is based upon the sanitary legislation of the Board of Health, in the form of appropriate sections of the Sanitary Code and supplementary rules and regulations.

Let us now consider briefly some of the facts that have made the sanitary control of milk supplies one of the most important public health problems of our communities.

Infant Problem.—Milk suitable for infant feeding must comply with the following requirements:

It must have the proper nutritive value; that is, it must not be impoverished by the removal of a portion or all of its fat, or the nutritive value lowered by the addition of water. It must be clean. In general it is agreed that the bacterial content of milk is an accurate scientific index of its cleanliness, but it is comparatively recently that the danger of bacterial contamination of milk has been appreciated. It has been found that infants under one year are very susceptible to poisoning by milk infected with excessive bacterial growth, particularly during the hot season, when the resistance of the digestive tract is lowered.

Milk infected with the germ of bovine tuberculosis may transmit tuberculosis to children, but is not apt to infect adults, while milk carrying the germs of typhoid fever, scarlet fever, diphtheria and tonsillitis, is dangerous to persons of all ages.

*Read at a meeting of the Practitioners' Society of New York, October, 1912.

Infectious Diseases and Milk.—Tuberculosis, typhoid fever, scarlet fever, diphtheria, and tonsillitis are the principal diseases which in this country are transmitted by means of infected milk. It is believed that the tubercle bacilli are in the majority of cases derived from the cow, but they may come from human sources. Typhoid bacilli in milk are always derived from man. The contagion of true scarlet fever transmitted through milk is considered as always coming from man, but there is a disease closely allied to it, the contagion of which is derived from the cow. Diphtheria bacilli are regarded as being always of human origin.

The streptococci exciting tonsillitis are believed to be derived both from cases of septic inflammation of the udder and from human sources. According to Park, about 3 per cent of all tuberculosis existing in New York City exhibits the bovine type of bacilli and is therefore probably caused by milk infection. Of 279 cases of tuberculosis in adults examined by him, only one case was due to the bovine type. On the other hand, 22 out of 84 very young children and infants examined were infected with the bovine type, or about 24 per cent.

Typhoid Fever and Milk.—During the last two years much light has been thrown upon the definite origin of outbreaks of typhoid fever due to milk infection, through special investigations carried on by the New York City Department of Health. Several such outbreaks were traced definitely to so-called "carriers," persons who have recovered from an attack of typhoid fever, but who remain infected and continue to excrete typhoid bacilli. One outbreak of 400 cases was traced to infection of a milk supply by a typhoid carrier who had had the disease forty-seven years ago. In another 50 cases were traced to a man who had had the disease seven years ago. These important new discoveries led the department to strongly urge the necessity of the pasteurization of all milk except that produced under special stringent conditions.

Public Protection of Milk Supplies.—In view of these sources of danger to the public health, what means can be employed to make public milk supplies safe?

The problem involves three distinct features:

(1) The prevention of adulteration, either by the addition of water, the removal of fats, or both, and the exclusion of all preservatives and, in fact, all foreign substances.

(2) The production of a clean milk, a milk low in bacteria, involving great care from the time of milking to actual consumption. This involves effort to insure the cleanliness of the cows and the milkers, properly instructed, clean barns, proper and thoroughly cleansed vessels and utensils which the milk comes in contact with, exclusion of dust at every stage, immediate reduction of temperature after milking, thorough icing during transportation, the sale under sanitary conditions in stores,

and finally, proper care in the hands of the consumer.

(3) The production of a milk free from pathogenic organisms, requiring first of all healthy animals, and subsequently, the careful handling of the milk at all stages to prevent the introduction of the germs of infectious disease through human agencies, flies and dust.

Methods of Public Control.—The general outlines of the methods adopted by boards of health and other governmental authorities in controlling the sanitary quality of milk supplies of cities are fairly well defined and generally accepted. It is recognized that a system of inspections of dairies where the milk is actually produced, supplemented by inspections of creameries and of the methods of shipment and handling all the way from the farmer to the consumer, is one of the necessary elements of this public control. Such inspection must provide for the detection of contagious diseases among those handling the milk, as well as for the improvement of sanitary conditions.

Whether these details are carried out under the supervision of municipal or State authorities is a matter of expediency largely governed by local conditions. Theoretically, it would be better that State authorities should exercise a uniform control over the production and sale of milk in all communities. In practice, some of our large cities have found it necessary, in the absence of thorough-going State control, to develop their own system of milk inspection in the country as well as in the city.

The control of conditions under which milk is handled and sold within the city is a still more usual function of the local authorities and includes the regular inspection of stores and wagons, with frequent chemical and bacteriological tests and the usual method of enforcing sanitary requirements by resort to the courts if necessary.

The magnitude of the problem which New York faces may be imagined, when it is considered that the city draws its daily milk supply of 2,500,000 quarts from 44,000 farms located in six different States, namely, New York, New Jersey, Pennsylvania, Connecticut, Vermont and Massachusetts. Some cream is also received from Ohio and Canada. The "milk shed" covers an area of 50,000 square miles. The milk is produced from approximately 350,000 cows, and shipped from 1,100 creameries over 11 different railroads, the shortest haul being 50 miles and the longest 425 miles. When it reaches the city it is received at 15 different terminals and eventually delivered in 5500 wagons and dispensed at 14,000 stores. It is estimated that about 127,000 persons are engaged daily in handling the city's milk supply and on the basis of the relative frequency of typhoid bacillus carriers in the population of New York City there may be perhaps a hundred such persons included in this army of milk handlers.

Milk inspection began in New York in the late 70's and early 80's, and this inspection work was conducted in co-operation with the State officials of New York and New Jersey. Then, however, the elementary forms of adulteration, consisting in the removal of cream and the addition of water, were the only points considered. Later, it developed that a knowledge of the bacteriological content of milk was of much greater importance so far as the public health was concerned than was its chemical composition. When it was found that the bacterial content of milk was an accurate index of the cleanliness of the methods used in its production, attention was more and more directed to the supervision of conditions at the farm, at the shipping stations and on the railroads. This work was continued in 1906, and it was then realized that successful control would never result until the milk was traced back to its very sources. This was the beginning of actual dairy inspection by the New York Department of Health. From two inspectors in 1904, the number has gradually risen until there are now 56 milk inspectors.

Legal Aspects of the New York Plan.—It was under the administration of my predecessor, Dr. Darlington, that inspection of milk in the country districts was first established. Perhaps one of the most interesting phases of this work is the legal basis through which the authority of the department is exercised throughout an area covering portions of six different states. The Sanitary Code requires that no milk shall be sold in the City of New York without a permit from the Board of Health, and the board maintains that it is entitled to ascertain the conditions under which milk is produced before issuing a permit to the dealer who buys that particular milk and brings it to the city. Under the operation of this system, it is rare that permission to inspect a dairy or creamery is refused. When such refusal is met with the department notifies the dealer, who then faces the alternative of refusing to receive milk from the particular farm or creamery under criticism or of having his permit to sell milk in the city revoked. The result, of course, is very salutary in excluding from New York City all milk from farms which do not meet the requirements. The question may be raised as to what protection other communities receive under this plan, since the producers whose milk is excluded from New York City doubtless find a market elsewhere. This exhibits the great defect of local control of milk supplies. It is undoubtedly far better that the State should undertake the control of milk production under adequate and uniform standards rigidly enforced throughout the State by a sufficient number of inspectors. New York State has an excellent Department of Agriculture and adequate laws governing the production of milk, but the appropriations made by the State for this work are totally inadequate to insure the character of the supervision of dairy farms which the City of New York believes to be necessary to the purity and wholesomeness of its milk supply. Even if State supervision in New York were sufficient, a similar question remains in the case of the six other states from which the city's milk is drawn. With these varying jurisdictions, the city has been obliged to face actual conditions instead of legal or constitutional theories and evolve its own system of supervising the milk at every stage from the dairy to the breakfast table.

Deficiencies in Local Milk Inspection and Recent Improvements.—For several years we have felt that our methods of controlling the milk supply were inadequate and did not accomplish the desired results, particularly in the following respects:

It is now a well-known fact that the general milk supply of every large city in the world is unfit for use in infant feeding. Two well-defined methods have been applied in New York to effect a change in this respect: first, the production of a special grade of milk, "certified" and allied grades, for infants, and, secondly, the general movement to improve the whole supply so that milk suitable for

infants might be procured everywhere where milk is sold. Each of these methods has been successful to only a very limited extent. After ten years less than 1 per cent of the city's milk is of the certified type or equivalent thereto and the expense of this class of milk is almost prohibitive for general use in infant feeding. In fact, it is a luxury within reach of comparatively few. What is needed is a safe milk which can be furnished at a price within the means of the masses.

The attempt to bring the general market milk to the degree of purity required for infant feeding can never be successful in a large city. In the first place it is economically not feasible, since too great a part of the total supply of milk is used for other purposes, for adults who do not require a milk of such special requirements and for cooking purposes where a still less degree of bacteriological cleanliness is necessary. It naturally follows that milk for the last two mentioned purposes can be produced and sold at lower prices than the special infants' milk. In the second place, although the system of surveillance has materially lessened the danger of infection of milk from the presence of cases of infectious diseases among the employees on the farms and in the creameries or from unhealthy animals, our present knowledge of the propagation of typhoid fever by milk infected by "typhoid carriers," and the fact that tuberculosis is so widespread among our dairy herds, have forced us to the conclusion that no matter how complete or well organized the system of dairy inspection, it will not be possible to render entirely safe the ordinary commercial milk which is produced and shipped to a city from so large a territory as is comprised in the New York City milk field.

In our opinion the only way in which the sanitary authorities can meet these conditions is by requiring the pasteurization at least of all milk that is not of special exempted grades. We have always been impressed with the necessity of dealing with milk to be used for infants as a separate problem. Since the requirements are so much more exacting for infants' milk and since it has been well established that this grade of milk is much more expensive to produce, and should command a higher price than can ordinarily be demanded for milk in general use, it was deemed wise to separate the two problems.

As early as October, 1907, in an address given at Milwaukee I took the position that the sanitary authorities should establish a system of grading our milk supplies, and that practically universal pasteurization must be insisted on in the interest of public health. Since January, 1910, the development of such a milk program has been one of the foremost subjects under consideration by the Department of Health. Early in January, 1912, on my recommendation the Board of Health of the City of New York officially adopted the following plan of grading and labeling of all milk brought into the city and sold there:

Grade A, for Infants and Children.—1. *Certified Milk*, milk certified by a Milk Commission appointed by the Medical Society of the County of New York or of the County of Kings, as being produced under the supervision and in conformity with the requirements of that Commission.

2. *Guaranteed Milk*, produced under the same standards as Certified Milk, but under the supervision of the Board of Health.

3. *Inspected Milk, Raw.*—This milk must come from tuberculin tested cows. Farms must obtain in an official score at least 75 points with a minimum of 25 points for equipment and 50 points for method. The milk must not contain more than an average of 60,000 bacteria per c.c. when delivered to the consumer.

4. *Selected Milk Pasteurized.*—Farms must obtain at least 60 points in official score; 20 at least for equipment and at least 40 for method. The milk must be pasteurized as prescribed by the rules and regulations of the Department, which, of course, provide for such temperatures and times of exposure to heat as have been shown by our researches to be necessary to render the milk thoroughly safe. This milk must not contain over 50,000 bacteria per c.c. when delivered to the consumer, and must be delivered in bottles, except on special permit in certain cases. Containers must be labeled "pasteurized," and the label must bear date and hour when pasteurization was completed, the place where it was performed and the name of persons or corporations performing it. The milk must be delivered to the consumer within 30 hours after pasteurization. Milk to be pasteurized must not contain over 200,000 bacteria per c.c.

Grade B, for Adults.—1. *Selected Milk, Raw*, from cows which are certified as healthy by veterinarians after physical examination. Farms must score at least 68 points, 25 for equipment, and a minimum of 43 for method.

2. *Pasteurized Milk.*—This milk must be delivered within 36 hours after pasteurization.

Grade C.—This grade is to be used for cooking and manufacturing purposes only, and includes all raw milk not conforming to the requirements of Grades A and B.

I will indicate briefly what it is expected that this plan of grading and labeling will accomplish.

For the Farmer.—It means in effect that farms will be scored, and a farmer will know what grade of milk he is producing and how he can produce a better grade if he so desire. The better grades of milk will command a higher price at the farm, therefore for the first time in the history of milk production an incentive will be given the farmer to produce a cleaner milk. This principle, of course, was established on a very small scale in the production of certified milk, but never before in production of milk for the masses. There is an apparent contradiction of this principle in the case of pasteurized milk, in which case under the present condition, a supply of milk of the cooking grade (C) may be brought into the higher grade (B) by pasteurization, without any material improvement of farm conditions. The advantage to the general public health of pasteurization is, however, so great that it was thought wise to encourage pasteurization to the fullest extent possible, without at this time making too many restrictions, but when finally worked out the general requirements for all milk, with the exception of that for cooking, will have to be further advanced so that there will be no setback in the movement for a cleaner milk supply, the fear of which condition has led so many persons to oppose the introduction of pasteurization.

For the Dealer.—The grading and proper labeling regulations will be a great incentive to the progressive and honest dealer who is willing and anxious to sell his products on a proper basis, and who by this plan will be aided in his efforts by official control. It will no longer be possible for the dishonest dealer to market the lowest grade of milk under false representations or to sell cooking

milk for infants. Those dealing only in the lowest grade, cooking milk, will have to sell the same as such or go out of business.

For the Public.—The users of milk will be enabled to purchase the quality of milk they require and for which they can afford to pay. This is particularly important in the case of milk for infants and children. For those who cannot afford to purchase the special grades offered for this purpose, specific instructions will be given under what conditions Grade B may be used, and in case of the poorer classes provisions have been made by the municipal authorities, through the Infants' Milk Stations of the Department of Health (at present fifty-five in number, located in various parts of the city) to supply milk for infants' use at a moderate cost, and without charge in certain special cases through the charitable agencies operating in conjunction with the department.

The plan carries with it the establishment of the broad principle that the milk sold from cans ("dipped" or "loose" milk) in the grocery store is unfit for use for infants.

The special requirements made for the production of raw milk, Grade B, its limitations to use for adults and the recommendation that pasteurized milk of the same grade is a safer milk, will encourage the extension of pasteurization as it was intended to do.

We feel that the time has come when just as radical changes as have been inaugurated in the requirements for the grading and labeling of milk, will have to be applied to the regulations for the sale of milk in stores. The situation is peculiar. Milk is sold at about 20,000 places. Every little corner grocer sells milk, not because there is any direct profit derived therefrom, but as a convenience to the customer who desires to purchase other commodities. There is therefore no incentive to the proper care of the milk. It must be understood that almost all of such milk is dipped from cans. No permanent reform can be inaugurated until the sale of this class of milk is limited to milk stores where other commodities are not permitted.

Infants' Milk Stations.—I have already referred to the fifty-five municipal stations for dispensing milk for babies which are now in operation under the administration of the Department of Health. This work was inaugurated in 1911 when an appropriation was made for fifteen experimental stations. A large number of depots were also conducted by private organizations, and the work was so successful that this year the city made provision for the much larger number. I believe, however, that this work is only in the developmental phase, and that the ultimate solution of the infants' milk problem must and will be found in the production of the special grades of milk suitable for infant feeding, and the placing of this milk on the general market so that it will be possible for mothers to obtain easily milk of the proper quality at reasonable prices in milk stores or from dealers. In that event the municipal and other milk stations for infants will doubtless gradually assume what I take to be their proper function of serving as centers for the education of mothers in the care and feeding of babies, and in the care of milk in the home.

Up to the time that the present system of grading went into effect different grades of milk were not officially recognized. We had special infants' milk, certified milk, inspected milk, all these being grades which the dealers advertised as suitable for babies without endorsement from the Department of Health. In other words, dealers had the liberty to place any form of label on milk that they pleased. We had also in the city a certain amount of pasteurized milk which was produced under more or less definite regulations of the department. All other milk supplied to the city was simply "milk"—not in any way guaranteed.

At the present time the system of grading includes three classes—A, B, and C milk. Grade A is safe milk for infants. It comprises certified and guaranteed milk; inspected raw milk from tuberculin tested cattle, and also a high grade of selected pasteurized milk. Raw and pasteurized milks are included in this grade because there is still considerable agitation upon the question of their relative values. Many physicians still prefer raw milk for infant feeding. Without trying at this time to settle that question we have provided for both types of milk in the A grade.

Grade B milk suitable for adults provides for a selected milk raw produced under good sanitary conditions. The tuberculin testing of cattle is not required, but simply the certificate by a veterinarian that the animal is shown by physical examination to be healthy, followed up by the opinion of veterinarians of the Health Department. Grade B also includes pasteurized milk.

All milk not conforming to these two grades is labeled Grade C and is recommended for cooking purposes only.

The regulations concerning the grading of milk went into effect on January 1 of the present year Many thousand dollars have been spent by dealers in complying with these regulations which also provide that every bottle and can containing milk that is brought into the city of New York must show the grade by tag or label. In the case of Grades B and C there is quite a large proportion sold in cans with labels which the consumer never sees. In the case of the milk sold in the grocery stores, people would never know whether they were purchasing B or C milk. We require of every store that deals in C milk that a sign be displayed reading: "THE MILK SOLD IN THIS STORE IS FOR COOKING PURPOSES ONLY." We distributed 6,000 such signs a few weeks ago.. It was only a month ago that we were able to enforce compliance with the labeling. We have also been able recently to make a census report of all milk coming into the city, showing the amounts of the different grades, A, B, and C. Of Grade A the city receives 35,000 or 40,000 quarts a day; of Grade B, 1,000,000; of Grade C, about 8,000 quarts. It is possible to change the C Grade of milk to Grade B by pasteurization, and we are encouraging this, although it requires a large outlay. To bring Grade C milk up to Grade B raw, the dealer has been obliged to go to the farmer and offer him more money for the production of that class of milk. The increase in price of 10c. a can stimulates the farmers to produce such milk and enables the dealer to obtain considerable amounts of B milk.

The next important step in the improvement of our milk supply is the betterment of conditions under which milk is sold. This is particularly true of milk sold in small grocery stores. At the last meeting of the Board of Health a resolution was adopted which in a measure was revolutionary. It dealt with the sale of milk in the store and its protection from human contamination, dirt, dust, flies, etc., and provided that after June 1, 1913, the sale of milk in cans should be prohibited in stores where

foodstuffs are sold which produce dust. Such loose milk can only be sold in special milk stores or in stores where foodstuffs are handled in the original packages. All stores can sell milk in bottles if proper icing facilities for the protection of the milk are provided.

LOCAL ANESTHESIA IN OPERATIONS ON THE RECTUM.

By CHARLES B. KELSEY, M.D.,

NEW YORK.

Possibly some readers of the Medical Record may recall that a number of years since in an article on the office treatment of hemorrhoids and other minor affections of the rectum I called attention to the possibility of substituting local for general anesthesia in operating upon many of these cases and also described a treatment of hemorrhoids by galvanopuncture, which seemed to me to have all the advantages of the injection treatment without its well-known dangers.

Since that time I have been steadily practising these methods in my office and it may be of interest to speak now from the standpoint of the results.

Since substituting weak solutions of eucaine for cocaine, both used hypodermically or under the mucous membrane, I have had no occasion to change the form of anesthetic. Quinine and urea I had great hopes from until I was discouraged by Wyeth's bad results and abandoned it without any fair trial. It has always been rather a weakness of my own in surgical practise when I found a good thing to hold to it until I was sure of a better, which will explain why I have never yet performed a Whitehead operation for hemorrhoids and never expect to do so.

Whatever surgery of the rectum is done under eucaine must be done without any very decided stretching of the sphincter. It is both useless and dangerous to try to overcome the sensitiveness of the whole anus by injecting an anesthetic subcutaneously to an extent which will permit of stretching the muscle. I tried it in the early days of cocaine and spent hours of anxiety over the untoward results though, fortunately, never having a fatal accident. This constitutes the first decided limitation to this method of treatment. Whatever is done must be either on the skin, as in fistula or fissure, or through a speculum, as in hemorrhoids or polypi, which cannot be extruded by straining. Were it not for this all of the minor surgery of the rectum could be done as well by local as by general anesthesia.

It is this inability to properly dilate the sphincter which makes the treatment with local anesthesia inapplicable to any but the simplest forms of fistula, for the ordinary fistula cannot be operated upon with precision and success unless the sphincter be first paralyzed. Where the sinus is straight and without branches, where there is one opening on the skin and one on the mucous membrane and the surgeon can satisfy himself that this is the condition, local anesthesia, and operation in one's office work most satisfactorily. Where this is not the case and the sinus is tortuous and bifurcated the attempt to cure in this way will generally be a failure.

And while upon this point it has often seemed to me that there is a way of curing fistula without any operation at all, which has never been tried out as it might be. I refer to the treatment by curetting, draining, and stimulating to healthy action which would be used on any old sinus not connected with the rectum. By it I have occasionally had successful results which have greatly surprised me and this not only in simple cases, but in cases so extensive that I have hesitated to inflict the injury necessary to secure a cure with the knife. Perhaps it is because a patient with fistula is usually willing to be operated upon and an operation is easier for the surgeon, while one with hemorrhoids is generally unwilling, that this method has not been more generally used. Or it is possible that the method is more common with the general practitioner than I am aware.

Another condition to which attention may be called is slight laceration through the sphincter from parturition—cases in which it is only necessary to freshen the edges of the laceration and bring the ends of the muscles together by a few sutures. It is not long since I traveled a considerable distance to do just this little thing upon a lady of wealth and position whose life was that of a semi-invalid from incontinence after three or four failures to effect a cure with all the advantages of general anesthesia. Whether she would try once more or not depended entirely upon whether she must take ether or not, and hence I had small chance to choose. There was nothing remarkable in the fact that the operation was successful with eucaine, the wonder being that it had not been successful before, as the tear was only through the sphincters.

From what I have said of the impossibility of stretching the sphincters under eucaine it follows necessarily that this method is not applicable to the cure of fissures of the anus by dilatation. But there is another way of curing a fissure to which it applies perfectly and that is by incision, and this treatment is just as successful as dilatation.

Inject the eucaine not into the fissure, but underneath it from a puncture in the skin a short distance from the fissure. Then with a small speculum expose the part, at the same time making the muscle tense and draw a sharp knife through it lengthwise once or even twice. Cut simply through the muscular fibers forming the base of the ulcer, not deeply into the cellular tissue. I have known it to fail to cure, but very seldom. I have also known thorough dilatation to fail just as often and for the same reason—the presence of prolapsing hemorrhoids which prevented cure by any method until they were removed.

Coming now to the treatment of hemorrhoids by galvanopuncture under local anesthesia, I desire to make my ideas, as well as the technique, as clear as possible, believing that the method has a certain well-defined surgical value.

Any hemorrhoid can be ligated and removed as well by local as by general anesthesia provided it can be brought into reach without dilatation of the sphincter. The same statement does not apply to the removal with the clamp and cautery, for although the cautery may be painless the clamp will not be. This is due to the fact that the pressure of the clamp affects a much wider area than the hemorrhoid itself, and requires a much more extensive use of the anesthetic to prevent pain than does the application of the cautery. Hence this method of cure, which is my favorite one under general anesthesia, is never used under eucaine.

But because the ligature may be used painlessly it does not follow that when a patient presents

himself with well-developed hemorrhoids requiring for their cure three or even four ligatures, he should be placed on a table in the office and all his hemorrhoids removed at one sitting. This is not a proper office procedure. The surgical traumatism is too great, and the amount of eucaine necessary would be more than I should care to use at one time. Hence my own rule is to remove the tumors one by one at intervals sufficiently separated from each other to permit of the entire disappearance of all pain and soreness caused by each application. In this way many cases are cured and many more may be so greatly benefited as to consider themselves entirely cured, though not radically so; for it often happens that all the bleeding and all the protrusion are due to a single large tumor entirely covered by mucous membrane and easily extruded by the patient or brought outside by a speculum. It is in such cases also that the galvanocautery treatment is most easily applicable.

When the tumor has been brought outside the sphincter puncture it at its most prominent part with a fine hypodermic needle and inject into its substance fifteen or twenty drops of a weak solution of eucaine. If the tumor becomes distended and grows whitish under the mucosa all is well and the application of the galvanocautery will be painless. But it may happen that even with more fluid than this there will be no visible distention and the cautery will not be entirely painless, though the pain caused by it in such a tumor as I have described is seldom severe even when no eucaine at all is used. The failure to get the local effect of the anesthetic I attribute to the fact that it is sometimes injected into a large vein and carried away into the circulation.

After allowing time for the eucaine to take effect, take a small and delicate galvanocautery wire, heated red, not white, plunge it into the tumor where the anesthetic has been deposited, and carry it well onward toward the center. The wire should be hot enough to burn its way easily, allowing for the cooling from contact, and it should be removed slowly, allowing it to burn itself loose. A white-hot needle plunged into a vessel and quickly withdrawn will be followed by hemorrhage. A red hot needle left in for a moment and withdrawn gradually will cauterize sufficiently to close any vessel which it may have opened. Where the tumor is large a second puncture may be made before it is replaced.

From such an application as this there is seldom any pain and the operation may be repeated on another tumor after an interval of two or three days. But after three or four such applications at short intervals the patient will begin to complain of some pain and soreness and this is the signal for stopping further treatment for a week or fortnight till all symptoms disappear.

And now what has been accomplished? A distinctly aseptic wound has been made in the substance of a vascular tumor, which will be followed by a slough, by cicatrization, and contraction, with decrease in size and vascularity, and the hemorrhoid will cease either to bleed or protrude. Moreover, the wound is from the surface inwards, there is a free exit for the products of inflammation, and the amount of tissue destroyed is absolutely under the surgeon's control.

Compare this condition with that produced by the injection of an irritant or caustic into the middle of the same tumor and leaving it there to work what result it may and find its own way out, and it will be evident why I advocate and practice this method to the exclusion of that by injection.

The one I claim to be safe, definite, and surgical. The other has often proved itself to be unsafe, a traumatism, the effect of which cannot be foreseen or always limited, and therefore dangerous and unsurgical.

The procedure thus far described, it will be noticed, is applicable only to hemorrhoids which can be brought outside the sphincter by an effort of the patient or the surgeon. Manifestly I have described the simplest first. The others, and they are the majority, require some little manipulative skill in the use of the speculum and some deftness of touch.

When the tumor cannot be extruded it will be necessary to work through a speculum, and one of cylindrical shape as large as can be used without too great stretching and with considerable bevel on the end will best answer the purpose. If the beveled end is introduced to the location of the tumor the latter will readily protrude into it and the subsequent steps are exactly the same as already described in cases where the hemorrhoids protrude from the anus. No forceps for holding the tumor are necessary. The speculum can be controlled with the left hand and the rest of the work done with the right.

Do not be in haste to remove the speculum after the cautery has been used and before making sure there is not too free hemorrhage. Generally, almost always, the oozing from the puncture will cease as soon as the speculum is withdrawn and the parts return to their normal position, but sometimes there will be enough blood to worry the operator, and while the speculum is still *in situ* he may think it best to introduce the cautery needle again at the same spot and at a dull red heat to control this bleeding by a fresh cauterization. A better way, however, when the oozing causes anxiety is to introduce a tampon of gauze through the speculum and leave it in contact with the spot.

A small tampon will give pressure enough; one which can remain till the patient goes next time to the closet, and very rarely will any at all be necessary.

The variety of hemorrhoid which causes the most difficulty is that which is in great part composed of the vessels and tissues at the margin of the anus. I do not mean the grape-like external venous tumor, which should always be treated by incision, but the internal tumor of long standing and considerable size, which is only manifest when the patient strains and then shows itself as a swelling on one side of the anus covered by the skin, but which cannot be extruded sufficiently to show the upper part covered with mucous membrane or be distinctly defined. These are apt to cause more trouble by this or any other method of treatment, because any wound (incision, ligature, or puncture) which involves the margin of the anus will always cause more pain and swelling than one confined to the mucosa of the rectum above the sphincter.

In such cases the tumor is best brought within reach with a bivalve speculum, one blade of which is largely fenestrated. This should be introduced with the fenestrum over the tumor, slightly opened, and then withdrawn until the hemorrhoid is pulled down by it into view. With the speculum holding the tumor thus within reach the eucaine and cautery are applied exactly as in the other case.

And now as to results. For at least fifteen years I have practised this method without an accident. There has never been an abscess or anything approaching it; never a moment of uneasiness on account of any bad result. A very few times, not more than half a dozen at the outside, have I had to reintroduce a speculum and put in a small tampon, as described, before I cared to allow the patient to leave the office, and this is the only difficulty I have ever encountered. The treatment, if not crowded too frequently, is almost painless, both at the time and subsequently, and it will certainly cure any case upon which it is used with sufficient thoroughness. But I do not consider the cure as radical as with either the ligature or the cautery. There is by this method a connective tissue tumor left in the rectum where there was before a vascular one. The blood vessels have been in part occluded and there is no more bleeding. The tumor has been so reduced in size that there is no longer any protrusion. The patients are, as far as they know, cured. But I usually warn them that after a few years (three, or four, or five) there may be some return which can easily again be cured by a few more of the same applications. Some of them return, many never do, because they remain without symptoms.

Finally I should like to be understood as not claiming that this method has any advantages over the clamp and cautery except the single one of avoiding general anesthesia. All I have ever claimed for it is that it is a safe, painless, and efficient method of relieving and curing a great many patients who would otherwise condemn themselves to lifelong suffering simply from an exaggerated fear of a surgical operation under ether.

While upon this subject it has often been a surprise to me that more advantage is not taken of primary anesthesia. There is a moment in the preliminary stages of etherization when half the operations upon the rectum can be done without the patient's consciousness, provided the surgeon is a fairly rapid operator and the patient is placed in the proper position before the etherization is begun. This does not particularly appeal to the patient, however, because to him ether is ether, be it much or little, and an operation is an operation, whether it be done slowly or quickly; but it enables the surgeon to do a good deal of work in his office for which a hospital would otherwise be necessary.

44 East Twenty-ninth Street.

RAILROAD HOSPITAL ASSOCIATIONS.*

By FRANK ALLPORT, M.D.,

CHICAGO, ILL.

This paper is written with the intention of provoking a discussion on the best and most equitable manner of remunerating surgeons for services rendered railroad employees, etc.

I desire to say at the outset that I am not opposed to medical men working for large corporations under a previously understood agreement, provided such an agreement is fair and equitable to all parties concerned and can be continued with mutual and growing respect between employer and employee. All other forms of business and professions (including the legal profession) are often carried on under spoken or written articles of agreement. In commercial matters, the more responsible the purchaser and the larger the order, the cheaper can he buy goods. Architects, engineers, etc., reduce their fees when dealing with selected firms of high credit, who agree to give them constant occupation. Lawyers adjust their fees to harmonize with conditions when constantly employed by corporations giving them large amounts of work. Why, then, should not physicians and surgeons agree to render their services at reduced and specified prices to railroad and other corporations giving them constant employment, provided such fees are of a character to enable them to maintain their self-respect and the respect of others? Such remuneration may be in the nature of a salary or may be paid for in accordance with the amount of work performed, but it should always be sufficient to bear inspection.

The company surgeon has a perfect right (when he reduces his compensation) to take into consideration four advantages undeniably connected with corporation work, viz.:

First, the pay is sure and prompt.

Second, his position as company surgeon inevitably leads to the acquirement of private patients, both connected and unconnected with the corporation.

Third, if his client is a railroad company he becomes possessed of certain transportation conveniences.

Fourth, the extension of his professional horizon carries with it increased work, enhanced skill and enlarged acquaintance.

Nevertheless, in spite of all these advantages, he should honestly feel that he is receiving a fair compensation for his labors, as only by this precaution can he maintain his own respect and the respect of others and deal fairly with his professional brethren.

Having thus settled, in my own mind at least, the justifiability of medical men working for corporations desirous of giving them regular employment at properly reduced compensation, let us proceed to a consideration of the best and fairest manner of effecting such compensation.

The railroad usually employs a chief surgeon at a fixed salary, into whose hands (with varying limitations) the surgical work of the road is intrusted. Until of late years this work has consisted in the surgical and medical care of injured men, the examination of men for service, the surgical supervision of personal injury suits, the appointment of assistant district and local surgeons, auditing bills and issuing vouchers, inspecting and commenting on personal injury reports, and transmitting the same to the claim and legal department. The chief surgeon's assistants resident in his own city were usually paid a small but fixed salary, and most of the surgeons residing outside of the home city were usually given transportation and reduced but fixed fees for each individual case, or were compensated by the receipt of transportation and a small annual salary. Surgeons living in very small towns, where railroad cases are infrequent, were (with some roads) merely given transportation from time to time as occasion arose. Many roads, however, invariably pay a small but definite fee for services rendered, no matter how small may be the size of the town. This method of dealing with railroad surgery has

*For a thorough exposition of this interesting subject, I beg leave to refer the reader to two valuable and interesting communications by Dr. W. H. Allport, of Chicago, in the January and February (1912) numbers of the *Journal of Political Economy*, from which I have derived much of the information necessary to the writing of the present article.

proven, on the whole, fairly satisfactory. It has been open, of course, to some abuses, but after all the surgeons were quite well satisfied, for they, as a rule, received fair compensation for their work, the men were contented because they were well cared for after injuries, and the only participant to this tripartite arrangement which manifested evident symptoms of restlessness was the railroad, which was compelled to assume this financial responsibility, which, after all, was no more than its proper moral burden, considering its responsibilities and privileges. All railroads have doubtless suffered a multitude of impositions, and yet, after all, the care of its injured employees should be a duty which it is quite willing to assume and which should be looked after with at least as much solicitude as is the repairing of its rolling stock, its rails, and its roadbed. I am free to say that, after a long experience in railroad work, it has been my observation that most railroads have conscientiously and cheerfully discharged their duty to their injured men, and if all roads would perform this portion of their business obligations with the same care and solicitude as is manifested by the Northwestern, the Rock Island, the Milwaukee, the Chicago and Eastern Illinois, and many others, there would be no occasion to write this paper or to discuss it. But there has crept into railroad management during the last few years a desire on the part of a few railroads under the excuse of philanthropy to shift the financial burden of the injured employees onto the shoulders of the men themselves. Thus has come into existence the various hospital or beneficiary associations connected with a few of the roads. Most railroads, as I have already stated, still manfully carry their own burdens and consider it their moral and business duty to care for their injured men, and it is to be hoped they will continue to do so; but there are danger signals in the air, and we who are railroad surgeons should do what we can to prevent the progress of an evil which, while still in its infancy, might easily grow until we all become the victims of an unfortunate miscarriage of justice.

Without going into details, these hospital associations are organizations that care for sick and injured railroad employees. The money for their support is raised by taxing each employee a certain sum (let us say fifty cents) a month, which is taken out of his own wages. Thus, for $6 a year he becomes insured against medical and surgical services for practically all diseases and injuries except those of a disgraceful character. These services the surgeons of the road are compelled to render for the small compensation which they receive. Under the ruling of some of these associations the men are compelled to accept membership, while in others the act is called voluntary, but it might as well be disclosed in its true light, for if a man does not join the association he is soon made to understand that he is *persona non grata*. In some of the associations the road is released from personal damage suits the instant that benefits are accepted; in others this is not the case.

The management of the association and its finances is conducted practically by officers of the road; the low salaried men may, it is true, be represented on the board of management by one of their number, but it is reasonably certain that his influence will not be very far-reaching.

These associations were originally planned for the benefit (if it is a benefit) of the poor men, the low salaried men of the road, but in at least one or two roads with which I am familiar the high salaried men from the president down have availed themselves of the privilege of membership, and I know of one high salaried official who required and secured the performance of a laparotomy under the $6 a year clause. When placed upon the defensive the roads seek refuge under the claim that they hold themselves responsible for any deficit that may arise from time to time in the management of the fund, but as a matter of fact it may be said that the membership fees are so arranged that there is practically no deficit; in fact, the truth is that in some roads there is a large surplus, which, of course, is held in the hands of the management. Inasmuch as the railway officials retain practically the entire management of the hospital association and the making and the unmaking of its laws, they certainly have it within their power to arrange the amount of the assessments to harmonize with the average disbursements. No one need therefore waste any anxiety upon the railroad, as it can be safely trusted to emerge from a consideration of the annual association budget with a steady pulse and an undiminished confidence in its own financial sagacity.

Most of the railroads that have adopted the hospital association plan, voluntarily and ostentatiously contribute a few thousand dollars for its support; but even though this contribution is a large one (which it is reasonably safe to say it is not), it would almost surely fall far short of equalling the annual sickness, funeral, and court expenses incidental to the old method of dealing with injured employees.

It will thus be seen that this adroit and ingenious scheme is a source of enormous saving to the road, as it almost, if not quite, entirely releases them from all financial obligations so far as the care of their injured men is concerned. It can therefore be readily understood why some railroads are so enthusiastic over the plan, for under the ostensible purpose of benevolent and unselfish philanthropy, based upon the Samaritan-like desire to see that the poor employees are properly cared for when sick or ailing, and properly buried when dead, they have slipped in the clause that they shall be properly attended when injured in the service, and shall be properly examined for service from time to time, which lifts a great load of financial obligation from the back of the corporation. It can also be clearly comprehended why the men are satisfied, for by the payment of a small monthly assessment they are insured against practically all doctors', hospital, and undertakers' bills, and are additionally compensated for the loss of an eye, a finger, a leg, etc.

A distinct objection to the plan, however, must be mentioned in considering matters from the standpoint of the employee, consisting in the inferiority of underpaid work. Under the hospital association plan the doctor is almost invariably insufficiently paid for his work, for it must be remembered that under this plan the doctor not only has to care for injuries received during service but almost all other forms of physical disability as well. He is thus compelled to care for typhoid fever, pneumonia, enlarged prostates, diphtheria, cancers, appendicitis, senile cataracts, catarrh, dyspepsia, mastoid diseases, trachoma, deafness, the fitting of glasses, etc. In view of the fact that his pay is ridiculously small and that he is constantly being consulted by the men for real or fancied diseases because it costs them nothing to secure his services, he is sure to become

imposed upon, disgruntled, and discouraged, and under these circumstances cannot enter heartily into his work nor render his best services. Thus, while the plan looks satisfactory to the insured man, he is reasonably certain sooner or later to receive unwilling and therefore inferior medical and surgical services.

I desire briefly to call attention to the commendable association plan adopted by the Chicago & Eastern Illinois Railway. A low assessment is levied on each man and an actual annual deficit is paid by the railroad. The fund is employed for sick and death benefits, hospital, and burial expenses. The company pays all doctors' bills and expects no release from personal injury litigation.

Another encouraging indication of the times is the fact that August 1, 1912, the Hospital Department of the Missouri Pacific & Iron Mountain System was turned over to the employees. The service is to be controlled by a Board of Hospital and Service Managers, to be composed of nine members selected from different departments of the railroad.

It has been interesting to myself, and might be to others, to read an article written by the superintendent of one of the largest railroad companies in this country entitled, "The Relief Department of the ——— Railroad: Its Advantages to the Company."

It is, of course, impossible to reproduce the entire article at this time, but I will make a few quotations from it to enable you to judge of the real mental attitude experienced by some railroad officials concerning the advantages of the hospital association plan to the railroad.

This gentleman begins his article by saying that "probably the greatest advantage which the railroad company enjoys through the operation of the relief department—the one most far-reaching in its effects—is the examination of applicants for employment and the subsequent close observance of the men by a corps of especially trained medical men." In other words, the medical man is expected not only to make the initial physical examination but also to keep the men under constant surveillance as to their bodily condition, habits, etc. This combined medical and detective work is meagerly paid for (when paid for at all, except by the presentation of a pass) out of the relief funds, thus affording the company an opportunity of obtaining highly valued services at the expense of the relief department. He then goes on to say that the existence of a relief department is a practical guarantee of immunity from damage suits. Statistics show that the relief department of this particular railroad company settled on a basis of benefits only "99.2 per cent. of the accident injury cases, and 97 per cent. of those of accidental death." It will be seen that this not only saves an enormous amount of money in damages alone, but, as this gentleman says: "The corps of claim agents is reduced, the expenses of the legal department greatly curtailed, and a great deal of unenviable notoriety is avoided in the trial of suits, and the newspaper comments thereon." Another item of great value to the road is its emancipation from the financial burden of caring for men who are suffering from injuries received in the discharge of their duty. He says: "The usual method of providing for such men is to carry them on the rolls at half pay. A relief department, especially if membership is compulsory on all classes of employees, relieves the company entirely of this expense." Why would it not be a good idea to organize relief departments in all the various departments of railroad service and compel the employees to obtain membership? Careful statistical calculations would enable the company to estimate their gross running expenses, and a per capita tax on all the employees could be levied under the guise of membership tickets in the various relief departments. In this way the company would experience "relief" from all its financial obligations, and the receipts would be all profit. It is surprising that this pleasant little arrangement has been overlooked by some railroads, and I am confident that now the idea has been suggested the philanthropy of these roads will extend much further in the future than it has in the past.

This gentleman's conception of the ease with which doctors can be imposed upon is evidently quite well expressed in his recitation of the duties of the company surgeon. "He is required to attend free of charge all cases of accidental injury to employees, passengers, trespassers, and others, occurring in any way in connection with the company's operations. His compensation consists only, in most cases, of an annual pass over the company's lines." He usually furnishes his own supplies. According to this superintendent, the medical man is expected to use his influence in securing the best hospital accommodations for the smallest amount of money, to suggest to the widow of the dead employee that she pay out of the death benefits to have the remains "fixed up" (to use his illuminating and sympathetic language) and buried. He asserts with great satisfaction that "it is a rare thing for his railroad to have to pay an undertaker's bill on account of an employee." He further indicates what is expected of the company surgeon in the following language: "The company surgeons, by reason of their great numerical strength and their high standing in private and public life, can be made an even more valuable asset to the company. These men are, as above stated, usually the best qualified medical practitioners in their communities. They are influential in private life and hold all sorts of political offices, from health officer, coroner, town councillor, or Mayor, to members of the State and National Legislatures." It is not difficult to see what he means by this language, and, to speak plainly, his willingness, not to say eagerness, to prostitute the medical profession in any way, from inducing them to work without pay and performing detective and sleuth services upon the men to imposing upon widows and ravishing public offices, seems too evident to need emphasis. Another service expected of the company surgeon can perhaps be best expressed in this gentleman's plain and unmistakable language: "Imagine a corps of several hundred men of influence, having peculiarly confidential relations with the employees, going into their families on occasions when they are especially susceptible to kindly acts, and it needs no straining of the vision to see what an immense amount of good to the company may be accomplished. The family physician's advice is asked on all questions, and it does no harm to be on friendly terms with him. His influence has been known in many instances to counteract that of the ambulance chaser, to the advantage of both the company and the man."

In other words, the company surgeon is to take advantage of his close and confidential relations with an injured man and his family at a time of shock and grief, for the purpose of inducing them

to deal gently with the corporation. This gentleman's further conception of the company surgeon's duties and character can be further conceived by another sentence which occurs a little later in his article, as follows: "The management knows it can rely absolutely on reports as to the character and extent of personal injuries on account of which claims are made; and when the trial comes on, if the doctor cannot conscientiously testify as the company would like to have him, he will at least do as little harm to its case as he can." Comments on the significance underlying this sentence seem to be entirely unnecessary. It is only to be regretted that this gentleman's acquaintance with the medical profession has been of such a character as to render it possible for him to express such sentiments. The value of the relief department to the railroad in question can perhaps be best summed up by the superintendent's statement that "the whole cost, including company's surgeons' salaries, fees paid other surgeons, and hospital expenses, was $1.85 per case. These cases involved operations of all sorts, from the dressing of a bruised finger to double amputations, trephining, etc." What a triumphant exhibition of high finance! It only costs $1.85 per case to care for all injuries, operations, etc., small and great, and even this expense has been shifted from the back of the railroad to that of the men, and has been rendered possible by the grossly unfair remuneration of the medical staff. The company evidently appreciates the services of the surgeons and does not fail to use them in season and out of season for almost any kind of work they can induce them to perform. Then why, may I ask, does the company not pay them at least decently, for their legitimate services? I think the answer can only be found by estimating the character of the company itself and the motives and moral equation of those gentlemen at whose door can be laid the conception and execution of these plans.

Having looked at the matter from the standpoint of the corporation and the men, let us as briefly as possible view the plan from the standpoint of the doctor. In the vernacular of the street he is the "goat," for he gets the worst of the deal from all standpoints; everybody prospers at his expense, and yet the entire scheme is absolutely dependent upon his cooperation. Formerly an important element in his compensation resided in the fact that because he was a company doctor he did work for and collected fees from many company employees for the care of diseased conditions not dependent upon railroad accidents. This source of income is now taken from him entirely, for the men all belong to the association and are at liberty to require his attendance upon them whenever they desire. Let me here present a concrete instance which will illustrate the effect the association plan may have upon the income of a railroad surgeon. I could offer many similar incidents, but one is enough to illustrate my meaning. I know an experienced eye and ear surgeon, living in a moderate sized city in a neighboring State, who has for years worked for a certain railroad running through his city. He was paid according to what he did, and this averaged him about $300 a year. Besides this he could secure trip passes and had a good many railroad patients for nontraumatic diseases, which considerably increased his income. When the hospital association plan was started on his road he was notified that he would receive the princely salary of $10 a month, for which he would be required not only to care for all the eye and ear injuries but would have to care for all the eye and ear diseases of the men as well; he can still get trip passes upon application. In other words, his compensation from the road has been reduced and his work greatly increased and much indirect financial compensation taken from him entirely. If this is a "square deal" it certainly does not accord with my own personal ideas of equity and justice. Of course, the first question to be asked is, "Why does he stand it?" "Why does he not resign?" This is a question that must be frequently asked, and its answer involves the greatest difficulty in the solution of this vexed problem, for, if the doctors would as a body arise and refuse to submit to such unjust, iniquitous, and dangerous schemes, the entire project would dissolve into thin air or the standards of compensation would be so raised that medical men could endorse the plan with no loss of self-respect. While the idea of contracting for a doctor's services must always be regarded with suspicion and reserve, the plan has evidently come to stay, and if this is true the people who are the real sufferers, viz., the doctors, should refuse to submit to such unjust conditions.

The entire matter assumes the appearance of a crude insurance scheme in which the essential laws of insurance and equity are grossly violated. No insurance company looking to the public for general patronage could exist a year under such conditions. It is only through the power that the railroad has over its employees, its arbitrary management of the insurance department, and the weakness of the medical profession that the railway hospital association as conducted by most companies can exist over night. If the men desire sickness insurance they can obtain it with very little additional expense from good and reputable companies, which will not place them under any obligations to their railroad. Most insurance companies have, however, found it inexpedient (except where large premiums are paid) to insure men against all diseases. The diseases for which the insured are permitted to apply for relief are definitely stated, and the fees which the doctor is allowed to collect are stated with equal definiteness. It has been ascertained that only by laying down strict rules of this nature can low priced sickness insurance be perpetuated with fairness and equity to the insurance company, the wage earner, and the doctor. If this is true it would hardly be expected that railroad companies could come to different conclusions, and, indeed, it may be answered, without fear of contradiction, that they could not continue such an arrangement at all if it was not for the cooperation of the doctors. The railroads employing the hospital association plan (with few exceptions) buy the doctor's services for almost nothing, and thus are enabled to continue the operation of a sickness insurance plan that would be utterly impossible if the doctors insisted upon receiving just and reasonable compensation for their labors.

It has been suggested that these associations should be for the benefit of poor men only, and that it should be distinctly understood that employees earning a salary of more than a certain amount are not available for membership. This would seem to be a suggestion that would occur to any fair-minded man, and should, of course, be adopted, as it would bar out much injustice and abuse of privilege; but, after all, it goes only a few steps in remedying the evil. In talking over the matter a short time ago with a prominent railroad official whose road has

recently adopted the association plan, he calmly, and with the almost inevitable surrender of humanity to commercialism so frequently observed in those dealing in purely financial affairs, delivered the edict that the entire matter was one purely of supply and demand, and must be settled along these lines. He declared that if the doctors were not satisfied with the idea and with their remuneration they should resign, and that there would be no difficulty in filling their places. I told this gentleman that I was unfortunately aware of the willingness of one doctor to supplant another under such circumstances, but that this did not make it right for a corporation to underpay its employees merely because it had the power, any more than it is right for department stores to encourage prostitution by paying unlivable wages to their girls because they have the power to do as they please, knowing as they do that they can easily fill the position of a departing girl. If might makes right, then reformers, philosophers, and philanthropists may as well fold up their tents and "quietly steal away."

The fact of the matter is that this unfortunate situation will have to be settled by the medical profession itself. A railroad that forms an association of this nature, by which it is relieved from the payment of its just bills for the care of its injured men and at the same time relieves itself from personal injury litigation by previously signed releases between the men and the road; a road which will scale down its doctors' bills to a point approaching invisibility merely because they know they can is a road with which it is merely wasting time to argue. It has chosen its course; it has performed a sharp financial transaction by which it saves thousands, and perhaps several hundred thousand dollars per annum; it passes in all the beauty of benevolence before its employees. Why, therefore, should it submit to argument; why should it make any change in its plans because, forsooth, the doctors are not satisfied? Why, indeed! If the doctors are not able to look after themselves why should the road bother itself about them? If they are weak enough to be imposed upon; if they have not sufficient *esprit de corps* to stand by one another and refuse to supplant a brother surgeon because he has had spirit enough to refuse to submit to unjust dictation; if doctors have not sufficient unanimity of thought and action to unite together and stand for righteousness and justice, then why should the railroad strain itself for the privilege of paying out large sums of money when such disbursements are entirely unnecessary? It can easily be seen that under these circumstances argument is useless and that time and energy can be better expended by vigorous and repeated appeals to the medical profession itself, as has been done with rather bright prospects for the future by the doctors in England in their opposition to the Lloyd George Insurance Bill. The author of this bill, in looking back over the business aspect of the medical profession and observing what easy victims they have always been in the hands of sharpers and how their ranks have always been torn asunder by internal dissensions and jealousies, naturally concluded he could make use of them in completing his insurance bill by suggesting, if not dictating, to them through Parliament what fees they should receive when practising under the act. In this perfectly natural conclusion, however, he found himself mistaken, for, amazing as it may seem to even a casual observer of the past, the medical profession of Great Britain, acting under the auspices of the British Medical Association, developed astonishing powers of cohesion, held mass meetings, passed resolutions and did not desert them, and up to the present time have refused to submit to the remuneration clause in the Insurance Act. All praise to the British medical profession! They have demonstrated something that no one believed existed, viz., the ability of the medical profession to stand solidly together for what they believe to be their rights. The Lloyd George's Insurance act cannot exist without the cooperation of the medical profession, neither can the railway hospital association exist without the sanction of the medical profession. The doctor is absolutely essential to the success of both plans. Why, then, should not the doctor be treated with the consideration which is his just due? Why should he not be suitably remunerated for his services? Why should he be expected to meekly submit to getting the worst end of every step of such iniquitous transactions?

The question has been asked, why does the surgeon not resign his position under the hospital association plan if he feels that he is being unfairly treated? There are a number of reasons why this step is so infrequently taken. In the first place, the surgeon has probably been connected with the road for years and dislikes to sever old ties and associations, especially as he hopes for better arrangements in the future. Then there is the wonderful and beloved pass, from which he hates to be separated. He perhaps hardly ever uses it, but he loves to look at it and to have others know that he has it, and then he can use it if he desires and take beautiful and desirable trips to distant parts of the country. He cannot bear to part with it, especially as he knows quite well that if he does some hated and objectionable professional rival would soon glory in its possession. He retains his position, then, on account of old associations, to retain his pass, because he hopes for better arrangements in the future, because it does furnish him a little sure and ready money, because he wants to keep the position away from somebody else, and because there is a certain amount of distinction incidental to the connection. These reasons are, of course, utterly insufficient and inadequate as an excuse for the surgeon to retain a position through which he sacrifices his self-respect and lowers his professional standard, but I believe them to be a truthful representation of the reasons why the surgeon continues to submit to the unfair dictation of a railroad hospital association. These reasons, however, do not relieve the railroad from its moral obligation to its surgeons, nor does it alter the fact that such unfair treatment results necessarily in the frequent employment of poor surgeons and even half-hearted service from good surgeons, which is, of course, a bad thing for both the road and the men. The doctors are, as is well known, the most charitable people in the world; they are constantly and cheerfully and freely giving their services to the poor gratuitously, but there seems to be no reason why they should regard railroads as objects of charity or semi-charity.

To my mind, the most menacing feature of the situation is the outlook for the future. It may not matter so much that the railroad or that corporation is placed on the hospital association plan; the question is, to what extent will this plan become adopted in the future? The storm of disapproval and opposition on the part of the medical profession towards the Lloyd George General Insurance Bill is of recent occurrence and well known; but it may not be so

well understood that the working out of this plan in some other European countries has produced disastrous but logical results to the medical profession.

The broad general plan of contract practice has been very generally used in various Continental countries for years, and assumes the form of an association insuring its clients against the expense of sickness, hospitals, death, funerals, etc. It usually applies not only to the man of the family but to his dependent household as well. The underpaid physician is, of course, a necessary element to the plan, and under its sinister influence the average income of Physicians in Austria, Bohemia, Germany, etc., is reduced to perhaps about $400 a year; while in England, with no such conditions existing (at least up to the present time), the average income of medical men is $3,000 per annum. This can be easily understood when it is known that in the city of Freiburg an association of this kind has been in existence for some years, and out of 16,000 families in the city 14,000 are insured. This has reduced medical fees to the association doctors to such an extent that office calls are valued at 15 cents, house calls about 30 cents, night visits 96 cents, minor surgical operations about 35 cents, larger surgical operations about $3; normal child birth $1.20, difficult obstetric cases about $3. Other cities in these countries show that medical fees for association doctors are about the same as in Freiburg, and it follows as a perfectly natural sequence that the fees of those medical men who are not employed by these associations are inevitably forced downward as a direct result of such fees as those just enumerated. An especially menacing feature of this plan is that rich people are beginning to obtain membership in these associations, and thus it would seem that the last hope of the unfortunate doctor was being surely taken from him and that he must soon seek some other and more self-respecting and profitable means of existence.

It is to be hoped that the remuneration for medical services in America will not be dragged down to the degrading level produced in Europe under the baneful influence of some forms of contract practice; but it would be of interest to know just how much a railroad hospital association surgeon in America receives on an average for office and house visits, operations, etc. I will venture to say that if most of these surgeons would compute this problem they would be surprised at, and ashamed of, the result.

It must not be forgotten that this paper refers merely to the hospital or beneficiary associations of railroad corporations; it was not intended to discuss the broad, general plan of contract practice, and I have only referred to the deplorable conditions in Europe for the purpose of demonstrating the inevitable result of contract practice when uncontrolled by a high sense of moral obligations.

Just what effect the new Workmen's Compensation Act will have upon the hospital association plan remains to be seen, but it is to be hoped it will put it out of business, although such an optimistic view of the future is hardly to be expected. It would not be necessary to wait for such developments if the doctors could be made to realize the power of medical combination. They absolutely hold the key to the situation; it is only necessary for them to use it with determination, tempered with reason and justice.

Directly connected with the subject of this paper comes the news from England that there is a distinct shortage of medical students in that country, which is occasioning acute unrest on the part of medical college authorities. There seem to be several reasons for this peculiar condition of affairs. First, the standard of medical education has grown much higher of late years; five years are now required for a medical education instead of four years, and this means a year's more time for study and the expenditure of probably $1,000 of extra money. Consequently many men have decided to seek other avenues of work, especially as the future of the practice of medicine and surgery is anything but flattering from a financial standpoint. There can be no doubt, moreover, that the Lloyd George Insurance Act has had a most depressing effect upon men who have contemplated entering medical schools. This has been so marked that the number of entries has decreased from 1,495 in 1910 to 1,232 in 1911. Such a decrease has never been seen before and has undoubtedly been occasioned by the Insurance Act and its sinister and humiliating influence on medical and surgical fees. Viewed in the light of the Lloyd George Insurance Act, the medical insurance companies on the Continent, the medical insurance organizations of railroads and other corporations in this country, a man must indeed be mentally astigmatic who cannot see that the remunerations and prizes incident to the practice of medicine will, unless better conditions develop, soon cease to attract the attention of level-headed men seeking for a life vocation. Some of you will doubtless be glad to see the ranks of the doctors thin out, and this may really be an advantage up to a certain point, but beyond that point the depleting process should not be allowed to extend. We must have at least a sufficient number of good doctors to care for the world's sick, but unless suitable remuneration is evident, impossible as it may seem now, there will eventually be a shortage in the medical profession.

In now leaving this subject for your consideration I beg to state that out of the chaotic conditions surrounding this vexed situation I have been able to arrive at several conclusions that seem to me should be carefully considered by the parties identified with all sides of the controversy:

1. A Railroad Medical Fee Bill should be established by medical associations. In doing so we should remember it is proper for obvious reasons that regularly employed railway surgeons may considerably reduce their fees to railroads for services rendered. The amount, however, should not be improperly low and should be fair and reasonable to both employer and employee. There has always been something mysterious about this subject, and it has never been a matter that has been openly understood as it should be. It is not expected that this fee bill will ever be universally used (there are always some men who prefer to work in the dark), but it would at least establish a standard and give an open expression of opinion from those who are best able to judge of what are the minimum fees which can be accepted by self-respecting railway surgeons.

2. The method at present in vogue with most railroads, whereby surgeons either receive reasonable fees for services rendered or receive a reasonable salary, is a fairly satisfactory plan and should be continued until a distinctly better method can be demonstrated.

3. Any plan should be discountenanced by the medical profession which seeks to reduce an already low remuneration by endeavoring to confer benefits

to railroads or their employees at the cost of the medical profession.

4. All railway insurance associations by which employees are insured against all forms of injuries or sickness are detrimental to the interests of the medical profession and should be discouraged. The diseases for which men may apply for relief should be carefully selected and definitely stated. This should relieve the doctors from caring for disgraceful diseases, most contagious diseases, and the innumerable partially or entirely imaginary diseases indulged in by poorly balanced and neurotic individuals who delight in haunting doctors' offices, especially where they can indulge in this morbid privilege without the payment of a fee.

5. If railroad hospital associations are formed adequate representation of both surgeons and employees should appear upon their advisory boards. Only men drawing small salaries should be admitted to membership, and the remuneration to surgeons should consist in adequate salaries or in payment for actual services rendered, based upon a low, but reasonable, fee bill. Employees should never be asked or required to sign personal injury releases to the company upon receiving benefits from the association nor should they be required to become members of the association unless they themselves desire to effect such an alliance.

6. It is useless to endeavor to abolish the broad general idea underlying contract practice; it, like the locomotive and the automobile, has come to stay. Our efforts should be directed along the line of regulation instead of along the line of suppression.

SUITE 1208, 7 WEST MADISON STREET.

ADDITIONAL REPORT UPON THE USE OF THE SPHYGMOMANOMETER IN EXAMINATIONS FOR LIFE INSURANCE.*

BY J. W. FISHER, M.D.,

MILWAUKEE, WIS.

MEDICAL DIRECTOR OF THE NORTHWESTERN MUTUAL LIFE INSURANCE COMPANY.

MORTALITY experience of the Nothwestern Mutual Life Insurance Company on 525 persons insured in the years indicated in Table V, and 723 cases rejected for the reason stated.

This is a continuation of my report made at the last meeting of this association, with simply an additional year of mortality added to the original cases contained in that report. The original report will be found in the abstract of the proceedings of the Association of Life Insurance Medical Directors of America, page 392 (MEDICAL RECORD, October 21, 1911, page 818).

We call your attention to a ten point increase in mortality in cases recorded in Table IV. You will recall that the mortality in my last report, Table V, was 54.062, while the addition of last year brings the mortality up to 70.37. It should be remembered that no fresh lives have been added during the year, and that there has been no effort in the 723 cases rejected in Table VI to determine as to whether there have been any additional deaths. The additional deaths recorded are simply those that have come to our notice through various sources.

*Read at the twenty-third annual meeting of the Association of Life Insurance Medical Directors of America, October 9, 1912.

Table X shows 22 additional impairments since my last report, and an increase of six points in mortality. From July, 1911, to June, 1912, inclusive, this company insured 43,158 lives. Thirty-two thousand nine hundred were under age 40, and 10,258 at age 40 and over. One-hundred and fourteen applicants were rejected for the year, with a high blood pressure only, under 40 years of age, showing one in every 289.6 lives rejected on this account. Seventy-seven applicants under age 40 were rejected, with one or more impairments other than high blood pressure. At age 40 and over, 235 applicants were rejected who had a high blood pressure with no other impairment, a rejection of one in every 44.65 lives. Three hundred and forty-nine applicants at all ages were rejected, in which the only impairment was a high blood pressure, or one in every 124.6 lives. At ages 40 and over, 124 applicants were rejected in which there was one or more other impairment than the high blood pressure.

For the year indicated above, 550 applicants were rejected where a high blood pressure was a factor, showing one rejection in every 79.5 lives. Of M. I. B. reports for the above period, 2.2 per cent. contained a high blood pressure impairment exclusive of the Northwestern.

The examiners of the Northwestern Mutual Life Insurance Company are furnishing the company with blood pressure readings in 84.64 per cent. of all examinations. The blood pressure is required in all examinations regardless of amount or age.

TABLE IV.

Mortality of Accepted Risks with Systolic Blood Pressure of 140-149 mm. Hg., With an Average of 142.43 mm. Hg. All Ages.

Years.	Number	Expected	Actual	Per Cent
1907	217	14.884	7.	47.03
1908	652	41.221	21.	50.94
1909	953	42.088	12.	28.51
1910	846	25.215	18.	71.39
Total.....	2,668	123.408	58.	47.00

TABLE V

Mortality of Accepted Risks with Systolic Blood Pressure of 150 mm. Hg. and Over: Average 152.58 mm. Hg. All Ages.

Years	Number	Expected	Actual	Per Cent.
1907	87	6.194	6.	96.87
1908	210	14.398	10.	69.45
1909	163	8.432	3.	35.57
1910	65	2.238	3.	134.05
Total.....	525	31.262	22.	70.37

TABLE V

Mortality of Applicants Rejected with Average Systolic Blood Pressure of 171.03 mm. Hg. All Ages.

Years	Number	Expected	Actual	Per Cent.
1907	40	3.193	10.	313.18
1908	120	8.429	13.	154.23
1909	210	11.095	16.	144.21
1910	225	8.408	9.	107.04
1911	128	2.163	3.	138.69
Total.....	723	33.288	51.	153.21

TABLE VII.

Mortality of Applicants Rejected with High Blood Pressure (Average 171.73 mm. Hg.) and One or More Other Impairments.

Number	Expected	Actual	Per Cent.
358	16.680	27.	161.99

TABLE VIII.

Impairments Recorded on Applications at Time of Medical Examinations of the 358 Cases Recorded in Table VII Above.

Arteriosclerosis Atheroma	Heart Murmur	Heart Hypertrophy	Albumin and Sugar	Albumin in Urine	Sugar in Urine	Albumin and Casts	Casts in Urine	Nervous Symptoms	Prostatic Disease	Miscellaneous	Total
53	69	17	10	111	15	10	6	21	5	41	358

TABLE IX.

Mortality of Applicants Rejected with High Blood Pressure Only. (Average 170.36 mm. Hg.)

Number	Expected	Actual	Per Cent.
365	16.608	24.	144 51

TABLE X.

Impairments Subsequently Discovered or Developed in the 365 Cases Recorded in Table IX Above.

Arteriosclerosis Atheroma	Heart Murmur	Heart Hypertrophy	Albumin and Sugar	Albumin in Urine	Sugar in Urine	Albumin and Casts	Casts in Urine	Nervous Symptoms	Miscellaneous	Total	Expected	Actual	Per Cent.
7	10	4	3	20	5	36	16	6	16	123	5.867	8	136.35

TABLE XI.

Risks Accepted as Shown in Table V. Average Blood Pressure of Those Who Died Was 152.78 mm. Hg.	Causes of Death	Risks Rejected as Shown in Table VI. Average Blood Pressure of Those Who Died Was 179.17 mm. Hg.
	Aneurysm aorta	1
	Angina pectoris	3
2	Apoplexy	13
2	Appendicitis	2
1	Arteriosclerosis	6
2	Cancer	
1	Cerebrospinal meningitis	
	Cirrhosis of liver	2
	Consumption	1
	Diabetes	1
1	Duodenal ulcer	
1	Gallstone	2
3	Heart disease (organic)	8
1	Nephritis	10
2	Pneumonia	
1	Prostatic hypertrophy	
1	Railway accident	
2	Rheumatism (acute)	
	Stokes-Adams disease	1
2	Suicide	1

In the above computations the expected deaths are the total deaths computed by the Actuaries Mortality Table; no deduction is made for benefits derived from medical selection.

The significance of the above figures can best be understood when they are compared with the company's general mortality experience. On all risks accepted during the same period, August, 1907, to January 1, 1911, the actual deaths to July 1, 1912, are estimated to have been not more than 43 per cent. of the expected. With the expected deaths in each of above tables adjusted to this basis, the actual deaths compare as follows with the expected:

	Expected Deaths Company's General Experience	Actual Deaths	Per Cent.
Table IV	53.065	58	109.30
" V	13.443	22	163.65
" VI	14.314	51	356.29
" VII	7.172	27	376.46
" IX	7.141	24	336.09

That is to say, the mortality in the above cases was from 9.30 per cent. to 276.46 per cent. in excess of the estimated general average mortality of the company during the same period.

HEART MURMURS AND PATIENTS.*

By BEVERLEY ROBINSON, M.D.,

NEW YORK.

Physicians know how much value is attributed to accurate auscultation of the heart. This is true especially of hospitals. To the scientific, careful attending physician not a little importance is given to difficult or obscure murmurs. Surely some of this knowledge is of slight moment in general practice outside of hospitals. Of course, we should be able to recognize a well-defined mitral, aortic, tricuspid, or pulmonic bruit. We should be competent, usually, to determine if the murmur is systolic or diastolic. When we have two murmurs we may, as a rule, distinguish and limit them. On the other hand, it may test our medical acumen to differentiate them thoroughly, and to state in a certain limited area, which murmur is heard, indicating positively the orifice affected. Whenever three or even more murmurs are heard it is no easy matter to make positive affirmations, if one is conscientious and acknowledges limitations to hearing. Thus it is that not infrequently one person who is conceded to have both a learned and a sensitive ear states he finds what another individual may question. The intelligence of both may be equal, but not their auditory power. Admitting what precedes to be true, should we conclude that the practical outcome is always great? Frequently, it is *not*.

The refinements of auscultation are not invariably important apart from hospital bed-side notes and special treatises on heart disease. What is essential to know in practice is the value of the cardiac murmur when discovered, as to prognosis and treatment.

Is it organic or functional? Does it depend upon inflammatory thickening, calcareous deposits, enlargement, or narrowing at the cardiac orifices? Are these conditions curable, or will they persist? If curable, in what length of time? If not, are they compatible with comfort and activity during life? Valuable deductions will depend upon careful, continuous observations in every case. The previous diseases or habits which have caused murmur must be investigated. The age, profession, or occupation, and antecedents of the patient must be carefully considered. With all this in view it will probably take several days or weeks before we can pass judgment advisedly upon cardiac murmurs.

By themselves and without obviously disquieting symptoms resulting therefrom, they may have

* Read before the Practitioners' Society of New York, October 11, 1912.

relatively minor importance if the patient be judiciously watched or treated. On the other hand, when annoying, painful, or threatening symptoms are already manifest, the immediate or prospective outlook is very different. Much of what precedes is well known to every well-informed physician. Even so, and in view of what I hear frequently, it seems timely again to emphasize it. I am convinced, as others are, that the essential matter in many cardiac disorders, acute or chronic, is *not* the existence of a murmur, but the intimate condition of the heart muscle and nerve supply. Is this organ competent or not? If it is, how long will competence last? What course must be followed so that the patient's actual condition shall persist? If the heart is already incompetent, in what way and by what means may we prevent untoward progress in this direction? May we expect the heart to become again normal by any system of treatment?

Any one or all of these questions can be answered wisely only after much thought and observation. The answer will depend somewhat, it should be added, upon the disease or efficient cause producing the murmur. Further, we should duly estimate the fact of the time which has passed previous to the occurrence of the murmur. Has it developed suddenly or rapidly? Has it become manifest during or subsequent to an acute disease? Has it followed a sudden strain or prolonged effort? When it occurred was the individual apparently in good health or not? Has the murmur developed little by little and become clearly defined only after weeks or months and subsequent to an attack of gout or rheumatism or during the course of syphilis, tuberculosis, malaria, neurasthenia? Does it come from overwork, mental or bodily, anxieties, too much, too little, or improper food? Is the patient an alcoholic, or a smoker?

In any event I now hold after lifelong experience that it is wrong and useless in the majority of instances to tell patients they have a cardiac murmur. It alarms them almost invariably, even those who have well-balanced minds and tempers, and the fight or worry continues despite repeated protestations and explanations. Sometimes, indeed, it takes a long while, if it is ever accomplished, to undo or neutralize the bad effects occasioned by the inconsiderate statement of a physician. The evil consequences are perhaps greater when it comes from the trusted family adviser than from the prominent specialist who has been consulted, with or without the knowledge and approval of the former.

How may the trouble be avoided? At times, I grant, it is difficult. It may, however, often be accomplished by acting squarely and humanely in the following way. During the examination of the heart, the physician must not say within the hearing of the patient that a heart murmur exists. If asked the direct question by a patient, the doctor should simply reply: *That* is a question I never answer in any case. With this the patient must be satisfied. Or better still (and that I now always do when a patient is brought to me for examination of the heart), before beginning the examination, simply to say to the patient, I never state precisely what I find; I will examine you carefully, take sufficient and accurate notes of your case, and talk fully and confidentially with your physician as to what I discover and what I advise.

If the patient comes to my office alone, sent or not, by his physician, I state that I will write to or communicate with the physician; or in the latter case I simply say in advance of an examination that I never tell patients what I find in their hearts. Occasionally, it is true, even at present, when the patient's heart seems absolutely normal and when there is evidently groundless worry and anxiety which I hope to relieve measurably or entirely by a positive assertion I do so frankly and with little or no hesitation.

When I am called upon for an explanation of my mental attitude in this whole matter I simply say I have come to the deliberate conclusion that it is wrong and foolish to act otherwise; indeed, I believe it is frequently criminal. I have seen too many men, women, girls, and boys made miserable and unhappy for years by other, and what I know is habitual behavior on the part of physicians.

I have now in my remembrance not a few patients whose lives during several years have been almost wrecked by ill-advised, cruel statements of doctors about their hearts. Some of them are still living and fairly comfortable after many years, although, if they had not come into my care, I doubt if it would be true. Others have died, it is true, but at all events they did not "die daily" as a result of an opinion which, if not incorrect in substance, was misinterpreted and the opinion once given could not be changed with satisfactory effects to the patient. Further, the instances of heart failure which occur suddenly and disastrously are often those in which nothing has been revealed of an alarming character, even to the best expert's examination. I have seen and known of not a few. I do not refer merely to cases following acute disease, strain, or great shock—but to those individuals who simply collapse and drop dead—without adequate cause, and no one has known, or even suspected that their hearts were structurally defective. Of course, it is right and proper at times to make known confidentially one's judgment, even when it is only provisional, to the nearest relative or friend, because great personal or family interests, present and prospective, may be involved and it is necessary that someone other than the physician should know the medical facts. This I understand and fully appreciate. I do not wish to be misunderstood. To guide and direct a patient with heart trouble wisely and carefully is one thing; to tell him something that can be of no possible service to him or others in any way is quite another matter.

Following the course I have indicated in what precedes, I have surely been of great service to many; I have done no injury to anyone, so far as I know. Finally, I affirm that I yield to no one in my desire to help scientific progress in regard to heart disease. On the other hand, I also affirm, that some extrarefined knowledge which has come from the use of the newest, complicated, and cumbersome instruments has not promoted the comfort or the cure of patients thus affected.

Advanced research is good and to be commended, but it has its place. Usually this should be the hospital ward. The bedside of the nervous or ill patient must, however, be strictly guarded whenever this is carried out so as *not* to be cause of unnecessary mental or bodily distress to the patient.

Both within and outside of hospitals we may be so solicitous in our pursuit of scientific accuracy as to lose sight of right doing from the humane standpoint.

REPORT OF A CASE OF URETERAL CALCULUS TREATED WITH OIL INJECTIONS.*

By WALTER S. REYNOLDS, M.D.,

NEW YORK.

With the newer methods of diagnosis at our disposal, cases of ureteral calculus *in situ* are diagnosed with much more precision than formerly. We are now not only able to say definitely that a calculus is present but are also able to localize its position. This is all of the greatest importance from an operative standpoint because it greatly simplifies the operative procedure necessary for the removal of the calculus so that the operation has now come to be a comparatively frequent one and one that has yielded very excellent results.

In some instances a calculus of considerable size will descend the length of the ureter and finally be expelled into the bladder. But the irregularity of the ureteral canal favors the stoppage of the concretion at one of these contractions with great uncertainty as to its further passage.

The descent of the calculus along the ureter gives rise to more or less severe pain, in many instances so intense that large quantities of morphine are necessary for relief of the pain, and even with extremely large doses the pain may not be entirely relieved. For the relief of pain which could not be controlled by morphine Bransford Lewis adopted a unique method. He injected 10 to 20 drops of 1 per cent. alypin solution through a ureteral catheter. The catheter was allowed to remain in place and the alypin solution injected whenever necessary. The location of the pain does not always indicate the side on which the calculus may be found. An *x*-ray should, therefore, always be taken of both sides.

Attacks of renal colic are accompanied by marked urinary symptoms, as frequency of urination, especially if the calculus is low down in the ureter, which is ordinarily not painful; hematuria more or less marked in nearly every case, and where not shown macroscopically it can frequently be discovered by microscopical examination.

How frequently the calculus would finally pass into the bladder it is impossible to say, but it has been estimated that 50 per cent. will pass under expectant measures. While the stone may undoubtedly remain for a considerable time in the ureter and produce no very great pathological change in the ureter or kidney, it would be a constant source of danger from blocking of the ureter or serious changes in the ureter or kidney. Interference with the passage of urine leads to hydronephrosis or pyonephrosis, with a possibility of entire destruction of the kidney. As the symptoms of hydronephrosis are frequently wanting, it might remain unsuspected until serious damage to the kidney had occurred. The possibility of these serious consequences renders treatment of some kind for the removal of the stone necessary where its expulsion is delayed in order to preserve the kidney.

The administration of any medicinal remedy internally is probably of little value in breaking up the stone or aiding in its expulsion and the virtue ascribed to some of the mineral waters is probably due to the quantity of water rather than to any quality of the water used. If copious flushing does not result in the passage of the stone some other method of relief must be instituted, and this usually necessitates surgical intervention.

A method of treatment has lately been employed which seems to offer some chance of assisting the passage of the stone into the bladder, thus avoiding a cutting operation. I am unable to say who first suggested this method of treatment, and therefore am unable to give due credit to the originator. I refer to the injection of oil into the ureter through a ureteral catheter. I have employed it in two cases, one of which was lost sight of; the other man passed the stone after a number of treatments. The passage of the catheter alone may have had some effect in aiding the progress of the stone in its descent.

The history of the case is as follows: G. B., a man 32 years of age, was first seen in the summer of 1911 at the Vanderbilt Clinic by one of our students, Dr. J. F. Hill, now on the Roosevelt Hospital staff, who, thinking the man might have a ureteral calculus referred him to me for examination. He was a barber and said that during the past year he had been obliged to stop work on several occasions on account of the pain in the back, which had been mostly on the right side. These attacks of pain or colic had been accompanied by frequency of urination and bloody urine. He had visited several clinics and dispensaries in search of relief, but no examination had ever been made which would indicate that a calculus was suspected. I immediately made a cystoscopic examination and found the bladder normal except that the opening of the right ureter showed some slight evidence of swelling and congestion. Ureteral catheters were introduced, the one on the left side passing without difficulty and drawing normal urine with seeming regularity. On the right side the catheter could only be passed about one and one-half inches, and the urine dribbled away slowly from the catheter. The urine was only slightly turbid with no evidence of blood macroscopically. He was referred to Dr. Edward Leaming at Roosevelt Hospital for an *x*-ray examination. His report was that there was a calculus present.

I decided to try injections of oil into the ureter to see whether it would be possible to induce the passage of the stone. I gave several injections of oil, but was never able to pass the catheter beyond the point where it was stopped on the first examination until later, when he came to my office. The man was lost sight of for some time, but came to my office on July 2, 1912, saying that he had had a severe attack of colic and feeling that the oil injections had relieved him, asked if I would continue the treatment. I gave him several injections and then, on account of moving, discontinued the treatment for a short time. I found that by inserting my finger into the rectum I was able to get the catheter by the obstruction shortly after he first came to my office, and this was subsequently done at each treatment and the oil injected well up the ureter. The passage of the catheter by the obstruction caused a considerable quantity of urine to flow from the catheter, showing that there was some obstruction to the free passage of urine. During the short time that I did not see him he had a severe attack of colic. He was seen again on October 1, and at this time was having pain during and just after urination. I suspected that the stone might be in the bladder, but was not prepared to examine him with the cystoscope and referred him to Dr. George Brewer at Roosevelt Hospital. An *x*-ray plate made at this time by Dr. Leaming

*Read before City (Charity) Hospital Alumni Society, Oct. 16, 1912

showed the stone in the bladder, and it was shortly passed during urination.

The stone is somewhat fusiform in shape, one and one-half cm. long and seven mm. thick. There was a small, sharp, projecting point near one end which has become broken off by handling, and the entire surface is rough and uneven.

The case, it seems to me, demonstrates the usefulness of this method of treatment in some cases at least.

132 West Seventy-third Street.

A SAFETY SCREW DRIVER AND SCREWS FOR LANE PLATES.

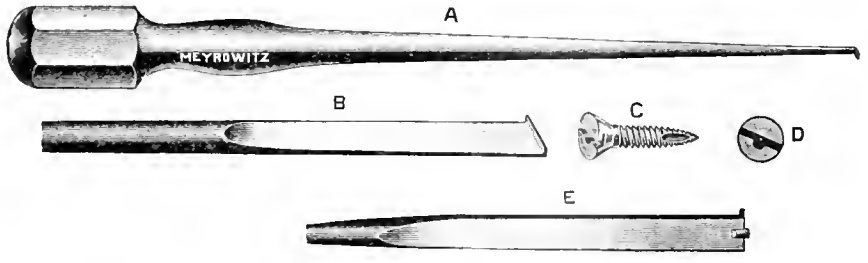
By ARNOLD WOOD,

NEW YORK.

This screw driver is so made that it will always catch the screw centrally and cannot slip or pull out of the slot on the head of the screw so long as the driver is held in a perpendicular position or nearly so. When the screw is home in place, a slight motion of the driver sideways will disengage it from the slot which is cut in the head of the screw, as shown in the illustration.

The advantages claimed for this instrument are:

1. Absolute security against losing the slot in the screw.



2. No pressure is required to keep the screw driver in position on screw, thus permitting a more delicate manipulation.

3. Time is saved in swabbing to find the head of screw, necessitated in slipping of the driver from the slot.

4. Protection from injury to surrounding tissues and consequently a lessening danger of infection.

5. A material saving of time in operation, owing to simplicity of technique.

Dactylomegaly.—Ramond and David apply this name to a group of cases in which there is a characteristic enlargement of the fingers or toes. The clubbed fingers of tuberculous subjects were recognized by Hippocrates, and the name "hippocratic fingers" was given to this condition. Trousseau perceived in this a grave prognostic sign. Pierre Marie described two forms of digital hypertrophy, namely, that which is associated with acromegaly and that which is a manifestation of pulmonary osteoarthropathy. Hanot and others described a form of digital hypertrophic osteopathy occurring in biliary disease, and still other observers described a similar condition in cardiovascular affections and in nephritis. David recognizes two forms of dactylomegaly: an essential or primary, and a secondary variety. The primary type presents itself in either of two forms. In one of these there is a concomitant hypertrophy of the nail. The finger has a lanceolate appearance or one resembling that of a serpent's head or drumstick. In the second form there is no enlargement of the nail which, however, is the seat of dystrophic lesions. The diagnosis of dactylomegaly presents little difficulty. It may be confounded with acromegaly or with Paget's disease. The deformities of the hand and fingers in chronic rheumatism and in arthritis deformans present a characteristic appearance. In the cheiromegaly of Charcot and Brissaud the hypertrophy affects the metacarpal bones and not the phalanges.—*Le Progrès Médical.*

Medicolegal Notes.

Opinion Evidence Admissible.—In an action for injuries it was held proper to permit a physician to testify that in his opinion the plaintiff suffered from "a traumatic neuritis" and another to state that in his opinion she was suffering from "a nervous condition due to a bodily injury, which is usually classed as traumatic neurosis"; such statements referring merely to the nature and character of the plaintiff's ailment, without suggesting the particular cause.—Torreyson v. United Rys. Co. of St. Louis (Mo.), 145 S. W. 196.

Malpractice—Excessive Damages—Both Defendants Not Necessarily Guilty.—In an action for malpractice against two physicians and surgeons the evidence showed that the plaintiff had been suffering for several years from a malady for which she was told a surgical operation would be necessary. She went to Dr. C., who examined her and found her anemic, run down in health, unable to work, and suffering from complicated uterine troubles—her uterus being enlarged and ulcerated, emitting a foul discharge and protruding so that she could only walk with difficulty—and the bladder and rectum were involved. Dr. C. told her that an operation was necessary, but that he did not do that kind of operation, and suggested that Dr. B. would perform it. On July 20 the operation was performed at a hospital by Dr. B., who removed the diseased uterus, fastened the bladder in its proper position, closed up the wound with a deep suture and surface stitching, and placed in it for drainage a narrow strip of iodoform gauze eighteen inches long, which was subsequently removed by Dr. C. Within a week an abscess formed between the vagina and the rectum, which was lanced by Dr. C. Three days after Dr. B. again opened the abscess and put some gauze in it, which it was claimed was afterwards removed by Dr. C. The abscess continued to suppurate and four weeks after the first operation the plaintiff was removed to her home. The defendants continued to visit the plaintiff until October 6, when, the abscess having failed to heal, the defendants concluded there was some foreign matter in it and advised an exploratory search with an instrument. This the plaintiff refused to submit to. On October 3 she had, without the knowledge of the defendants, called in Dr. R., who examined her and found pus coming from the abscess. A few days later Dr. R. performed an operation with a grooved director, enlarging the fistulous opening of the abscess so that it could be examined with a finger. He extracted through the mouth of the abscess two pieces of surgical gauze, one about six or seven inches square, the other about one and a quarter inches square by a quarter of an inch thick. Soon after the abscess healed and the plaintiff began to get well. The cause of action was based on the theory that the defendants had negligently left the gauze in the plaintiff's body at the time of the first operation. The jury returned a verdict for $6,000 from which the plaintiff remitted $4,000. It was held that this was very much larger than a reasonable compensation for any damages sustained by the plaintiff and called for a reversal of the judgment. It was also held that, as one of the defendants might, under the evidence, have been found guilty and the other not guilty, it was error for the trial court to give the jury instructions which assumed that if one defendant was liable both were liable.—Hansen v. Crocker, 160 Ill. App. 514.

Exhibiting Personal Injuries to Jury.—It is within the discretion of the trial court to permit the plaintiff in a personal injury case to exhibit his injuries to the jury, in order to show their extent or to enable a surgeon to demonstrate their nature and character. It is also discretionary to permit tests and experiments in the presence of the jury in a proper case and under proper safeguards. But where there are no wounds, no injuries that can be seen by the jury, it is improper to permit the exhibition of plaintiff's person for the purpose of conducting experiments to prove that he will cry out with pain, or that his muscles will grow rigid when his legs are manipulated in a certain manner. When it appears that the probable effect of the exhibition will be, not to instruct the jury as to the nature and extent of the injuries, but to excite their sympathies or inflame their passions, it should not be permitted.—Landro v. Great Northern Ry. Co., Minnesota Supreme Court, 135 N. W., 990.

THE INVASION OF THE UNFIT.

IN an address before the Mental Hygiene Conference in this city on November 14, Mr. William Williams, U. S. Commissioner of Immigration, inveighed forcibly against the weakness of the defences against the admission of insane and mentally defective immigrants to this Port, a matter to which we have frequently called attention. It is no exaggeration to say that the exclusion of the subjects of mental disease is of vastly greater concern to this country than is the quarantining of cholera, smallpox, plague, or any other infectious disease. The introduction of cholera or of plague into New York would be unfortunate, but even if the disease became epidemic for a time, which is improbable, the application of modern sanitary methods would soon arrest it and the loss of life would be inconsiderable. But the admission of mentally defective immigrants strikes at the very roots of the nation's existence. It is from these and their descendants that the criminal classes are largely recruited; they crowd the insane asylums, they furnish the Guiteaus, the Czolgoszes, and the Schranks, the Lefty Louies, and the Gyp the Bloods, and they start vicious strains leading to incalculable misery, pauperism, and criminality in future generations.

It is the duty of the officers of the Public Health Service at Ellis Island to safeguard the country against the admission of these lumps of poisonous leaven, but it is the duty of Congress to enable the Service to perform its difficult task effectively, and in this duty Congress has thus far signally failed. The unthinking are prone to blame the immigration authorities for passing the many defectives that now enter the country, but, as Mr. Williams points out, the force at Ellis Island is utterly inadequate in numbers to prevent this influx. Laws are useless without a sufficient number of officials to enforce them. A force of twenty-one medical officers at Ellis Island can hardly be expected to pick out all the insane and mentally defective in over 2,000 immigrants passing under their observation every day. During the past ten years there has been an average of nearly 2,500 immigrants entering the Port of New York every day, or over 100 a day to each inspector. Who is the alienist who would pass on the mental condition of fifteen persons an hour, most of these, moreover, speaking an unknown tongue and able to communicate with the physician only through an interpreter! There are not even twenty-one inspectors available for the mental and physical examination of the immigrants, for there is a multitude of other duties engaging the attention of the medical officers of the Public Health Service. There are at times several hundred patients in the hospital and many more, adults and children, with minor ailments have to be looked after.

Mr. Williams says, and he is very moderate in the statement, that there should be at least three times as many medical officers stationed at Ellis Island as there are now, and he also recommends that an inspector should be placed on board every transatlantic steamer bringing immigrants to this port. Such an officer, coming in daily contact with the steerage passengers during the five to twelve days of the ocean passage, would have the opportunity to study them carefully and leisurely and would thus be able to detect many cases of mental disease which now elude the vigilance of the inspectors during the necessarily hurried inspection upon arrival. This, of course, cannot be done without the sanction of Congress, but although it has been twice recommended to that body no action has yet been taken.

The newspapers are very free with advice to the Governor-elect of this State in relation to appointments and other local matters, but they ignore the opportunity which he has, while still a member of Congress, to introduce a bill of far greater import to the State of New York and the Nation at large than anything they have suggested. Mr. Sulzer, we doubt not, feels fully the responsibility which will soon weigh upon him in the government of this great commonwealth. One of the greatest of these, if he does not recognize it now he soon will, is the care of the insane. The State Hospitals are already overcrowded, and the number of unfortunates that must be taken care of is constantly and alarmingly increasing. The passing of a bill by Congress, increasing the medical staff of Ellis Island and providing for inspectors on the transatlantic steamers would go far to solve this one, at least, of the problems that will vex the future Governor. Mr. Sulzer can at this time do no more signal service to the State, over which he has been called to rule, than to introduce such a bill and urge its passage.

THE HEALTH OF THE BUSINESS MAN.

THE health of the city dweller is being discussed from various points of view. There are many who claim that to the conglomeration and massing of persons in large centres are due the physical and mental defects which are so prevalent now and which are said to be increasing. By many authorities recently the back to the land cry has been loudly voiced as the most potent remedy for progressive degeneration. On the other hand there are those who argue that living in the country, at any rate, in the way the American farmers generally live, is by no means productive of good health

and is responsible for the many digestive troubles to which the American farmer and family are prone. These assert that, as a rule, the city boy and girl and the city man and woman are healthier than those of the country. But on one point all are agreed, namely, that city life should be made as healthful as possible. Much is said nowadays concerning the stress and strain of business life and these enemies of health appear to be almost as greatly in evidence in supposedly easy-going Europe as in this, which it is the fashion to call the land of hustle and bustle. In London a few weeks ago a conference was held under the auspices of the Incorporated Institute of Hygiene (*Medical Press and Circular*) to discuss the health of the business man. Sir Thomas Crosby, the Lord Mayor of London and a medical man of some note, said that during an experience of sixty years' practice in the city he had remarked a great change of views with regard to the health of the city office toiler, and he believed that the health of the clerk was at the present time well looked after. He also pointed out that the improvements made in drainage and water supplies had been wonderful and that, of course, the worker had benefited thereby. Sir William Bennett was inclined to think that matters sanitary were still susceptible of great improvement, and Dr. Olsen remarked that the business man was naturally a brain and not a muscle worker, and, therefore, did not need the heavy meals that many city men were accustomed to eat. Especially in his opinion should hurry at meals be avoided and the consumption of meat in the middle of the day was also deprecated. Dr. Cameron Gillies thought that the rush and worry of city life was a fruitful source of dyspepsia. This was not owing so much to errors of eating or drinking but to the high strung nerves of many of the workers. Dr. Farquhar Buzzard held the view that mere rush and a sedentary life were not mainly responsible for ill health. Hereditary causes were fruitful of trouble, and bad habits, such as over-drinking, over-eating, and over-smoking, brought about many breakdowns. He did not believe in muscular exercise for neurasthenia, but in recreation. Dr. Cahill thought that the business man had on the whole an easy life and that his health and longevity compared favorably with those of other classes. Another speaker said that the business man ate less and drank less than formerly and consequently enjoyed better health. Most of the speakers expressed the opinion that but little should be eaten in the middle of the day and some seemed to think that two good meals in the day were quite sufficient. The most important part of the London Conference was that which dealt with the eating and drinking question. A man who does not take enough exercise or who does not perform sufficient manual labor to enable him to digest and assimilate a large quantity of food and particularly flesh food, should be very careful as to quality and quantity of food he ingests. Such a man does not require much meat and after a certain age the less meat he eats the better will it be for him and assuredly he should not eat much in the middle of the day—for the matter of that he should not drink much, either. As for exercise, that is a more debatable point. The majority of businece men take too little regular exercise and many sporadically take too much. In this instance the personal equation is almost all important.

"GENUINE" EPILEPTIC CRISES IN NON-EPILEPTICS.

The fundamental distinction which held good for years between "epileptic" and "epileptiform" convulsions has long been regarded by progressive neurologists as untenable. Several types of individual who cannot by any stretching of criteria be regarded as epileptics are nevertheless known to have convulsive attacks in every way characteristic of true epilepsy Conversely there is no reason why an epileptic should not have attacks which, occurring in sound subjects, would simply be styled epileptiform. Bratz's so-called "affect epilepsy," which so closely resembles the genuine convulsions that the subjects are placed without hesitation in asylums and colonies, was found not to be epilepsy only after prolonged observation. In recent years neurologists have reported cures of these or similar cases, after years of confinement in institutions, by Freudian psychoanalysis. Another category of this pseudoepilepsy is seen in Oppenheim's psychasthenic convulsions. Narcolepsy, so called, is hardly distinguishable from *petit mal*—in some cases perhaps only because there are no evidences of the epileptic constitution or of other epileptic manifestations.

At the recent session of the Society of German Neurologists the entire subject of epilepsy and its congeners received such a discussion as has not perhaps befallen it in years (*Deutsche medizinische Wochenschrift*, October 24). Redlich prophesied that all other criteria must give way to the study of the epileptic disposition which must of necessity be the sole foundation of all true epilepsy. In this connection we must bear in mind that many subjects of this constitution have never exhibited epileptic manifestations. We therefore have to study more deeply the factors which bring out the manifestations. Binswanger and others do not hope for much aid from studies based on etiology plus anatomy, although very clean-cut epilepsies of this nature are constantly encountered. Minute anatomical changes like Alzheimer's gliosis (found in some 40 per cent. of autopsies) are better explained as the result of the convulsions than as an anatomical foundation. From another point of view other frequent anatomical finds like sclerosis of the cornua of Ammon are mere evidences of a hypoplastic brain and stand in no causal relation whatever with epilepsy.

Peritz discussed induced spasmophilia in adults. About 20 per cent. show an overexcitability of idiomuscular sensibility. He claimed to be able to produce in neuro- and psychopathic subjects by means of Aschner's test (pressure on the eyeball) slowing of the pulse, lowering of blood-pressure, a pathological blood picture, an entire series of vasomotor symptoms, and finally epileptiform attacks and absences. In other words, there appears to be a vasomotor component in epileptic and other dis-

charge phenomena. The independent vegetative existence of the autonomous nervous system has naturally often been assumed to figure in spontaneous nervous outbreaks.

Meyer announced that in true epileptics convulsions could be promptly precipitated by various substances—large doses of sodium chloride after salt starvation, urea, and even simple salts like sodium citrate and carbonate. These reactions may be used for diagnostic purposes as they never induce convulsions save in true epileptics.

THE UNITED STATES PUBLIC HEALTH SERVICE.

The Public Health Service, which was placed at the last session of Congress in the position of increasing its already well-recognized efficiency, receives considerable attention in the annual report of Secretary MacVeagh. The latter emphasizes the fact that Congress has favored the policy of developing this important phase of governmental activity. Although not intended to replace or interfere with the public health activities of cities or States, nevertheless, the Public Health Service may materially aid the latter and at the same time may fulfill certain independent functions. For these purposes it requires adequate appropriations. These amounts will at any rate seem insignificant in comparison with the immeasurable returns which they will yield in public health and happiness. The Secretary points out that the usefulness of the Public Health Service is being promoted on every hand in spheres of activity that can be performed only through the agency of the Federal Government.

These statements emanating from an important member of the Cabinet should tend to allay the feeling, which has been fostered in recent years, that the Public Health Service is in an uncongenial official atmosphere. Referring to the supposed advantages of uniting the Public Health Service with other bureaus, some of whose activities are more or less related to health matters, the Secretary says: "It is doubtful whether large economies and better administration can be secured by the consolidation of bureaus from different departments. Take for example the Public Health Service. That now has a head and organization of its own and individuality of its own—and stands alone face to face with its own work only; and practically the only association of the head of the department with a service like the Public Health Service is to render assistance to that service when it cannot get assistance in any other way, and to give it protection when it cannot otherwise be protected; and, finally, to make sure—as there must be somewhere somebody to make sure—that the right men are in charge of the work. The statement made the other day by a well-known municipal health officer that the Treasury Department is apt to take only the money view of public health is a conspicuous evidence of the insufficient consideration given the subject. This Public Health Service can and will develop, without interruption, to the full boundaries of its own province if it is given the comparatively small appropriations that are required. Then, after the development, which nothing now obstructs, its form of organization can be reconsidered. Meanwhile, it would be a great mistake to complicate this distinctive, clear cut, comprehensive, and independent work with any other work—and especially to associate it with other bureaus which have their own independent existence and reason for existence; because this would bring it into relations, which, to say the least, it does not need, and would forfeit, in any plan that has been suggested, its actual independence. It would not absorb but would be absorbed."

Tuberculosis Among School Children.

In the campaign against tuberculosis no part is of greater importance than that of safeguarding school children against infection. Philip of Edinburgh insists that if the tide of tuberculosis is to be stemmed the child must be so reared that he will be immune to infection, and that, in fact, the problem of the prevention of tuberculosis resolves itself into the problem of properly caring for the child. Nietner, General Secretary of the German Central Committee for the Prevention of Tuberculosis, recently delivered an address on tuberculosis in childhood at the Medical School of the Royal Hospital for Diseases of the Chest, London, in which he dwelt upon the vital importance of school medical service, cooperation of teachers, care of teeth, and school hygiene in the waging of the campaign against the disease. He was especially emphatic as to the importance of the rôle of the school physician in such a campaign and was of the opinion that the office of school doctor should be a whole-time appointment, and only in exceptional cases a part-time duty, and the school medical service should be made general throughout a country. He believed that the colleges for teachers should also be included in the school medical service, as well as the trade schools. He pointed out that while it is the children belonging to the lowest classes who chiefly call for medical supervision in the elementary schools, in the higher schools it is the age of puberty which is chiefly associated with pathological phenomena, for which fact a too arduous program of school work at a period of active physical development must be held, at least, partially responsible. Nietner's paper was for the most part a description of the thorough way in which Germany is endeavoring to cope with tuberculosis in children, and as such is worthy of the attention of other nations who are not yet equipped for the fray so adequately as is Germany. There is no doubt that the problem of tuberculosis is above all the problem of tuberculosis in childhood.

Infectious Diseases Incidental to School Life.

At a meeting of the Ulster Medical Society, held in Belfast on November 7 (*Medical Press and Circular*, November 13, 1912), the president, Dr. R. W. Leslie, discussed infectious diseases incident to school life, their early recognition, treatment, and control. For eighteen years Dr. Leslie had acted as medical officer to one of the largest boarding schools in Ireland and was, therefore, well qualified to speak with authority on the subject. He had noted that outbreaks of infectious ailments almost always occurred in the winter half of the year and chiefly in February and March. The commonest ailment by far was measles, but the most important from various points of view was scarlatina. The difficulties of diagnosis in the early stages were great, yet it was precisely at this period, he said,

that the disease was most infectious. Careful watching was necessary in every case of sore throat. With regard to measles Leslie said it was remarkable that there had never been a case in the school between April 1 and September 30, in any year. Mumps came second to measles in frequency. In several cases of the latter disease acute pancreatitis had occurred as a complication and orchitis was noted in more than 10 per cent. of the cases.

News of the Week.

School Inspection.—Dr. Ira S. Wile, the recently appointed member of the Board of Education of New York, has protested to the Mayor against the action of the Board of Aldermen in practically wiping from the City Budget for next year the provision for medical inspection of the parochial schools in this city. Dr. Wile points out that there are approximately 130,000 children in these schools, for the proper inspection of whom it was proposed to add to the present force of medical inspectors and supervising nurses, which is sufficient only for public school inspection, one medical inspector for each 9,000, and one nurse for each 4,000 children. From this minimum allowance, however, the Aldermen have dropped nine inspectors and eight nurses, thus leaving 81,000 children in the parochial schools without medical inspection and 32,000 without the attention of a supervising nurse. This so-called economy has the effect of nullifying the money spent on medical inspection of public schools, since each uninspected school is a possible focus for the spread of infection.

New Radium Fields.—Rich deposits of radium have, it is said, been discovered near the Salzburgerkopf in Austria.

Physicians' Study Travels.—At a subscription dinner held December 7 in Philadelphia, a committee was appointed to organize the American Society for Physicians' Study Travels, Dr. James M. Anders being elected chairman. All American physicians interested in foreign study travels are invited to correspond with the chairman, 1605 Walnut street, Philadelphia, Pa. It is announced also that in connection with the International Medical Congress to be held in London next summer, plans are being made in this city for the organization of a study tour for physicians, leaving New York on July 3, visiting the most important capitals and medical centers on the Continent, and ending in London the week of the Congress. Details may be obtained from Dr. Richard Kovács, 236 East 69th street, New York.

Rural Nurse Corps.—The project of the Red Cross Society for the establishment of a rural nurse corps throughout the country took definite shape recently when the promise of an annual contribution of $5,000 for this purpose was received.

Personal.—Col. William C. Gorgas, chief sanitary officer of the Isthmian Canal Commission, sailed from Panama for Ecuador on December 4 for the purpose of making an estimate of the cost of the proposed sanitation at Guayaquil. Col. Gorgas has declared his intention of making every Southern port within seven days of Panama as free from disease as is the Canal Zone itself.

Dr. Roland G. Curtin of Philadelphia has been elected vice-president of the New England Society of Pennsylvania, and Dr. Marcus E. Dwight has been chosen physician to the same society.

Prize Essays.—The Committee on Prize Essays of the Medical Society of the State of New York offer the following suggestive, though not arbitrary, subjects upon which competitors for the Merritt H. Cash Prize and the Lucian Howe Prize, of $100 each, may submit essays: (1) Diagnosis and treatment of syphilis of the central nervous system. (2) The present status of serum therapy. (3) Latest research relative to cancer. (4) The order and sequence of vascular and cardiac disease. (5) The function of the State in limiting the increase of imbeciles and degenerates. (6) Surgery in functional and organic disorders of the stomach. Essays submitted in the competition must be in the hands of the chairman of the committee, Dr. Albert Vanderveer, 28 Eagle street, Albany, N. Y., not later than April 1, 1913.

Medical Congress Museum.—A committee, headed by Prof. A. Keith of the Royal College of Surgeons, London, has been formed for the purpose of organizing a museum in connection with the XVIIth International Congress of Medicine to be held in London in August, 1913. It is felt that the collection of museum material in one center possesses obvious advantages over the plan of leaving each section to collect and house the specimens required by the readers of its communications, and that the study of the available material will be enhanced by the coordination of the various departments. The committee is, therefore, seeking exhibits from provincial and foreign institutions and from private collections, it having been decided to leave the collections of the London hospitals undisturbed. The committee will defray the expenses of transit of the exhibits, and will insure them against damage and loss, besides taking every reasonable precaution for their safety. Anyone willing to place material at the disposal of the committee is requested to communicate with the Honorable Secretary of the Museum Committee, Dr. H. W. Armit, Ravenhurst, Talhot Road, Wembley, England.

Antehymeneal Medical Inspection.—At a recent convention of the Episcopal Diocese of Nevada resolutions were unanimously adopted in which the clergymen of the State pledged themselves to demand a certificate of health from each of the contracting parties before performing the marriage ceremony.

Gifts to Charities.—By the will of the late Mr. Theophilus J. Zurbrugg of Mount Holly, N. J., the sum of $250,000 is placed in trust for the erection and maintenance of a hospital at Riverside, N. J. Besides this, $5,000 is left to the German Hospital of Philadelphia for the endowment of a free bed, and $5,000 also to the Burlington County, N. J., Hospital.

Mt. Sinai Hospital, the Montefiore Home for Chronic Invalids, and the Visiting Guild for Crippled Children of New York, each receive $2,500 by the will of the late Mr. Ferdinand Hermann of this city.

By the will of the late Mrs. Mary A. Johnson of Philadelphia, the sum of $5,000 is bequeathed to the Presbyterian Hospital of that city for the endowment of a free bed in memory of the testator's daughter.

Harvey Society.—The fifth lecture of the season will be delivered on Saturday evening, December 14, at the New York Academy of Medicine, by Prof. Frank Burr Mallory of the Harvard Medical School, Boston, on "The Infectious Lesions of Blood Vessels."

German Medical Society.—At the annual

meeting held in New York on December 2, the following officers were elected for 1913: *President*, Dr. G. Seeligmann; *Vice-President*, Dr. H. Fischer; *Recording Secretary*, Dr. M. Rehling; *Treasurer*, Dr. S. Breitenfeld.

Association of Resident and Ex-Resident Physicians of the Philadelphia Hospital.—The twenty-sixth annual reunion was held in Philadelphia on December 3, Dr. Lawrence F. Flick presiding, and Dr. Benjamin F. Stahl acting as toastmaster. Among the speakers were Dr. J. Solis-Cohn, Dr. Joseph S. Neff, Dr. J. Ewing Mears, Dr. Theodore Diller, and Dr. Richard C. Morris.

Frederick County (Md.) Medical Society.—At the annual meeting held in Frederick the following officers were elected: *President*, Dr. Morris A. Birely, Thurmont; *Vice-Presidents*, Dr. S. S. Maynard, Frederick, and Dr. Ralph R. Browning, Myersville; *Secretary*, Dr. B. O. Thomas, Frederick; *Treasurer*, Dr. H. P. Fahrney, Frederick.

Williams County (O.) Medical Society.—The following officers were elected at the annual meeting of the society, held on November 22: *President*, Dr. J. A. Weitz, Montpelier; *Vice-President*, Dr. F. E. Solier, Bryan; *Secretary-Treasurer*, Dr. D. S. Burns, Bryan.

Prize Essay on Diabetes.—The Society of Carlsbad Physicians announces a prize to be given for the best essay on "The Treatment of Diabetes Mellitus, with Special Reference to Balneotherapy." The jury will be: Hofrat Prof. Dr. Ritter v. Jaksch of Prague, Prof. Dr. Luethje of Kiel, Prof. Ortner of Vienna, Prof. Dr. Schmidt of Innsbruck, and Dr. Edgar Ganz, President of the Society of Carlsbad Physicians. It remains optional with the judges to award either one prize of 5000 Kronen, or two prizes of 3500 Kronen and 1500 Kronen, or three prizes of 3500 Kronen, 1500 Kronen, and 1000 Kronen. The competition is open to physicians of all countries. Any language may be used. The time of contest expires December 31, 1913. Any further information may be obtained from the Society of Carlsbad Physicians in Carlsbad.

Obituary Notes.—Dr. Maurice Francis Sullivan of Brooklyn, a graduate of the Dartmouth Medical School, Hanover, N. H., in 1887, died at his home on November 29, aged 48 years.

Dr. Samuel J. T. Ritter of Bethlehem, Pa., a graduate of the Eclectic Medical College, Cincinnati, in 1897, died at his home of pneumonia on December 4, aged 36 years.

Dr. Nathan G. Ward, of Philadelphia, a graduate of the Jefferson Medical College, Philadelphia, in 1893, formerly assistant in laryngology at the Jefferson Hospital Dispensary, clinical professor of laryngology and rhinology in the Medical Department of Temple University, Philadelphia, and a member of the American Medical Association, the Pennsylvania State and Philadelphia County Medical Societies, and the American Academy of Ophthalmology and Oto-Laryngology, and attending laryngologist and otologist to the Samaritan and Garretson Hospitals, died at his father's home in Elizabeth City, N. C., on December 4, aged 40 years.

Dr. George Ernest Jarrell of Notasulga, Ala., a graduate of the Maryland Medical College, Baltimore, in 1904, and a member of the Alabama State and Macon County Medical Societies, died at his home on November 25, aged 32 years.

Dr. Charles Erskine Brayton of Stonington, Conn., a graduate of the College of Physicians and Surgeons, New York, in 1873, a member of the American Medical Association, the National Association of Railway Surgeons, and the Connecticut State and New London County Medical Societies, and a former president of the last, and for six years health officer of his borough, died at his home on December 2, aged 61 years.

Dr. George Edwin Jones of St. Augustine, Fla., a graduate of the Ohio Medical College, Cincinnati, in 1859, a member of the American Medical Association and of the Indiana State Medical Association, and a veteran of the Civil War, having served as assistant surgeon in the United States Navy, died at his home on November 30, aged 77 years.

Dr. John Ely Brackett of Washington, D. C., a graduate of George Washington University, Department of Medicine, in 1870, a member of the Medical Society of the District of Columbia, and emeritus professor of the principles and practice of medicine in the Howard University School of Medicine, died at his home recently after a long illness, aged 66 years.

Dr. Jaquelin E. Knight of Waycross, Ga., a graduate of the Atlanta College of Physicians and Surgeons in 1909, and a member of the American Medical Association and the Georgia State and Ware County Medical Societies, died at his home on November 18, aged 26 years.

Dr. Henry Moore of Indianapolis, Ind., a graduate of the Kentucky School of Medicine, Louisville, in 1864, chairman of the board of trustees of the Indiana State Tuberculosis Hospital at Rushville, died suddenly at his home on December 2, aged 71 years.

Correspondence.

PROPHYLACTIC VACCINATION AGAINST TUBERCULOSIS.

To the Editor of the Medical Record:

Sir:—The notoriety given by the public press in this country to the claims made by Dr. Friedmann of Berlin before the Berlin Medical Society on November 6 last, interests the writer more particularly on account of Dr. Friedmann's statement that he has vaccinated 360 children within the last year with a vaccine consisting of living tubercle bacilli, that had been found non-virulent by laboratory experiments. The *Berliner klinische Wochenschrift* of November 18 contains Friedmann's paper in full, and also the discussion which followed its presentation. In the latter, several of those participating made it clear that, with the evidence at hand, the use of a living virus, which for the time had lost its virulence for laboratory animals, was not justified and implied serious risks. Citron called attention to the experience of Pasteur, with a presumably non-virulent living virus of chicken-cholera which though first apparently successful, for some unknown reason regained its virulence later, and instead of protecting, caused veritable epidemics in the fowls which had been injected for the purpose of their protection.

It appears to me that even with the risk of using a living virus, Dr. Friedmann has not supplied the slightest evidence that he has conferred any degree of resistance or of immunity on the children which he inoculated. The only evidence which he sets forth for this purpose, namely that these children are "so far free from scrofula" can scarcely be called evidence of immunity, nor does

it preclude the possibility of his having actually infected them, since an intra-muscular injection of tubercle bacilli does not necessarily produce clinical evidence of tuberculosis in the time which has intervened, and need not do so until many years later.

Comparing Friedmann's work with that of Dr. von Ruck of Asheville, as reported in the MEDICAL RECORD of August 31, 1912, one cannot but be gratified with the precautions and extreme care employed by him, with a vaccine the use of which could imply no real danger, since it contains only extractives of tubercle bacilli, likewise from a non-virulent culture proven to have been so for over 10 years. But for this evidence of safety and the additional evidence of its value I could never have consented to its use in some 400 children of the Baptist Orphanage here and under my medical charge.

The evidence of its value has been demonstrated as completely as this is possible to do by the presence of specific antibodies in the sers of vaccinated animals, and in their complete protection against an infection much more virulent than those made by Dr. Friedmann, who admits that he lost all his animals of tuberculosis in spite of his vaccination, after infecting them with a weakly virulent culture that killed on an average after 110 days, whereas the infected control animals of Dr. von Ruck all died in less than half this time. Dr. von Ruck demonstrated further that the serum of non-vaccinated children had neither bacteriolytic nor germicidal power and contained no specific antibodies, or at most but a very limited amount; whereas they were present in large amounts on the fifth day after vaccination, and he showed their correspondence with the bacteriolytic and germicidal power of the serum *in vitro* and *in vivo*. Although all animals infected with virulent tubercle bacilli acted upon with serum taken before vaccination became tuberculous and died, all animals infected from the same culture acted upon with serum taken after vaccination, withstood the infection and remained free from tuberculosis. In recent re-examinations of the children in whom I am particularly interested the same bacteriolytic and germicidal power has again been shown without exception, and in a new series of 120 children, vaccinated within the last three months, the same results have been obtained.

In the difference between this pioneer work done in our own country and the results shown by Dr. Friedmann of Berlin there is a most complete refutation of the latter's postulate that for the production of immunity in tuberculosis a living virus is absolutely essential and that an inflammatory infiltration the size of a nut to half an apple must be produced and must continue for a month or two at the site of injection for its full development.

C. A. JULIAN, M.D.

THOMASVILLE, N. C.

THE PREGNANT WOMAN, TUBERCULOSIS AND HER SAFETY.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—It appears that in my paper on this subject in the MEDICAL RECORD of November 16, several fundamentals were not elaborated. This omission was due to taking too much for granted and staying too closely by the text. The good results of treatment there mentioned should be attainable by any physician, or if not obtained, then the cause of failure will be found in carelessness or inattention to details of simple nature. In the care of a tuberculous pregnant woman the advantages of fresh air, ample diet and abundant exercise are well known. Every such patient that I have seen had already, or previously, been carefully advised as to their value; but each woman also had some difficulty which rendered the advice futile, because past carrying out. Considering air, diet, and exercise as an indispensable trinity of therapeutic measures then I have yet to see the tuberculous pregnant woman who could possibly avail herself of the instructions of her medical adviser if she were left in the condition in which she came under my care. Lucky ones might utilize two of the factors, but many could use none of three to their fullest benefit. The physician had ordered the unattainable and had taken no single step to make it available. What is the profit in telling a woman to live out of doors, to practise deep breathing, and to sleep in the open, if we ignore the easily observed fact that stuffy or obstructed nostrils are the rule among the class of patients under discussion? Are not the nostrils the entrances for air? Does not the thoracic pump begin at, and demand, a free intake if its mechanism is to work normally? One thing a pregnant woman should have is oxygen in abundance; and the results of advising plenty of fresh air to a patient with an obstructed nose are exactly what one would expect. Oxygen minus, carbonic dioxide plus, and the bacilli may dance with joy like the "Morning stars," hardly to the motive of "Good will to men" though. In the presence and under the baleful influence of a diminished intake of oxygen, therapeusis is lame, indeed. Therefore, in the name of "horse sense" the physician must either free that nostril or refer the patient to some man who can and will free it. Among non-tuberculous pregnant women absolutely typical normal nasal passages are rare, but among tuberculous ones the common and usual finding is that one or both nostrils are in such bad condition that mouth breathing, with consequent dust inhalation, is a habit.

As to diet, its careful regulation becomes a farce if the patient's teeth are so irregular that she has note a "bite" in her mouth; why not test the matter with wax? The test is easily applied, and my results show that never have I found a perfectly normal bite, consequently the usual liquid diet of milk and eggs does benefit the patient markedly because the digestive tract is no longer upset as a sequence of ineffecive or incomplete mastication. If you cannot bestow upon the woman a good bite, possibly you may feed her so much milk, eggs, and cream that she can eat nothing else; but it seems better to me to call in consultation some one who can and will mend the bite before advising the patient to go upon a full diet which she cannot chew nor prepare for absorption, and which, if persisted in, means only ruin for the alimentary canal, upon the kind offices of which so much depends in the safe carrying of the fetus. In the matter of exercise two conditions should be pointed out: *a*. Walking is the form of exercise most generally available. *b*. The walker is over-weight and gaining. This often breaks down her feet. Call them fallen arches, chronic sprain, or any term that pleases you, but the pregnant woman's feet are frequently in such condition that she either cannot walk at all or can only

do so with an inconvenience and handicap which vary from undue fatigue to positive pain. If tender feet are found in connection with a pendulous, unsupported abdomen swinging freely at each labored step, why then, insistence on long walks is a cruelty, severe and inexcusable, save only on the plea of ignorance.

Summary.—A pregnant tuberculosis patient to be treated successfully must have: (1) A free nose; (2) a good bite; (3) good feet; (4) a proper abdominal supporter. Otherwise the advice upon the subjects of fresh air, of elaborate and careful diet and of long walks in the open air signifies nothing.

Dr. Arthur Jacobus, who kindly read this letter, suggests that my direction or prescription in the first paper is indefinite, so I will state that I am now prescribing a mixture of one part lysol, ten parts ichthyol, and twenty parts aq. menth. pip. in half teaspoonful doses, taken in four ounces of water before each meal, and eight grains of calcium creosote after each meal. He also suggests that I use the words chewing or grinding teeth, instead of the expression bite. This is a good point, but I would explain that by the word "bite" I intended to convey the result of the meeting of two sets of opposing teeth in perfect apposition, and the expression, "the patient has not a good bite in her mouth," means that no two opposing teeth meet perfectly. It is not at all rare to find teeth in such poor apposition that when the jaws are closed the tongue may be touched, practically anywhere, by a match or tooth pick thrust between them by the hand of the examiner. Quite a different condition from the almost solid wall with which the normally placed teeth protect the tip of the tongue. It makes small difference in ultimate result whether the teeth are missing or malocclided. Mastication is bad or lost, that is all. The alimentary canal suffers in any case. The doctor also points out the importance of regular bowel action. As an expert is tuberculosis he knows the imperative need of a daily evacuation, but with the pregnant woman afflicted with tuberculosis, if the bowels are not carefully looked after you may then have stercoremia gravidarum, and this has a death rate to the mother of one in two and one child in three is delivered alive. I need hardly point out that, in the presence of the eclampsia which accompanies stercoremia, tuberculosis becomes negligible.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE B. M. A.'S SPECIAL MEETING OF REPRESENTATIVES —ANNUAL MEETING OF R.C.S.—DISCUSSION ON RESPIRATORY NEUROSES—OBITUARY.

London, November 22, 1912.

The special meeting of the representatives of the B. M. A. has been held and a decided position taken up. Mr. Lloyd George now knows for certain that he cannot dictate terms to the profession. On Tuesday, after full discussion, more than 200 delegates being present, it was almost unanimously resolved that the latest proposals of the Chancellor are "unworkable and derogatory to the profession." The consequence of this is that "service under the Act and Regulations as at present constituted" must be declined. As the members of the B. M. A. number a majority of the profession this decision practically shows that the threats of Mr. Lloyd George are vain, for it would be impossible for him to bring the "medical benefits" of the Act into operation by the appointed day, January 15. After this it was proposed that the last offer of the Chancellor affords an opportunity of conferring with him and the Commissioners "with a view to the settlement of the points on which the demands of the profession have not yet been met." This was discussed in all its bearings and evidently commanded the approval of nearly if not quite all the representatives, but to make the position perfectly clear it was agreed to take a vote by card. The result of the card vote was announced on the opening of the second day's meeting (Wednesday). It was a very great surprise; in contrast with the overwhelming majority for the first resolution declining to work the Act, the second, informing the Chancellor that any further proposal from him would be considered, was only carried by the barest majority. The representatives' votes were equal within one, viz., 100 and 101, representing the card poll as 9,292 and 9,269.

The State Sickness Committee was then reappointed. Next, five delegates were nominated to confer with the Chancellor. But with that love of complex arrangements which is a defect of the B. M. A., these five gentlemen are not told to conclude an agreement, but to report to the State Sickness Committee, which in its turn is to report to the Council. Even this body cannot act effectively, for if any change in the conditions now existing be proposed it is to report the matter to the divisions in the United Kingdom, and these are directed to call meetings of all medical men in their localities, whether members of the B. M. A. or not, and take a vote as to acceptance or rejection of the terms offered. Is not that an excellent example of "How not to do it"?

The position does not seem much different from what it was a month ago, except that Mr. Lloyd George knows that he must make some concession. It is hoped he will confer with the five deputies early next week. It is feared by many that the wily politician will be more than a match for them. Another member of his Advisory Committee, Sir John Collie, has withdrawn from it.

The annual meeting of Fellows and Members of the Royal College of Surgeons was held yesterday when a resolution was passed approving the action of the Council "as far as such action went" in reference to the Insurance Act. The limitation is suggestive of the usual do-nothing policy of the college. The mover held that an amending act was imperatively required and public opinion would support the demand. The seconder said they had only to put sufficient pressure on the government—the Commissioners being only its tools and creatures. Sir V. Horsley said the original central question was as to remuneration and that could not be severed from their social status. Mr. Geo. Jones thought it was not desirable to do anything more than endorse the action of the Council. This was done "as far as such action went," and then another resolution was carried regretting that the Council had not called a general special meeting of the Fellows and members to consider the Insurance Act.

The Medical Society of London last week held a debate on Respiratory Neuroses. It was opened by Dr. Samuel West, who discussed them in two groups, according as they are associated, or not, or lead to dyspnea and its consequences—cyanosis

and suffocation. Those so associated are spasmodic asthma, laryngeal spasms, and whooping cough. Those without dyspnea, etc., are paroxysmal tachypnea, the air-hunger of diabetes mellitus, and uremia and periodic respiration in its two forms of grouped respiration and Cheyne-Stokes breathing. In true asthma the breathing is slow with a greatly prolonged expiratory phase. The post-expiratory pause is absent, replaced by a post-inspiratory one. The muscles of inspiration are in full action, but there is little, if any, expiratory recoil. The passing off of the attack is indicated by a gradual return of the expiratory movements. The multiplicity of causes which provoke an attack is remarkable, but there must be also a predisposition and this cannot be located in the respiratory center in the medulla, but must be looked for above this—possibly in the brain itself. *Laryngismus stridulus* and allied spasms were accounted for by Dr. West in the same manner and even whooping cough he spoke of as a respiratory neurosis, though admitting the facts showed it was an infectious zymotic disease, the stress of it falling on the upper respiratory centers. Passing to his second group, he said that *paroxysmal tachypnea* is comparable to tachycardia in some respects, but not so important, for he had not seen it lead to any serious result. He would place it among these neuroses in a category by itself as the cardiac disturbance is by itself.

The *air-hunger* of diabetes and uremia, "steam engine breathing," usually comes on abruptly or must arise in the higher center, a conclusion supported by its association with or following coma. Some chemical body would seem to be the excitant.

Cheyne-Stokes breathing occurs in various conditions and is always of gravest significance. It is seen in the course of a disease of the nervous system above the medulla or where there is heart failure, mostly of left ventricle. But it has been recorded as occurring in a healthy person asleep or fatigued or aged, but very rarely. It has been shown to be sometimes set up by drugs and a similar state has been observed in animals. Dr. West dismissed these reports as of no clinical import, although interesting, as they might be in other respects, and said when the symptom was seen in a patient it indicated either cardiac failure or some morbid condition of the central nervous system above the medulla and pons.

Grouped respiration was a striking contrast as being very slow—not more than 8 to 12 as against the 40 to 120 of Cheyne. Moreover, it had no clinical significance. The general conclusion submitted to the society thus appears to be that in all the respiratory neuroses it is not to the center in the medulla, but more likely in the cortex that we must look.

Sir David Ferrier acknowledged Dr. West's lucid description and classification, but thought there is still room for investigation of the neuroirritability on which these spasmodic attacks ultimately depend. He doubted whether whooping-cough could be considered in the group, for it is infectious and evidently has a definite *materies morbi*, so differing from a true neurosis, and as much may be said of the emotional manifestations met with in hysteria. But he agreed that asthma is a true neurosis, and as Hughlings Jackson said, has close affinities with epilepsy. All essential symptoms of an asthmatic attack have been shown to be explicable by the constriction of the bronchioles from irritation of the vagus, the state of the membrane being secondary to this irritation. Inspiration is relatively easier but is obstructed, so it is not correct to call it a state of expiratory dyspnea. The contracted muscles, in fact, are the inspiratory. The expiratory, as the abdominal, are flaccid. Sir D. Ferrier went on to say he saw more of Cheyne-Stokes breathing than the other neuroses, as it so often occurs in cerebral cases, but he doubted if there was a satisfactory explanation of its mechanism. Such must apply to all conditions. But though it occurs chiefly in cerebral and cardiac failure it may occur in a normal state, in infants, in persons asleep, in hibernating animals, under some drugs. But more important than these it may be produced artificially in healthy persons. Haldane showed that breathing deeply while comfortably seated in an easy chair brings on apnea in two minues; this continues two minutes further, and then as ordinary breathing returns it is at first as Cheyne-Stokes, which gradually dies away. In the explanation it must be remembered that the normal respiratory excitants are fall of oxygen pressure and correlative increase of carbonic acid—the immediate excitant of the center which is highly sensitive to the heart variation. Excess of CO_2 causes hyperpnea; excess of O apnea. With lower O pressure the center becomes more sensitive to CO_2 and responding more energetically brings on hypernea, which dies away when O is increased and the CO_2 is washed out. A pause follows and the cycle is repeated. It has been shown that inhalation of air containing more than 2 per cent. of CO_2 (the amount which maintains the normal stimulation) may abolish Cheyne-Stokes symptom. So will inhaling pure O, which excites the center to send out forcible impulses and so wash out the CO_2 from the alveoli and the blood. Dr. Hector Mackenzie remarked that asthma might cease after an acute illness, which confirmed the idea that it was a neurosis. Dr. Leonard Guthrie regarded some other symptoms as due to lessened control of the higher center and spoke of such neurosis as somatic and psychosomatic. He had rarely met asthma and epilepsy in the same patient. But he thought there was association with "dead fingers." In young children asthma simulated bronchitis with more urgent symptoms which sometimes disappeared suddenly.

Dr. Buzzard was not sure the higher centers were concerned, but though scientific work tended to inculpate the lower. In sleep and slight cerebral depression the Cheyne-Stokes breathing did not occur, but only with depression so deep as to involve the lower centers.

Dr. Batten said in paroxysmal tachypnea the breathing was inverted, *i.e.* the pause came after the inspiration.

Dr. Steele-Perkins had seen an attack similar to an asthmatic one in an epileptic prevented by bromide.

Dr. Poynton had seen cases with enlarged thyroid, but no other sign of Graves's disease, but subject during pregnancy to attacks of severe dyspnea. Such attacks also were seen in salicylate poisoning and resembled those of diabetic coma.

Dr. V. Bell suggested that the relationship to insanity might be connected with narcotics as many asthmatics formed a habit of taking morphia or cocaine which had been prescribed with relief at first.

Dr. G. T. B. Blick of Broome, West Australia, has died in London, in his forty-fifth year. He had held a number of professional posts at Broome and

was the author of "Medical Experiences in Northwest Australia" and also of "Diver's Paralysis." He was M.D., Durham, and held the double qualification of the London colleges.

Brigade-Surgeon Lt.-Col. Wm. Owen died on the 13th, aged sixty. He graduated in Dublin in 1873 and served in India.

OUR BERLIN LETTER.

(From Our Regular Correspondent.)

THE GERMAN PUBLIC HEALTH ASSOCIATION—DISEASES CAUSED BY FOODS AND CONFECTIONS—MEAT POISONING—CAMPAIGN AGAINST THE MOSQUITO.

BERLIN, October 15, 1912.

THE convention of the German Public Health Association, which was held in the early part of September, was the occasion for the presentation of a series of papers of eminent practical importance, which it is hoped will become the starting point of numerous reforms in improving the health of the people. "Diseases Caused by Foods and Confections" was the subject of a paper by G. Mayer of Munich. Statutory enactments and improvements in technical processes have diminished the prevalence of certain diseases, such as poisoning by metals. There still occur, however, instances of poisoning from flour containing lead, which contamination is to be attributed to the fact that millstones are filled with lead. Ergotism, which formerly was so prevalent, has not appeared in Germany during the past thirty years, owing to the introduction of modern milling machinery. The contamination of margarine has given rise to cases of poisoning in Hamburg and thirty other German cities. The occurrence of wholesale methyl alcohol poisoning in Berlin during 1911, when there were affected 160 individuals, with 89 deaths, came up for discussion. Cases of toadstool poisoning still arise. Instruction in the schools and an efficient control of markets are important means of preventing the occurrence of this form of poisoning. Cases of fish poisoning are nowadays exceedingly rare, although Germany consumes annually seven kilos of fish per unit of population. It is important to note that a series of river fish, as the barbel, the pike, and the lote, at the time of spawning are poisonous, and that the roe especially causes severe diarrhea. Cheese poisoning is still observed, but only in certain parts of Germany. The instances of poisoning resulting from the use of egg preparations and even of potatoes are to be attributed to bacterial decomposition. Special care is necessary with reference to the use of crabs, since these are not prepared in a cleanly manner and are preserved with boric acid. The use of boric acid and other chemical food preservatives is strongly condemned.

Since 1860 trichinosis has affected 15,479 individuals in Germany. The introduction in 1900 of the official inspection of cattle has caused a rapid decline in the occurrence of this disease. In Bavaria, however, in which there is no such inspection, the prevalence of trichinosis has increased. It is particularly in the country where the inspection of cattle is lax that cases of illness contracted from diseased cattle are more common than in the city. During the past thirty years there have been reported 5,500 cases of meat poisoning. In 66 of 111 epidemics of this form of poisoning sick cattle were the cause. During the past twenty years there have been reported 600 instances of poisoning by the *Bacillus proteus* which is found in infected meat. The *Bacillus botulinus* which sometimes contaminates sausage meat has caused during the past thirty years 800 cases of poisoning with 200 deaths. The *Bacillus enteritidis* of Gaertner has given rise to 2,000 cases of poisoning in the past twenty years. The examination of sausage meat shows wide differences in bacterial content. The author counted sixteen million bacteria in one gram of sausage meat. The majority of cases of sausage poisoning occur in the kingdom of Saxony. It is recommended that the use of meat sterilizers be enforced in the meat industries.

The mosquito pest and its eradication was the title of an interesting paper by Professor Heymann of Berlin. The importance of this problem is indicated by the fact that the author had received appeals from thousands of places to give advice and assistance with reference to ridding these places of mosquitos. Many watering places and health resorts have suffered greatly throughout their entire existence from the presence of these pests. The patients in tuberculosis sanatoria and the soldiers in barracks have suffered from the same cause. In fighting the mosquito it is necessary to wage the war in two campaigns, one during the summer and the other during the winter. In the former the object is to prevent the development of new broods of mosquitos, and in the latter the object is to destroy the hibernating insects. The important measure in the summer campaign is the removal of the breeding places. Large areas of swamp may be artificially drained, while smaller ones may be removed entirely. The addition of chemical insecticides and the introduction of animal species that feed on the mosquito may effect the destruction of the larvæ and pupæ.

The winter campaign consists in the discovering of the hiding places of the mosquitos in enclosed spaces or in the fields, and then destroying them by means of smoking-out, burning, or the application of chemicals. A national campaign against the mosquito requires the training of an efficient personnel, composed of disinfectors and street, country, and forest workers. The public press and the public officials should cooperate in the work. The campaign should be extended over two winter and four summer months. Only when this work is continued for a number of years does it offer any promise of success.

2. The Treatment of Pulmonary Tuberculosis by Artificial Pneumothorax According to the Method of Forlanini. G. M. Balboni.
3. Under Ether. H. T. Bailey.

1. The Nineteenth Century and a Living Pathology.—W. J. Mayo regards John Hunter as the dominant figure of medicine in the eighteenth century. He was anatomist, physiologist, and pathologist, and the great surgical philosopher of his time. In the early part of the nineteenth century anatomy, especially regional anatomy, became the subject of more accurate study. France led in this field of work, bringing anatomy to a high stage of development, and with it a specialized surgical technique, thus in her turn becoming the great medical center of the civilized world. The discovery of the germ origin of disease made Pasteur the greatest benefactor the world has ever known. Virchow placed cellular pathology upon a sound footing. Lister applied the germ theory to the treatment of wounds. Anesthesia and asepsis enabled surgery to assume an im-

portant part in solving the discrepancies between post-mortem findings and the nature of the disease as it existed during life. Surgery was positive and active, and one organ after another became the object of this form of study during life. Tait was the pioneer in abdominal surgery. Fitz made known to the world the part played by the appendix in the causation of infections in the abdominal cavity. It is now generally recognized that chronic irritation is a factor in the causation of carcinoma. Experimental investigation has been an important factor in revealing living pathology. Surgical experimentation has created distinct advances in the surgery of the cranium, the thorax, and of the blood-vessels. The *x*-rays have disclosed many of the inner secrets which have heretofore baffled the clinician and the surgeon. By what means can this great accumulation of the knowledge of disease be applied to aid individual patients? There is but one answer to the question—cooperation in medicine. Medicine must no longer be practised individually but by groups of men, each one bringing the results of his work and studies to bear upon the case.

2. Artificial Pneumothorax in the Treatment of Pulmonary Tuberculosis.—G. M. Balboni states that the theories advanced as to the cause of action of therapeutic pneumothorax are based on the mechanical immobilization of the lung and the diminished circulation resulting therefrom. The compressive action of the pneumothorax brings about its results in accordance with the general precept of surgical therapy, that the reparation of the solution of continuity demands the permanent evacuation of the contents and the bringing of the walls into contact. Forlanini's theory is that the destruction of pulmonary tissue and the resulting cavities are nothing less than solutions of continuity which do not heal because they are never completely emptied, but are, on the contrary, kept irreducibly gaping or open by the relative rigidity of the thoracic cavity. A properly produced pneumothorax frees or separates the lung from the thoracic wall, immobilizes and compresses it, reduces the cavities and empties them, and by the coalition of their walls brings about their obliteration and cicatrization. Another factor also comes into play. Whatever may be the manner of entrance into the lung of the pathogenic germs that cause phthisis, the successive spreading of the process comes about usually through the respiratory tract. Some part of the septic material, as it is being expelled during expiration, is easily drawn back into the lung during inspiration, causing the continuous formation of new foci of infection. The immobilization of the lung overcomes this, the prevailing, if not the only, cause of the continual spreading of the process. Thus the other lung, if not already diseased, is protected; the spreading of the infection into other parts of the body, such as the larynx and intestines, may be prevented; and a means of combating the spreading of the disease in general may be secured.

10. The Surgery of the Spleen. W. J. Mayo.

1. Gastric and Duodenal Ulcers.—W. E. Deeks believes that the following chain of conditions leads up to gastric and duodenal ulcers. A sugar starch diet, to the exclusion of fruits and vegetables, ferments and forms irritating diffusible organic acids which stimulate the gastric glands and give rise to hyperacidity. On the other hand, the same diet tends to a lessening of peristaltic action, and constipation, which are followed by anemia with lowered cell resistance. The combination of hyperacidity with lowered cell resistance in an anemic mucous membrane is sufficient to bring about a loss of continuity in the mucous membrane with the attendant bacterial invasion. Mechanical irritants of any sort may assist to the same end. With this theory as to the etiology of gastric and duodenal ulcers the author has devised the following plan of treatment: In severe cases with hemorrhage, he advises absolute rest in bed and a liquid diet for two or three days until the vomiting ceases and there is no more hemorrhage either into the stomach or duodenum. The liquids should consist of orange juice without sugar, milk, and broth. Then gradually one should add eggs, meat balls underdone, fresh fruits and green vegetables cooked, particularly those of the softer kind, like squash. After six to ten days every variety of meat, fish, green vegetables, and cooked and uncooked fruit can be given. Care must be taken to exclude in every form sugar, potatoes, bread, toast, cakes, and pastry. The only medication given is dilute nitric acid before meals from the onset of the attack. It is given with the object of destroying the bacteria of starch and sugar fermentation in doses of from fifteen to twenty drops of the dilute preparation in half a tumbler of water.

3. Urethral Drainage in the Treatment of Chronic Urethritis.—G. H. Persson states that suitable drainage in the urethral canal is indicated in the treatment of urethritis, because it provides for rapid elimination of pathogenic bacteria and their products. Sterile drainage is of great value as a diagnostic means to determine the presence of gonococci in doubtful cases. Antiseptic drainage serves the same purpose in the urethral canal as applications of gauze in surgical treatment of wounds. Drainage material used in the urethra must be absorbent in character, without which property it is useless. Lactic ferments are indicated in the treatment of chronic urethritis, because these bacteria when properly used have germicidal effects on the offending organism in the urethra. Certain lactic ferments produce under favorable conditions bacterial products which increase the activity of cells with which they are brought in contact, thus promoting the absorption in this instance of the perigranular infiltration that is the characteristic pathological factor in chronic urethritis. The requirements necessary for success are, first, a proper method of application by which drainage may be introduced without discomfort to the patient, and, second, the use of an emollient substance which acts as a lubricant without making the drain nonabsorbent and in which the desiccated ferment finds a favorable medium for development. This medium must be prepared with the aim in view of preventing the natural death of the ferment by neutralizing the excess of lactic acid when this reaches a point where it acts destructively to the organisms which produce it. This medium must also contain elements in the presence of which the lactic acid organism produces a large amount of enzymes, or that bacterial product which causes increased local cellular activity and induces the formation of bacteriotropic substances.

4. The Borderline Case in Mental Deficiency.—M. S. Macy has observed 125 cases of children in all of which, in the original series of examinations, appeared more or less definite signs of mental deficiency, including from two to four years' retardation according to the Binet-Simon tests, and also in every case a number of physical inefficiencies or deficiencies. These children, after careful study and consultation of experts, were all classed as feeble minded and recommended for special pedagogical treatment, as well as medical and hygienic care. Without exception these 125 patients, following upon proper medical and hygienic treatment, and having the advantage of intelligent and specialized pedagogical care during the period of from two to four years, have so far recovered from their "feeble-mind-

edness" that they have been able to resume and maintain their place in classes of children of their own age. For about thirty two per cent. medical care is still necessary; about thirty per cent. more are still handicapped by their sensory inefficiency, but not sufficiently so for any one to-day to class them as feeble minded. The author emphasizes the fact that schools—not institutional—and medical and hygienic care has accomplished the transformation in these cases.

7. Diet in Carcinoma.—E. G. Kessler notes that Beneke found the cancer cells rich in cholesterin. He assumed cholesterin to be a product of the proteins, which, however, is not proved, and he therefore recommended the removal from the diet of cancerous patients not only of cholesterin and lecithin, but also of all nitrogenous substances. To a certain degree traditional experience practically coincides with the postulates of Beneke. Observation shows that cancer occurs spontaneously less frequently among herbivora than among carnivora. Ethnographic observation shows that cancer appears more frequently in races having a high consumption of meat. In the literature there are frequent reports that the growth of cancer is strongly favored by an excessive meat diet. The proteins of the meat diet are all rich in sulphur, and in the author's opinion ought to be reduced. The diet which he would recommend in carcinoma would be as follows, to be modified according to the taste of the individual: Breakfast: Tea or coffee with sugar and cream (not milk, on account of the lactalbumins), little bread with much butter, fresh or cooked fruit. Dinner: Soup, of fruit or cereals or vegetables (not meat broths), peas, lentils, beans; for change, meat, two ounces at the most, purée of potato, dumplings, edible roots (carrots, beets), boiled or preserved fruits, rice, salads. Supper: Fruits with rice, potatoes with butter, salads. The amounts should be plentiful. The necessary quantity of casein, one or two ounces, can be mixed with butter and used with the various meals.

2. The Young Child and the Common Infectious Cold.—By T. S. Southworth. (See MEDICAL RECORD, Vol. 81, page 1160.)

3. Occurrence and Etiology of Clubfoot.—A. Ehrenfried states that congenital talipes occurs approximately once in every thousand births, and in one-tenth of all infants with congenital deformities. Of the two important types, equinovarus constitutes about 80 per cent. and calcaneovarus 20 per cent. Forms which cannot be classified under one or the other of these divisions are rare. The fixed type of calcaneovalgus is less common than the potential type. Equinovarus on one foot and calcaneovalgus on the other is quite unusual. Clubfoot is known to have appeared in near relatives in 5 per cent. of the cases. About 33 per cent. of all the patients are firstborn; in about 16 per cent. delivery is difficult; in 4 per cent. birth is premature and in 2 per cent. illegitimate. The condition appears in twins or triplets four times as often as in single pregnancies. It is accompanied by other congenital deformities in 12 per cent of all cases. There are three etiological factors to be considered: heredity, evident in 5 per cent.; early intrauterine causes, depending on faulty nutrition from a diseased condition of the chorionic villi, evident in 10 per cent., and mechanical causes operating later in intrauterine life, accounting probably for most of the remainder. In the last class, poor hygiene of pregnancy and work during pregnancy are undoubtedly causal factors of considerable importance.

4. Social Service in the Children's Dispensary.—By M. Ostheimer. (See MEDICAL RECORD, Vol. 81, page 1161.)

5. Monkeys and Rheumatic Fever.—O. M. Schloss states that his experiments fail to show that the blood of patients suffering from rheumatic fever contains an infectious virus capable of affecting rhesus monkeys. Either the causative agent of the disease is not present in the circulating blood in sufficient quantity, or, if it is present, rhesus monkeys are immune to its influence.

6. Serial Radiography in Gastrointestinal Diagnosis.—By L. G. Cole. (See MEDICAL RECORD, Vol. 81, page 1165.)

7. The Origin of Tube Casts.—H. B. Erdman believes that tube casts of all kinds, excepting the epithelial and fatty varieties, more frequently come from the protein elements of the blood, through temporary or permanent insufficiency of the glomerulus than from the tubular epithelium. Leaking of the tuft during the periods of hyperemia does not imply serious injury to the thin walls of the capillaries. Slight traces of albumin in the urine are not incompatible with good health. The diagnostic value of polynuclear leucocytes is often exaggerated as they are found in the average urine, and may be increased by the mildest irritation. Their value in the diagnosis of nephritis is slight unless they are incorporated in casts or obtained by catheterization of the ureters. In estimating the value of casts one should bear in mind that the kidney is subject to normal wear and tear, and this may be exaggerated at times without serious import; also as age advances slight kidney changes are apt to occur, often being focal in the senile and arteriosclerotic kidneys. Tube casts give no reliable information as to the functional power of the kidney.

8. The Operation of Litholapaxy.—A. T. Cabot points out that the mortality of this operation is 1.6 to 6 per cent., while the mortality of suprapubic lithotomy is from 10 to 20 per cent. He believes that litholapaxy is the operation of choice in all uncomplicated cases of stone. The litholapaxy outfit, while not very expensive, adds considerably to the surgeon's apparatus, and may seem a serious burden to a general surgeon who sees few cases of stone, and who therefore resorts to lithotomy when such a case occurs in his practice rather than send the patient to another operator. This position is strengthened by the belief that there is special danger requiring special skill in litholapaxy. These imagined difficulties are greatly exaggerated; there is less danger from litholapaxy without experience than from suprapubic lithotomy in experienced hands.

1. The Cardiovascular System in Pulmonary Tuberculosis.—S. R. Douglas Powell states that the minute vessels are attacked very early in the lesions of tuberculosis and the tuberculous nodule is distinguished from all other growths by the early destruction of vessels and the caseation and necrosis which ensue. The early destruction of vessels in the lesions of tuberculosis is of advantage to the patient, for, were it not for this destruction, fatal hemorrhage would be a very frequent termination of advanced cases of the disease. The heart's action is almost invariably quickened in tuberculosis. A slow pulse when met with is always of good augury. The systemic blood pressure ranges rather low in some acute cases of tuberculosis, but may recover almost, if not quite, to the normal in chronic and quiescent cases. It is probable that the pulmonary arterial pressure is at least relatively high. A rise of systemic blood pressure in the course of tuberculosis is an indication of improvement and of favorable augury in prognosis. The author is of the opinion that the heart in pulmonary tuberculosis does not share in the wasting of other muscles. Consumptives on the whole have a much better circulation than they are given credit for, their hearts are relatively good, and a low blood pressure in them is mainly attributable to depressed cardiac function from excessive absorption of bacterial products. In some cases of advanced but quiescent phthisis one meets with great irritability of the heart, with attacks of palpitation or disturbed action easily provoked by exertion, emotion or dyspepsia, disturbances attended with great distress, sometimes with almost anginal suffering. There are cases of one-sided disease, with a fibroid and contracted lung; the heart is cramped on all sides in a restricted chamber with rigid parietes, instead of being surrounded by resilient structures whose peripheral influence is aspiratory to its cavities. In chronic and quiescent cases of tuberculosis the stagnant bacterial products may not get at all in the general circulation, or so gradually or in such small quantities as to cause little or no constitutional disturbance. If in such patients quietude is replaced by activity, the circulatory activity and blood pressure are raised in the perifocal zones, and there is brought about increased absorption of the bacillary products. The hurried breathing further increases the disturbance in these areas. It is upon the basis of this autoinoculation that the system of graduated labor in the sanatorium treatment of tuberculosis has been introduced as a means of bringing about autoinoculation and thus producing a gradual immunity by progressive stimulation of phagocytic action and of other agencies antagonistic to the bacillus.

2. Clinical Significance of Regular Tachycardia.—T. Lewis notes that there are forms of this condition. The first is the simple or physiological type of tachycardia. The other two forms are subdivisions of a single class—namely, the pathological type of tachycardia; they may be termed simple paroxysmal tachycardia and auricular flutter. The increase in the heart rate that occurs as the result of exercise, emotion, and fever, and that occurs in exophthalmic goiter, in chronic alcoholism, pulmonary tuberculosis, and other toxic conditions, is of the same nature in all of these cases. The rate of impulse formation in the region of the superior vena cava is increased, and both auricles and both ventricles participate in the altered rate. Whatever the mechanism, the fact remains that this is a simple exaggeration of a normal phenomenon. How is an acceleration of the heart's action of this type to be recognized? The heart-rate falls conspicuously when the patient lies down, it rises when the erect posture is reassumed, and it is increased by exertion and by excitement. Electrocardiagrams provide a valuable and the only method of estimating whether an individual heart beat has been propagated along normal channels or not. If the beat arises in an abnormal center the course of the contraction wave is necessarily altered and the beat gives rise to an abnormal type of curve. The second kind of tachycardia is of this type and includes the pathological forms of tachycardia; it arises, not at the normal center, but at some point away from it, and the new center is usually an auricular one. It occurs in short or long paroxysms, whence the term which describes it. But these are not the sole characteristics of this form of tachycardia, although they are among its chief ones. When simple tachycardias come and go, they come and go gradually; the pathological types of tachycardia appear and disappear abruptly. In auricular flutter, the third type of tachycardia, the rate surpasses 200, the maximal known limit being 335 per minute. The new rhythms arise in the auricle and probably away from the normal center; they also start and finish abruptly; they are also uninfluenced by posture, exercise, and other similar factors to a remarkable degree. Auricular flutter, besides being characterized by the greater rapidity of the heart beat, differs from the former group of cases in two respects: Although the rate of auricular contraction is extreme, being usually between 270 and 300 per minute, it is but rarely that the ventricle keeps these paces. In most instances this chamber beats at half the auricular rate, and the grade of acceleration is thus disguised.

3. The Cholera Vibrio in the Biliary Passages.—E. D. W. Greig reports the history of a case of cholera which presented several interesting and suggestive features. After the acute phase the patient lived for twelve days, dying from uremia. The cholera vibrio was found in the bile and there were pathological changes in the gall-bladder. The presence of the comma bacillus was demonstrated in the consolidated area in the lung. The pathological investigations indicated that the changes found in organs were the result of toxic action, the origin of this poison being probably the cholera vibrio growing in the bile. As the cholera vibrios die the intracellular toxin is liberated and passes into the system. The appearance of the cecum was striking. It resembled very closely the condition found in the large intestine of rabbits after the subcutaneous or intravenous injection of Shiga bacilli. From a consideration of the facts presented in this case the author believes that it will be necessary to revise the present conception of the distribution of the cholera vibrio in the tissues of man, and this revision may help to clear up certain unexplained problems connected with cholera.

1. A Clinical Study on the Avenues of Rheumatic Infection: Based Upon Examination of 75 Cases of Sydenham's Chorea. W. P. S. Branson.
2. A Possible Test in the Differentiation Between Human and Bovine Types of the Tubercle Bacillus. J. Fraser.
3. The Soil and the Seed in Tuberculosis. H. Sutherland.
4. A Note on Rat-Bite Fever, with Report and Temperature Chart of a Recent Case. R. W. Cruickshank.
5. A Ruling Habit Strong in Death. C. H. W. Parkinson.

1. The Avenues of Rheumatic Infection.—W. P. S. Branson concludes from his clinical studies that Sydenham's chorea and rheumatic fever are due to one and the same infecting agent. The action of the rheumatic poison upon a specifically predisposed central nervous system produces a characteristic nervous instability which may precede the appearance of choreic movements by some weeks, and may in other cases itself constitute the sole evidence of the choreic tendency, the phase of movements never becoming developed at all. The emergence of choreic movements is determined by emotional stimuli acting upon a central nervous system thus previously disequilibrated. The commonest avenue of rheumatic infection is the tonsil, and next to it the nose. The first essential of rational

treatment of rheumatic infection is restoration of the upper air passages to a healthy condition. Irrigation and thorough cleansing of the nasal passages, combined with antiseptic treatment of the nose and pharynx, should be a routine item of antirheumatic treatment; and the operation of enucleation should be performed without delay upon all rheumatic children who exhibit chronic enlargement of the tonsils or of the tonsillar lymphatic glands. Chorea is a common sequel of scarlet fever, but the appearance of movements is usually postponed until the patient has left the fever hospital.

2. Differentiation Between Human and Bovine Types of Tubercle Bacillus.—J. Fraser finds that just as the general reaction of the rabbit to infection by the human or bovine bacillus varies greatly in degree, so does the local reaction. The best situation in which to demonstrate such a local reaction is the synovial membrane of the knee-joint. Infection of the knee-joint of the rabbit with a bovine bacillus produces an intense reaction with acute synovial tuberculosis; infection with the human bacillus results in a chronic synovial thickening. The test is of value as quickly distinguishing between the human and bovine types of the tubercle bacillus.

3. The Soil and the Seed in Tuberculosis.—N. Sutherland has noted that there is more tuberculosis among the children of consumptives than among the children of healthy parents. This may be due to their exposure to infection, to their lowered general health, or to their heredity. There is more tuberculosis among the children of infectious consumptives than among the children of non-infectious consumptives. This must be due to exposure to infection *plus* lowered general health, inseparable from it as the result of the stage of the disease in the parents. Therefore it is not heredity which determines whether the children of consumptives will develop the disease, but the existence of certain immediate factors which are under one's control.

Paratyphoid Bacilli and Congeners Outside the Human Organism.—Weber and Haendel conclude by reason of cultural finds with Loeffler's green solution and differential media of various kinds that there is a family of bacteria which occurs in three great groups. First the typhoidal bacillus in the narrow sense; second, a group to be considered in detail which consists essentially of paratyphoid bacilli, and third, coli bacteria. The second group is much the more complex and comprises a number of species which differ much among themselves. The first subdivision, paratyphoid bacilli in the narrow sense, comprises the paratyphoid B. of Schötmuller and related germs which cause meat poisoning, the bacillus of hog cholera and that of psittacosis. The second subdivision comprises the so-called Gaertner group inclusive of species which are pathogenic to rats. The third subdivision resembles members of the first and second in all respects save failure to respond to serological tests. Members of the third subdivision seem to be nearly ubiquitous, occurring in the dejecta of healthy men and healthy animals of all kinds used for food, in sausage and preserved meats, in other foods, ice, and water. Under certain conditions these bacteria may perhaps become pathogenic, while under ordinary conditions, in comparison with the paratyphoid and Gaertner subdivisions, they behave as saprophytes. They confer no immunity against the regularly pathogenic forms, as may also be inferred from the failure to agglutinate, etc.

Rupture of Bronchi in Thoracic Compression.—Schönberg having seen three cases of this form of traumatism investigated the literature of the subject and finds records of but thirteen other examples. The sixteen cases are analyzed, some of the results being as follows: In twelve patients the compression occurred from having been run over, and in three others the conditions under which the compression resulted were practically the same. The adult is much less likely to suffer from bronchial rupture because the ribs break. The oldest victim was 47 and but three were over thirty; while nine victims were children, three of whom were under five years of age. In the child compression of the chest of this sort may cause hardly any injury to the osseous system. In the sixteen cases, however, the majority, irrespective of age, suffered fracture of the ribs along with rupture of the bronchi, although the youngest victims of all appear either to have escaped outright or to have sustained less severe injuries (some data are defective). In regard to rupture of bronchi, the left was injured in eight cases, the right in six, while in two the lesion was bilateral. The nature of the injury was probably nothing beyond a direct crushing of the tube with resulting rupture. The only alternative is this or force—compressed air—acting from within, and the latter is hardly conceivable. The compression is doubtless effected by the breast bone. The sixteen cases are all autopsy finds and nothing is known of a recovered case, or of diagnosis during life, death having supervened in a few hours. The accident considering the frequency of thoracic compression is extremely rare.

Habitual Pareses of the Vocal Cords.—Gutzmann regards these as engendered by autoimitation but not necessarily as hysterical. After a child has suffered from a temporary paresis it begins unconsciously to imitate the condition, until a habit state is induced, manifested as hoarseness, whispering voice, or inspiratory stridor, according to the muscles involved. The affection almost invariably occurs in childhood, persisting sometimes into adult life. When first appearing in adult life, beyond the habit spasm period, they may be classed outright as hysterical. In habit paresis there still remains voluntary control of the muscles, so that this condition must not be confounded with true paralytic affections.

November 19, 1912.

Cure of Sarcomatosis of the Skin with Thorium X.—Herxheimer first refers to the disrepute into which this resource has temporarily fallen as a result of certain fatalities. The author has used up to seven injections weekly each in twenty-five cases of severe dermatoses (mycosis fungoïdes, leucemic tumors, carcinoma, etc., and relates incidentally the following: Patient, a male aged 58, never really ill, who had recently noted several nodules on one side of the buttocks. The process diffused itself so rapidly that within a brief interval there were similar formations over the entire surface. Some of these grew as large as a half dollar, and they even appeared in the mucosa of the buccal cavity. The viscera were not affected and the blood state and general condition but little affected. Two trial excisions were made and the microscope appeared to show multiple sarcoma of the skin. Mycosis fungoïdes and leucemic tumors as well as so-called sarcoids could be excluded. As such an affection may be depended on to cause death the case was deemed one suitable for thorium X. A dose of one million Maché units was injected every eight days. None of the untoward symptoms said to follow the use of these injections in large dosage was observed. After the first three injections some of the lesions had disappeared and no new ones were in evidence. After seven injections hardly any evidence of tumor growth could be seen, even the pigment deposits which sometimes were left behind having ultimately vanished. The case may recur, and the treatment may fail outright in similar cases, but as it stands thus far the result leaves nothing to be desired.

Sodium Chloride in Anaphylactic Shock.—Langer in animal experiments has shown that the administration

per os of small doses of sodium chloride in the course of treatment with heterologous blood serum appears to have greatly diminished the severity of the anaphylaxis which normally results from a second serum injection at a later period. That some relationship exists between the action of sodium chloride and anaphylaxis was first shown by Heilner. The method has not yet been tested on man, although it evidently belongs in the same class as calcium chloride in this respect.

Hygiene in Goethe's Day.—Schule calls attention to some of the disadvantages with which Goethe had to contend. Most of his night work was done by candlelight and he often snuffed the candle with his fingers. Arrangements for heating and ventilation were very defective, conducive to colds, and the poet's death may perhaps be traced directly to this cause, as his last illness at an advanced age was doubtless due to exposure. There was no mean between the hot zone about the iron stove, and the cold, draughty air at a distance from the latter. Goethe, however, had a bath tub and used it regularly. The house was a superior one for the age, and the poet had the great advantage of having it so divided that his private chambers were quite distinct from the housekeeping apartments. There were conveniences of all kinds and in such a house such modern conveniences as elevators, steampipes, electric light and telephone were alone lacking, for in other respects there was evidently little to be desired.

November 21, 1912.

Malignant Tumors in Childhood.—Usener first refers to Steffen's monograph on this subject, published in 1905. He investigated the material of the Leipzig Children's Hospital during the years 1907-8 for additional material of this sort, and out of 173 tumors of all kinds found four which were malignant. These were all sarcomata, affecting respectively the clavicle, right kidney, abdominal wall, and jejunum. The ages of the children ranged from 4½ years to 13 years. Steffen collected notes of thirty-three cases of sarcoma of the long bones, in only one of which the clavicle was the seat. Malignant growths of the kidney, on the contrary, are frequent in early life and Steffen mentions 222 cases. These are spoken of as comprising sarcoma, carcinoma, and mixed growths, the term hypernephroma not being mentioned in this connection. The locations in the integument and intestine are both unusual. Some thirteen tumors developing in some portion of the small intestine have been recorded. In regard to the cutaneous site the few cases on record may have been congenital.

Preparation of Carbonic Acid Snow.—Heusner, after giving credit to Pusey of Chicago for the introduction of this resource into dermatology in 1905, enumerates a number of methods for obtaining the same, none of which it appears is ideal. There is no difficulty about the mere preparation of the snow as such, for it is only necessary to allow the compressed gas to escape from the proper opening in the bomb, just as happens in using ethyl chloride. But the snow should be gauged, and accurately localized. Hence it is by some solidified first, and a portion of the snow of the desired size applied after the skin has been protected by collodion or plaster. The snow may be allowed to form in a buckskin bag attached about the bomb opening. A drawback is the loose state of the snow which requires kneading and compression. It may be forced into small molds, with formation of cones or cylinders. One device allows the gas to escape directly into a perforated brass tube in which it solidifies. A valvular opening makes it possible to apply the snow directly to the skin. The jet may also be projected into a hollow cone with the same result. Still another device enables the snow to appear as a cylinder from the collecting tube as the result of pressure from a piston. All these resources satisfied the primary requirements, but some dermatologists object to metallic apparatus on account of its conductivity for heat which causes the snow to melt quickly. Others reply that metal is indispensable for sterilization. The author further believes that a carbonic acid snow generator ought to be useful in other directions besides that of cautery. It is superior to ethyl chloride as a local anesthetic, it not being inflammable, and is also a good hemostatic. His apparatus is desired to met all these requirements and can be made to furnish both snow and vapor. As the author's work is still incomplete and as he will shortly publish a full account of his apparatus and its uses, the technical details may be omitted here.

Treatment of Placenta Previa.—Zinke of Cincinnati gives a summary of the newer methods for managing this condition. He enumerates them in the following order: 1. Rest in bed with ice bag to abdomen. 2. Tamponade. 3. Induction or furtherance of labor; puncture of membranes or bringing down a foot. 4. Use of bags for dilatation. 5. Manual or instrumental dilatation. 6. Vaginal or abdominal cesarean section. Some of these measures supplement while others compete with one another. The last nine cases of the author ended fatally for three mothers and seven children. These occurred in private practice, the author having been summoned as consultant only. The management was the same for all—tamponade, podalic version, and slow extraction. This series is contrasted with one of Pankow's in which all the mothers (8) survived and all the children were delivered alive as a result of cesarean section, and similar results are being reported elsewhere on the continent. The author naturally leaned toward this and similar forceful interventions, but on account of the prejudice against them on the part of English speaking obstetricians and the public at large, the conservative Braxton Hicks management appears to be the only course open. Private patients shrink from the sudden hospital trip and private houses are not suitable for surgery. The two mortalities speak for themselves.

Diabetes and Tuberculosis.—C. M. Montgomery states that the evidence which he has collected does not show that tuberculosis occurs more frequently in diabetes than in the general population at the same age periods. However, one is impressed by two facts: (1) the lowered opsonic index to the tubercle bacillus and a number of other bacteria in diabetes; and (2) the large number of cases of diabetes late in the course of the disease developing a very acute, extensive, and rapidly fatal form of pulmonary tuberculosis. Tuberculosis occurs more frequently in diabetes than in certain other chronic diseases. The frequency of tuberculosis in diabetes varies with a great variety of different circumstances. In the author's 25 collected autopsies on diabetic patients, 6 showed active pulmonary tuberculosis varying in acuteness and extent of involvement, and 1 showed adrenal tuberculosis without tuberculosis elsewhere. Out of 355 autopsies collected from the literature since 1882, including also the author's 25 cases, 138 (38.9 per cent.) revealed pulmonary tuberculosis, mostly in an acute form. In some structures, for example, the bones, the author could not find a single case of tuberculosis in a diabetic patient. When diabetes and tuberculosis are associated the diabetes can usually be shown to the primary disease, in a number of cases it is impossible to show which is the primary disease, and in no case that the author has encountered has the tuberculosis been definitely proved by the evidence furnished to be the primary disease. When diabetes and tuberculosis are associated in the same patient either disease may show certain modifications in course and symptomatology, but often each disease runs a course apparently independent of the other. Like the clinical course the autopsy findings may reveal nothing unusual in regard to the tuberculosis, but in a number of cases one meets a tuberculous process that is marked by acuteness, the extensiveness of the disease, and a tendency to the early development of cavity formation. From the number of cases that have improved both as to their tuberculosis and their diabetes, one cannot consider the combination of diabetes and tuberculosis as necessarily more hopeless than the diabetes or the tuberculosis alone. The prognosis in many cases depends largely on the treatment.—*American Journal of the Medical Sciences.*

Insurance Medicine.

Medical Examiners from the Standpoint of the Medical Director.—In a paper read before the American Association of Medical Examiners, at Atlantic City, on June 4, 1912, Dr. Oscar H. Rogers, Medical Director of the New York Life Insurance Company, discussed medical examiners from the standpoint of the medical director. He divided medical examiners into two groups: First as to whether they are medical examiners in large cities, whether they give a great deal of time to their work, or whether this is only an incident. This division is made in order to determine by a system initiated by the New York Life Insurance Company whether the work of any examiner is good or otherwise. In looking over the work of the many examiners who do insurance work regularly, it is found that questions asked are answered in 98.5 per cent. of all cases. Rogers thinks that the point should be emphasized that the nearer the country practitioner brings his work up to the excellence, or up to the level of the answers made by the city examiners, the more efficient his work will be. Also, another fault to be found with medical examiners is their delay in answering letters. Another point is the failure to give sufficient detail as to any impairment in the health condition of the applicant; that is in at least one per cent. of the cases the medical examiner fails to make his pen picture of the applicant's condition definite and clear. Another point is incorrect diagnosis, or failing to find what should be found. This, according to Rogers, is mainly due to carelessness. Here again the city examiner shows up splendidly, with 0.25 per cent. as compared to the country examiner with nearly 1 per cent. Rogers concluded by stating that physicians throughout the country received as compensation for their share in the insurance business approximately eleven and one-half millions of dollars annually.—*The Lancet-Clinic*, Sept. 21, 1912.

Accident Prevention by Insurance Companies.—In a recent lecture on industrial accident prevention Mr. Van Schaack, director of Bureau of Inspection and Accident Prevention, Aetna Life Insurance Company, Hartford, Conn., said that there has been prevalent to some extent a supposition that a liability company's sole function has been to collect premiums, and that too little of the money thus received has gone out in actual payments to injured persons. The first part of this supposition is ill founded, he said, as those who are in the business know full well, though he would subscribe fully to the latter part. Too little has gone to the injured persons, but this has been on account of conditions over which the companies have had no control. They would much prefer that all the money expended for claims, outside of necessary and proper administrative expenses, should go to injured persons, but unfortunately they do not make the laws, have no control over the activities of the omnipresent claim promoter, and cannot prevent juries from rendering excessive verdicts. If the companies had their way they would gladly see that every injured person who had a real claim received proper compensation—no less, no more. Van Schaack went on to point out that his company, and presumably all insurance companies, use every effort to prevent accidents and after suggesting various means of so doing concluded that in considering possible plans of industrial accident insurance it would be well to keep this accident prevention feature prominently in mind. The laws may be stringent, every means of assuring a fair compensation to every injured workman who deserves it should be taken, but every agency engaged in furthering the work of preventing the accident, the most important thing of all, should be retained.—*Insurance Engineering*, September, 1912.

The Service of the Industrial Physician.—Koelsch used this term in the sense of inspection or supervision of trade industries from the hygienic viewpoint and upon the initiative and responsibility of the industrial organs. Medical cooperation in the supervision of industries is a new thing, for until recently it was objected to as unnecessary. The child's health can be controlled in a measure from birth up to the shop door but not beyond the latter. There are, indeed, official medical men nominally concerned with the welfare of factory hands, but this relationship represents only a private concession. The requirements of factory hygiene comprise such problems as the amount of space allotted to workers, the position of the latter while at work, protection from light and sound, proper temperature and air pressure, exclusion of dust and bacteria, and numerous other factors, neglect in regard to which may be highly prejudicial to the worker's welfare. The questions of woman and child labor and the general relations of the worker's health to that of the entire community also belong here. The field covered by this line of medical effort is extensive and varied. The incumbent would have to do expert work in private and forensic relations. He must cooperate with the non-medical inspectors and he comes in contact in regard to damage compensation with the medical men who have actual charge of the workmen, and also with the authorities of the various benefit societies. There should be organization and control of the medical men appointed by the Government to examine newcomers and make periodical examinations of the workers in dangerous trades. We know that these examinations are not carried out according to the design of the authorities. They lack the official quality, and should be standardized and made to include instruction of the worker. Finally, the industrial medical inspector must undertake the various hygienic examinations. The air must be analyzed for dust and gases, the illumination, moisture, temperature, the drinking and waste water should all be investigated. In occupations where disinfection is obligatory the efficacy of the latter should be checked up by cultures. Any suspicion of the presence in individual workers of occupational disease—anemia, lead line, etc., should be verified or disproved. The medical man should also do what he can to enlighten the workers directly and through literature with factory hygiene. These matters will eventually be taught in the trade schools. He should have certain hours outside of his regular consultation time to receive the workers and their employers and give his services in all ways save, of course, those of actual treatment. Finally, there are many subjects which have an indirect bearing on the workers' health—in fact nearly all medical subjects possess in theory such a bearing; and the medical inspector also has opportunities of turning his experiences into knowledge for the common good by reporting interesting cases and statistics. The industrial or factory inspector will eventually have the same status as the school physician, who was a long time in arriving at his present position.—*Zeitschrift für Versicherungsmedizin*, July, 1912.

Book Reviews.

DIABETIC COOK BOOK. By ANNA COLBY KNOWLTON. Price, $2.00 net. Englewood, N. J.: Published by the Author, 1912.

THIS book of recipes is dedicated "To those whose diet, for one reason or another, is restricted as to starches and sugars, and who may be interested in a more varied dietary than that which ordinarily is available under such circumstances." On glancing over the recipes and seeing the infinite variety of breads, cakes, and desserts of which patients on this restricted diet can partake, one is inclined no longer to pity them, so far, at least, as the table is concerned. The author presents forty-one recipes for bread, biscuits, muffins, and griddle cakes; twenty-two for cake; sixty-five for desserts; six for sauces; five for pies and pie crusts, and three for ice cream. With a new kind of bread or muffin every morning for six weeks, and a different dessert for dinner every day for nine weeks, the diabetic can have no cause to complain of monotony in his diet. The author claims that the recipes given have been recorded from practical experience and that each of them has been verified repeatedly, so that any person with ordinary culinary skill can obtain satisfactory results from their use. The book ought to be very serviceable in any family in which some one of the members is obliged for therapeutic reasons to partake very sparingly of starches and sugar.

MIND CURE AND OTHER ESSAYS. By PHILIP ZENNER, A.M., M.D., Author of "Education in Sexual Physiology and Hygiene." Price, $1.25. Cincinnati: Stewart and Kidd Company, 1912.

THE title of this little book is misleading. It is not a tiresome and impractical book on mind-cure, so much as a very practical one dealing with topics of vital interest. The author's previous book, on "Education in Sexual Physiology and Hygiene," received very favorable comment and afforded an example of how this subject may be approached and taught to the young. The present volume comprises a series of essays in the form of addresses delivered to educational organizations. It is an attempt to correct many popular errors, and to overcome ignorance in regard to topics which need to be taught to every generation. The subjects discussed are all in the line of preventive medicine. In an excellent chapter on mind cure, the author states that mental healing has a great usefulness but very definite limitations. "That usefulness ceases," he states, "wherever mental influence does not effect pathological processes." Very nicely put. "Quackery and osteopathy, though to a large extent such in fact, are ostensibly not mind cures, and are a harm only in so far as they bring the wrong treatment to the individual case." No statement could be more fair than this. There are chapters on Prevention of Nervous Disease—Training the Child; on Treatment and Prevention of Alcoholism; Social Disease—Woman's Problem; Defectives; Medical Inspection of Schools and the School Physician; Truancy; Eugenics, etc. Physicians may find this a useful book to recommend to parents and teachers. It is worthy of a wide circulation.

SALVARSAN IN SYPHILIS AND ALLIED DISEASES. By J. E. R. MCDONAGH, F.R.C.S., Surgeon to Out-Patients, London Lock Hospitals. Price $3. London: Hodder & Stoughton, 1912.

OF all the publications on salvarsan, none are more comprehensive or practical than this work. The objects for which it was written are (1) to describe salvarsan and relate its history and that of its forerunners, (2) to explain the method of its injection, (3) to estimate its potency as a specific against the *Treponema pallidum*, (4) to state with impartiality what it does do and what it does not do, what are its uses and what its abuses, (5) to demonstrate these facts by actual cases cited as evidence, and thus to arrive at an accurate estimate of its value. In the chapter on Toxic Symptoms, he shows the necessity of using freshly distilled water, proper preliminary preparation of the patient for the injection, and explains the occasional increased toxicity of the drug by the presence in the human body of organisms other than those which salvarsan is destined to destroy. With regard to neurorecurrences, he believes that their occurrence were almost as frequent as when salvarsan was not used, hence he concludes that they signify inadequate treatment. A short section is given to the discussion of fatal cases due to 606 and contraindications for its use. The intravenous method of injection is given preference, but his syringe and technique are more cumbersome than other models. In considering the effect of salvarsan on Wassermann's reaction, attention is called to the far-reaching significance of Gennerich's (Kiel) and Miliar's (Paris) deductions from their observations that an injection of 606 occasionally changes a negative Wassermann to a positive. McDonagh testifies to the correctness of their observations and advises that repeated studies extending over a fortnight be made following this provocative injection. Adequate attention is given to the action of salvarsan in primary, secondary, tertiary, and congenital syphilis, and syphilis of the nervous system. The clinical histories are clearly written and not burdened with inconsequential details.

ESSAYS ON GENITOURINARY SUBJECTS. By J. BAYARD CLARK, M.D., Assistant Genitourinary Surgeon to Bellevue Hospital, Consulting Genitourinary Surgeon to the Elizabeth General Hospital, Fellow of the New York Academy of Medicine, Member of the American Urological Association, Member of the American Association of Genitourinary Surgeons, etc. Price $1.25. New York: William Wood & Company, 1912.

AN idea of the character of this book may be obtained by mentioning the titles of the essays: Cystoscopic Diagnosis in Vesical and Renal Surgery, Tuberculous Kidney, Gonococcic Infections and the Physician's Responsibility, Some Necessary Principles in the Diagnosis of Surgical Conditions of the Upper Urinary Tract, Gonorrheal Prostatitis, Comparative Value of Some Urethral and Other Germicides, On What is New in Genitourinary Surgery, Is Genitourinary Surgery Justified as a Special Branch of Medicine? The By-ways of Prostatectomy, and The Gonococcus. The first seven have been published in various medical journals. The essay on gonococcic infections is well timed and should be read by every practitioner since it shows statistically the devastations of the gonococcus; facts well known to the urologist and due to almost criminal ignorance of general practitioners. He ends this essay as follows: "It may be said, the largest, and surely the saddest, part of this great public evil has its origin in the peoples', our neighbors', our friends', our patients' ignorance of the subject. The only key to the situation is the light of true knowledge, and the only source at present of this light is the medical profession, of which you and I are members." The essay entitled "Is Genitourinary Surgery Justified as a Special Branch of Medicine?" is philosophic in nature. What is said therein of genitourinary surgery applies to any specialty, since a specialty only justifies itself, when as a body its members can show superior art and skill. The essays on Tuberculous Kidney, Gonorrheal Prostatitis, and Urethral Germicides have been excerpted in contemporary medical journals. The views and opinions expressed are rational and wholesome, the literary style is excellent.

HANDBUCH DER NERVENKRANKHEITEN IM KINDESALTER. Von Prof. L. BRUNS, Oberarzt a. d. Hannoverschen Kinderheilanstalt und Nervenarzt in Hannover; Prof. A. CRAMER, Geh. Med.-Rat. Direktor der Kgl. Univ. Klinik für psychische und Nervenkrankheiten in Göttingen; und Prof. TH. ZILHEN, Geh. Med.-Rat., fr. Direktor der psychiatrische und Nervenklinik der kgl. Charité in Berlin. Nut 189 Abbildungen im Text und 3 Tafeln. Price 30 marks. Berlin: Verlag von S. Karger, 1912.

THIS volume is a most comprehensive one. It deals not only with those nervous diseases that occur mostly in childhood, but it discusses also those nervous diseases that occur occasionally in childhood, though found chiefly in the adult. The first section, under the authorship of Cramer, takes up the following subjects: nervousness, hysteria, epilepsy, chorea, stuttering, and fits in childhood. The second section, by Bruns, deals with the diseases of the spinal cord and peripheral nerves, and also with with polymyositis, myositis ossificans, multiplex progressive, and ischemic muscular paralysis. The third section is written by Zielhen, who discusses the diseases of the brain and of its membranes in childhood. Each of the divisions is a veritable treatise on its particular group of subjects. Thus in the first section 244 pages are devoted to the functional neuroses. The second section on the spinal cord and peripheral nerves comprises 300 pages. The last section on the brain and meninges consists of 421 pages. It is difficult to pick out any one portion of the book for special comment, so admirably does the work cover the entire ground of the nervous diseases of childhood. There are many excellent illustrations and a complete index. The general practitioner, the neurologist, and the pediatrist will find this book useful both as a text and as a work of reference.

Society Reports.

SOUTHERN MEDICAL ASSOCIATION.

Sixth Annual Meeting, Held at Jacksonville, Fla., November 12, 13, and 14, 1912.

(*Concluded from page* 1053.)

THE PRESIDENT, DR. J. M. JACKSON, MIAMI, FLA., IN THE CHAIR.

Some Economic Questions Related to Syphilis.—Dr. ISADORE DYER, New Orleans, said he had employed salvarsan in a number of cases, and he had had no serious accidents, but he was still regretting that he was led to the indiscretion of employing a remedy which in his humble opinion had no advantage over other tried medications, properly administered, for syphilis. The States were deliberating the establishment of laws requiring health certificates before marriage licenses were issued. It was more important to protect marriage contracts by requiring treatment for such diseases as syphilis than it was to aim at a restriction on natural inclinations. Hospitals for syphilis should be established in every State, not, as was claimed, as an incentive to vice, but as a deterrent. If syphilities were required to be hospitalized for the treatment of their disease, it would reduce the occurrence of syphilis and would encourage proper treatment. The South had its peculiar problem in this regard with the negro population, which it was hard to educate in sanitary or moral prophylaxis. The whole question of syphilis was alive in our present society, and needed the careful study of those interested in the future generations of our people. While treatment might be of great importance, of more importance was the study of the ways and means to educate the profession and the public in the care and in the prevention of syphilis and its consequences.

Importance of the Recognition of Syphilis in Circulatory Disease.—Dr. JOHN T. HALSEY, New Orleans, said the conclusions to be drawn from facts, indicated, *first*, that syphilis very frequently produced lesions of any portion of the circulatory system, and that it did so during the early stages. A routine Wassermann test should be and could be made in all such cases, nor was there any doubt that if this be done, much unnecessary suffering and disease would be prevented. *Second*, those who treated syphilis in any stage, but particularly in the early phases, should be on the lookout for evidence of disturbed circulatory function, and, when such was found, they should not be satisfied to treat the syphilis alone, but should treat the heart as well. The coexistence of circulatory disease and positive or presumptive evidence of syphilis called for energetic antisyphilitic treatment, and it could not be too strongly emphasized that iodide of potassium alone was not sufficient. Such patients must be given mercury or salvarsan, the choice between which should be governed by various considerations.

Hygiene of Syphilis.—Dr. OSCAR DOWLING, New Orleans, pointed out that as a preventive measure, segregation of the prostitute class, while unsatisfactory and undoubtedly a legalization of vice, afforded opportunity for medical supervision and treatment. Stringent, practical regulations, humane, adapted to local conditions, and rigidly enforced, would give results worth the effort involved. But to be effective there should be no favor, no laxity, no escape. Certainty and justice should be the keynotes. The best means of getting rid of syphilis or any similar disease was to educate the people by energetic, practical work daily. Vigilance in the control of bad practices, activity in the practical things pertaining to home life, enforcement of every health ordinance and regulation were means which spread the gospel of cleanliness and health. The hygiene of syphilis was the same as the hygiene of other contagious diseases. From its nature, specific work should be done to enlighten everyone as to its origin and to correct the false notion that it was contracted only in one way.

Syphilis of the Ear.—Dr. N. M. HEGGIE, Jacksonville, Florida, had seen only eight cases of primary labyrinthine deafness within the year, two of which were probably due to mumps and one to traumatism, leaving but five to be classified as syphilitic. In view of the fact that labyrinthine syphilis was not amenable to local treatment, he would advise patients to avail themselves of the treatment recommended by a syphilographer, just as readily as were the lesions of another organ.

The Effect of Antisyphilitic Remedies on the Wassermann Reaction.—Dr. WILLIAM LITTERER, Nashville, Tennessee, drew the following conclusions: 1. From the serologic point of view, injections of the biniodide of mercury gave better results, while the protiodide pills were the least satisfactory. 2. Apparently there was no very great difference serologically between the administration of salvarsan intravenously or intramuscularly in treating secondary syphilis. 3. Neosalvarsan appeared to be more efficacious than salvarsan. 4. In the primary stage of lues, especially before the appearance of a positive Wassermann and chancre excised, repeated intravenous injections of salvarsan or neosalvarsan gave promise of aborting the disease in quite a number of cases. 5. Serologically a combination of mercury and salvarsan appeared to have a distinct advantage over the administration of either of the drugs. 6. The Wassermann test as a therapeutic guide in the treatment of syphilis was paramount if one wished to carry it to a successful termination; in fact, it was the only method available of controlling the external manifestations of the disease.

Syphilis of the Eye.—Dr. DUNBAR ROY, Atlanta, Georgia, said the longer he practised ophthalmology and the more extensive became his experience, the more he realized the importance of considering syphilis as the most important factor in connection with ocular diseases. Diffused interstitial keratitis was exceedingly rare in the acquired forms of syphilis, and yet a number of cases had been reported. Iritis in various forms was by no means infrequent during the secondary stage of syphilis, less frequently during the so-called tertiary stages. Paralysis of the various muscles of the eye was frequently caused by syphilis. Ophthalmoplegia interna or paralysis of the sphincter of the pupil, usually unilateral, was by no means an infrequent form of syphilis. According to Alexander, three-fourths of such cases were due to syphilis, while, according to Uhthoff, only one-fourth. Disease of the eye due to congenital syphilis frequently showed many of the symptoms which were seen in the acquired variety. Usually those cases of the congenital variety were comparatively mild because the severe ones died either *in utero* or soon after birth.

Syphilis of the Nose and Throat.—Dr. H. H. MARTIN, Savannah, Georgia, said the secondary lesions occurring in the nose and throat were interesting, and sometimes troublesome, but were usually self-limited and seldom caused serious or permanent damage. They were of considerable diagnostic value and furnished fairly accurate indications of the progress or arrest of the disease. The tertiary lesions, on the contrary, played havoc with the bones, cartilages, mucous membranes and fibrous tissues of the nose and throat, and since they most often made their appearance some years after all active symptoms of the disease had disappeared, we must be constantly on our guard against them. In the nose a tertiary lesion might exhibit merely the symptoms of a bad cold, but the secretions very rapidly became purulent and offensive, and a careful inspection would reveal the lesion in the form of a more or less diffuse infiltration, or in a periosteal or perichondral abscess. The treatment of syphilis of the nose and throat was essentially constitutional, but there were some local measures which had proven valuable in his hands, and among them the mixture of calomel and lime water, known as "black wash." This could be used as a douche, a spray, or a gargle, and was especially valuable in the specific coryza of the new-born, in ulceration and in necrosis. The tincture of iodine was very useful in treating ulcerations when they were accessible. The secondary lesions required no local treatment and were best left alone.

Chronic Nasal Diphtheria.—Dr. CLIFTON M. MILLER, Richmond, Virginia, reported three cases of nasal diphtheria. In one case the nasal discharge was blood-stained with a blood crust around the margin of the nares. The third case differed from the others in that the diphtheritic condition in the nose was chronic and lasted about six weeks, during which time the child had several attacks of follicular tonsillitis, which, in his opinion, were due to the mouth-breathing and lowered resistance. Bacteriological examination of the throat during one of the attacks showed the absence of the bacillus of diphtheria, which was present in the nasal discharge. The diagnosis in all of these cases was confirmed by bacteriological examination. All of them occurred in private practice. The circumstances surrounding the patients were good.

Treatment of Chronic Laryngeal Stenosis.—Dr. HOMER DUPUY, New Orleans, after giving a description of some specially devised intubation tubes, drew the following conclusions: 1. When a laryngeal stenosis is the result of hyperplastic changes, some form of dilatation is the most logical method of overcoming it. 2. Gradual, systematic dilatation by intubation offers very favorable prospects of success. 3. The tube with a low-retaining swell and a wide head would seem to meet a want in the

treatment of this form of stenosis. 4. In children, hypertrophic laryngitis is largely responsible for a chronic laryngeal stenosis. 5. In this particular affection tracheotomy is more apt to induce connective tissue changes than to effect a final cure.

The Surgial Importance of the Breast.—Dr. E. DENEGRE MARTIN, New Orleans, said that if one-tenth of the time and labor expended in the elaborate operations devised for the cure of cancer had been devoted to its prevention, more women would be alive to-day to sing our praises. An important duty was the instruction of patients as to the care of the breasts. The expectant mother or nursing woman should be taught how to care for the nipples, for infection through a fissured nipple would not only lead to abscess and sometimes to complete destruction of the gland, but would leave scars to light up at some future time into inoperable carcinomata. In an experience of more than 150 cases of cancer of the breast upon which he had operated, three-fourths being on colored women, the latter already malignant when operated upon, he was not able to-day to point out more than four of these who had lived over a period of six years, and only twelve whites. Here the percentage was larger because they were seen earlier. Every week he turned away from his clinic cases too far advanced for even temporary relief. The surgeon who picked his cases would of necessity get the best results, but the benefit should always be given to the patient, even if it meant but a short prolongation of life. The mortality from operations was less than two per cent., and his, with 50 per cent. in advanced cases, was less than one per cent. These statistics were improving daily, so far as cures were concerned. Still, the prevalence of cancer was on the increase, and we could and must reduce it.

Tubal or Extrauterine Pregnancy.—Dr. J. HUGH CARTER, Memphis, Tennessee, said we should operate in all cases as soon as possible, as we never knew when hemorrhage was going to take place, even after it had seemingly been stopped. The six cases he had seen, four of which were his own, operated on by himself, two being of about six weeks' duration, and the other two about four and one-half months, all recovered. The other two he saw while an interne at the City Hospital. One occurred at full term, the operation being done during shock. The patient died in a short time. The other one, about two months, recovered after a long convalescence from subsequent infection. As to what operations should be done, he did not believe one could say until the abdomen had been opened. Then the operator should do whatever he thought best. Each patient and the conditions found in the abdomen must be dealt with individually. He would insist upon a careful diagnosis of each case of suspected tubal pregnancy as early as possible, thereby giving the patient a much better chance for her life.

Clinical Value of the Tuberculins in the Diagnosis and Treatment of Tuberculosis.—Dr. WALLACE J. DUREL, New Orleans, said in his personal observation of several hundred cases, it was evident that of eighty cases which were treated previously to 1909, of all those discharged as apparently well, and who were given the tuberculin test, the test proving negative, not one relapsed, yet many of the cases showed a distinct positive reaction upon their discharge and afterward relapsed, and three died since. This evidence convinced him that repeated tuberculin tests would show whether treated and supposedly cured cases were free from any tubercular focus, active or latent, regardless of its size or location, and that the negative reaction meant more than a mere toxi-immunity in such cases. The clinical therapeutic value of the tuberculins was exemplified in the tabulated records of 80 cases of tuberculosis treated in Louisiana previous to 1909. In this report, in the first stage, 13 cases were treated, with recovery of all, and no relapse until 1912. In the second stage, 16 cases were treated, with recovery in 10 and arrested in 1. In the third stage, 30 cases were treated, 14 apparently well, and 16 arrested. In 1912 one of the apparently well cases had relapsed, and one died. Of the arrested cases, three relapsed and two died. Of the third stage, 21 cases were treated; not one got well, 9 were arrested, 10 were improved, and 2 non-improved. In 1912 16 of the 21 cases had died. These figures taught the practical lesson that the early diagnosed cases of tuberculosis could be treated with far better and more lasting results than the advanced cases.

Surgical Complications in the Abdomen During Typhoid Fever.—Dr. CHARLES M. REMSEN, Atlanta, said that if we would put typhoid on a true pathological and surgical basis, view it from this standpoint, and look upon it as a potential abdominal calamity, and if we would familiarize ourselves with the signs and symptoms of the normal typhoid abdomen and with each separate case, and if we would realize that with speedy operation under proper conditions there need be little fear for the safety of our patient, and, if we would make as our criterion for operation the absence of a certainty that perforation did not exist, rather than a certainty that it did exist, and if we would realize the fatal issue that was involved in delay, it was not possible, but certain, that many cases of typhoid dying from perforation, entirely unrecognized, would be reduced to a minimum, and the cases of recognized perforation would enter more and more into their true surgical sphere and be eliminated from the known causes of death in typhoid fever.

Some Modern Factors of Safety in Surgery.—Dr. J. SHELTON HORSLEY, Richmond, Virginia, in summing up the recent factors of safety in surgical operations, advised anoci-association, reducing infection by conserving natural immunity and by the elimination of dust, transfusion of blood, arterial suturing, and the practical application of the surgeon's knowledge of pathology to the diagnosis and extirpation of malignant tumors.

The Discrepancy between Clinical and Postmortem Findings in Cancer of the Stomach.—Dr. W. A. BRYAN Nashville, attempted to show how we might discover more cases of cancer before the post mortem, or, preferably, before they had passed the chance of successful operation. His answer to this question was by revising our conception of the symptoms of cancer of the stomach and getting rid of the notion that it could not be present until a lot of symptoms had manifested themselves, when, if we would stop a moment we must know that they grew out of necessarily late or at least well advanced changes. We must forget these and study stomach cases that came to us until we could be satisfied that the symptoms were due to stomach pathology, or were referred from elsewhere. We must cease to think in terms of indigestion and search for real causes. When such cases were found a careful study of them for a week or so would impress upon our minds the probability of a serious lesion and help to determine its nature. Laboratory methods and skiagraphs were to be employed in conjunction with clinical study. Finding a tumor by palpation was very important; but the patient was much more fortunate who had his tumor found before it could be felt, and lastly, if the case was indicative of cancer, the whole of the facts should be laid before him, and he should have the privilege offered by exploratory incision. Personally, it would take no very grave suspicion of cancer for him to request exploration.

Milk Ordinances.—Dr. V. H. BASSETT, Savannah, Ga., read a paper on this subject in which he advocated publicity as a factor in securing and enforcing ordinances providing for the control of the production and sale of milk.

Fly-Borne Typhoid and Its Control in Jacksonville.—Dr. C. E. TERRY, Jacksonville, Florida, said the flyproofing of privies was protection against infection, and he was convinced from inspections made of these places, prior to the passage of the screening ordinance, that, second only to stables, they furnished the most prolific fly hatcheries in the city. What was true of Jacksonville, was likewise true of many Southern towns and cities where the sewerage systems were inadequate to the requirements and where the old type of privy was in common use, and in such communities he was convinced that the screening of these places would bear fruit in reducing typhoid mortality as it had in Richmond, Asheville, and this city.

Medical Inspection of Schools in South Carolina.—Dr. L. ROSA H. GANTT, Spartanburg, South Carolina, said in her paper that in common with the 8000 club women of her State, and as a physician, she wished to enlist the members in the fight for the medical inspection of school children of the South, together with a more thorough teaching of personal hygiene and the laws of health in the public schools of the Southern States.

Serum Treatment of Cerebrospinal Meningitis.—Dr. CHARLES C. GREEN, Houston, Texas, said that in Houston they had 182 cases with 74 deaths, giving a death rate of 40.6 of all cases, including those treated with and those treated without serum. Out of the total number of cases treated, 29 did not have the serum, consequently the death rate ran up rather high; having 21 deaths out of 29 cases, giving the enormous death rate of 72.4 per cent., which, although high, was even lower than the usual death rate where the serum treatment was not used. But of the 153 cases treated with serum, 53 died, giving a death rate of 35.5 per cent., showing a reduction of 37.9 per cent. in favor of the serum therapy. He had taken the number of cases that had the serum within 24 and 36 hours after the onset, and the death rate in these was only a fraction over 20 per cent.

The cases from which these statistics were obtained constituted the entire number of cases which appeared in Houston last winter, and were not only treated by the health officers, but by the physicians at large, some of whom were not familiar with the disease nor with spinal puncture. He believed that if all of these cases could be treated by men who were familiar with this procedure, the death rate would be still lower.

Pediatrics.—Dr. WILLIAM WESTON, Columbia, S. C., said the study of pediatrics dealt with that period of development in which functional activity was greatest, and during that period occurred diseases which seldom or never occurred in later periods of life. During the first year of life there occurred the greatest development of the nervous system. The brain grew almost as much during the first year of life as during the rest of life. Dentition and many other steps in development all had a special significance and should receive careful consideration if the aims of the pediatrists were to be fulfilled. Some of the more important aims were: Preservation of the race by studying the anatomy, physiology, and pathology of infancy; the effects of heredity, of infant hygiene, and of feeding. Only after thoroughly familiarizing ourselves with these elementary requisites could we successfully equip ourselves for the practice of pediatrics and be able to interpret symptoms in a rational and satisfactory manner. Then the pediatrist could justify his pretensions by so lowering the mortality table as to be well within the bounds of reasonable expectancy.

Some Mooted Points in the Feeding of Infants.—Dr. JAMES D. LOVE, Jacksonville, Florida, said that for some years past it was his practice, when the co-operation of hospital attendants and intelligent mothers had to be secured, to employ a very simple form of milk modification, using top milk and a diluent in proportion varying from 1 to 4 to 1 to 1, sugar and salt being added to maintain the ratio these should bear to the other constituents. But intelligent cooperation was sadly lacking in most of the feeding cases, standard top milk unobtainable not infrequently, and in many particulars the simplest form of modification through the use of percentage formulæ and top milk was fraught with difficulties which had led him to the adoption in routine private practice of the still more simple dilution of whole milk with water or some cereal decoction. In this view he had the support of many eminent clinicians and pediatrists. His individual experience led him to the conclusion that the average child could be successfully fed on simple dilutions of whole milk, and that it was the exceptional child that required a system based on percentages and the employment of top milk. With the present unsanitary dairy methods in vogue throughout the South, and even with the quasi-sanitary precautions practised by a few of the dairies, he regarded the use of raw cow's milk, especially during the summer months, as the greatest menace known to children. His own practice was to boil milk during the heated season for from three to five minutes, and during the cooler months to employ pasteurization where such was practicable. Under suitable conditions and for limited periods he regarded condensed milk and some of the proprietary foods as highly useful adjuncts. It was his custom to employ condensed milk or some of the proprietary foods in certain cases where it became necessary to remove the baby from the mother's breast during the heated period of the year, to be followed later with the use of cow's milk.

Tamponade Treatment of Accessory Sinuses and Its Effect on Intraocular Inflammation.—Dr. WILLIAM S. MANNING, Jacksonville, Florida, said it was particularly in so-called "idiopathic" cases or those in which there was apparently no cause for the inflammation that he found this treatment of special value. In these cases the ordinary methods were almost valueless. He was thoroughly convinced that chronic frontal sinus and ethmoidal infection was the sole cause of many of these so-called idiopathic cases of choroiditis and retinitis. A tampon, of such length and size as would snugly fit between the middle turbinated body and the septum and extend from the exterior portion of the nose to the sinus posteriorly, was first saturated with an aqueous solution of argyrol, 40 grs. to the oz., and then introduced. Through capillary attraction, it would deplete the proximate soft tissues and drain the ethmoid cells and other sinuses. In order to drain the maxillary sinuses, these tampons should be placed under the scroll of the middle turbinated body and above the upper part of the inferior turbinated body. It was his custom to allow them to remain *in situ* for from 20 minutes to one hour. The first effect was congestion of the conjunctiva, sneezing, and nasal discharge. On removing the tampons when infection was present, they would be found to be bleached on the upper surface, and sometimes throughout, the bleaching being in proportion to the amount of infection. He had treated by this method five severe cases of idiopathic retinochoroiditis in which blindness threatened, and in every case had obtained splendid results. He had treated by this method twenty-six cases of iritis, and marked improvement followed in all except two, in which syphilis was an etiological factor. By far the largest class of cases that he had treated, however, had been those of obscure frontal headache variously diagnosed as malarial, gastric, refractive, etc.

Gangrenous Tonsil.—Dr. U. S. BIRD, Tampa, Fla., said that so rare was this disease that it was not a textbook nor reference book subject. Five cases only could be found in medical literature, all of which were fatal. In addition to these he now personally reported five cases, four in patients of his own, and one in the practice of a brother physician. These five cases, as compared to the five previously reported, suggested some interesting conclusions. In the first five cases the mortality was 100 per cent. The cases that he reported included two deaths, but neither of these was due to gangrenous tonsil, which in these cases appeared to be an intercurrent condition, more or less due to the general depression that had rendered them vulnerable to such attacks. In his fourth case only were operative measures indicated. When a small area was involved and the general condition was good, instrumentation was indicated; but in great depression and extensive involvement, two conditions that seemed to be associated, active interference might result unfortunately. Only one of his cases was of interest in connection with pathology, the noma bacillus being present. Unless his experience proved to be unique, it might be assumed that gangrenous tonsils, and the recoveries therefrom, were more observed than the literature suggested.

Thrombophlebitis of Orbits by Ozena Bacillus-Death.—Dr. M. FEINGOLD, New Orleans, Louisiana, said it was freely admitted that many an affection of the eye and the orbit was dependent upon a primary disease of the nose and its adjoining cavities, but certain points needed further discussion. He saw in consultation a girl of fifteen years who had an edema of the upper and lower lid, so extensive that the eye could not be opened voluntarily. There was a hard infiltration through the upper lid to the depth of the orbit. The temperature was about 101 degrees. The patient denied that there had been any previous affection of the nose. An operation was immediately performed, and an extensive focus of sticky, grayish, gelatinous pus was found and evacuated. Necrotic bone was also discovered in the orbit. The patient stood the operation well and spent a comfortable night. The next day, however, pulse and temperature gradually rose and patient complained of pain in the head. Probing revealed no further focus, but the edema on the right side had increased and dilated veins were visible over the forehead and nose. Atrophic retinitis was found in each side, with crusts and pus in the middle meatus, under them. On the following day the Killian operation was performed, and pus was found in the frontal and sphenoidal sinuses. After the operation the patient gradually grew worse and died on the night of the following day. The temperature had reached 106.1 degrees, with profuse perspiration and very labored respiration. The pus was found to contain a pure culture of bacillus mucosus capsulatus. No postmortem was obtained. The interesting points in the case were that a sinus affection might be latent for some length of time, and that orbital affection might be brought about by the affection of the adjoining nasal cavities.

Cesarean Section.—Dr. JOHN M. WILSON, Mobile, Alabama, said the most common indication for cesarean section was a contracted pelvis, but there might be other causes, such as uterine myoma, located at the lower part of the uterus, and ovarian cyst with adhesions, cancerous or undilatable cervix. This operation might be employed in some cases of placenta previa, as well as in some cases of eclampsia with a very rigid cervix. The success of cesarean section depended greatly upon the time when it was performed, the best results being obtained in those cases that could be given the proper preparation and operated on just before or at the beginning of labor. Those cases gave the worst results that had been in labor some time and had had repeated examinations made on them, which were likely to produce, as stated before, an exhausted patient and an infected uterus. Here was seen the importance of the obstetrician making an early diagnosis of any pelvic deformity, or obstruction of any kind that might call for a cesarean section. In this way we would have the chance of properly preparing the patient for a major abdominal operation.

The Early Beginning of Tuberculosis with Especial Reference to Its Confusion with Malaria.—Dr. William Redin Kirk, Hendersonville, North Carolina, said that without attempting to go into physical diagnosis in detail, he would like to call attention to a few points in connection with the recognition of tuberculosis in its early stage. Altered breath sounds were the rule, and not the exception in early cases. Lessened motion of the diaphragm was an early sign; William demonstrated it by the fluoroscope. It was also observed by Litten, whose shadow test was familiar; and Kronig had called attention to the fact that the motion of the lower border of the lung was diminished when the lung was involved to a small degree, and Pottinger claimed that the entire side lagged even in slight involvement of the apex. Exploration of the entire chest was always necessary, but especial care should be used in observing certain areas, the apices, front and back, the first intercostal spaces, the area under the scapula, which was partly uncovered when the hand was placed on the opposite shoulder, the area on each side of the vertebra between the scapula and the lower lobe of the lungs. Rist, in a recent paper, claimed the lower lobe was almost invariably the site of the initial lesion in children, and that the apex was involved secondarily in both children and adults, explaining that cough forced infectious material into the apex. Of the accessory means of diagnosis, he should have only a few words to say. Search for the bacillus should be thorough, and negative cases examined repeatedly, for while finding the bacillus was the only absolute proof, a negative result was not positive evidence of the non-existence of tuberculosis. Too often patients were assured they had tuberculosis upon this evidence alone. The general practitioner was not expected to make use of Arenth's method of differentiation of the nuclei of the neutrophiles, the opsonic index and other more difficult laboratory means of diagnosis, but in all suspected cases he could and should use some of the tuberculin tests, Moro's, Von Pirquet's, or the old method of the subcutaneous injection of Koch's old tuberculin.

The Diagnosis of Plague.—Dr. R. L. Wilson, Charleston, South Carolina, said that in plague work great care should be taken in handling infected animals, tissue, cultures and other material. Even persons accustomed to bacteriological laboratory work had to be reminded of danger, as several laboratory cases of infection were on record. The principal things to look out for were fleas from animals, skin abrasions, soiling of fingers, using of pipettes and smoking. To summarize the principal points in diagnosis. 1. Typical lesions, especially characteristic buboes. 2. Production of the disease in animals by inoculation. 3. The unmistakable presence of the plague bacillus in smears, cultures and in inoculated animals.

Symptoms and Clinical Diagnosis of Bubonic Plague.—Dr. J. Birney Guthrie, New Orleans, Louisiana, stated that the appearance of the patient sick with bubonic plague was somewhat similar to that of one under the influence of alcohol. The face was swollen, the eyes injected. There was a general loss of coordination, staggering gait, thick and stammering speech. This speech disturbance frequently extended into convalescence, and with persistence of lymphatic enlargement and recent scars of suppurating buboes, might furnish the clew to identification of a previously unreported case. The recognition of cases of bubonic plague, where it was known to exist, presented small difficulty to the physician. It was the identification of the first cases, especially if they were of mild type, which would present the severe problem in diagnosis. In a suspicious case careful and continuous observation of the superficial lymphatic glands should be maintained and puncture with the needle and examination of aspirated fluid made by smears and culture methods. Finally, let this be emphasized, the early identification beyond any doubt of bubonic plague depended upon the microscope. It was the duty of the attending physician to submit to the bacteriological laboratory slides made from the fluid aspirated from every suspicious bubo and from sputum in every case of pneumonia showing more than ordinary depression at the outset with a bright red sputum instead of the typical rusty sputum of ordinary pneumonia. The services of the public bacteriologist should be available. Possibly it might be wise to require the specimens to be submitted. The only hope of limiting an outbreak was that of a prompt diagnosis of the disease. To-day every seaport of the world was menaced by plague, and the menace would be still further increased by the opening of the Panama Canal. It therefore became the duty of every one of us who practised medicine in a seaport to keep constantly in mind the possibility of encountering the disease. To this end examination of the superficial lymphatic glands during the progress of every acute febrile case became a matter of necessary routine.

Treatment of the Plague.—Dr. Isaac Ivan Lemann, New Orleans, Louisiana, said unfortunately the story of the plague therapy was brief and discouraging. The mortality rate of those stricken, without previous prophylactic treatment, was still in the neighborhood of 90 per cent. Our chief and first attention must, therefore, in this disease above all others, be given to prophylaxis. Several methods of producing active immunity had been proposed. Haffkine, working in India in 1907, proposed his well-known prophylactic. This consisted of a bouillon culture of the pest bacilli, killed by heat and carbolized so as to represent a 0.5 per cent. solution of phenol. The dose of this varied from 0.5 to 1 c.c., and in special cases as much as 20 c.c. were given, according to Jackson. Llewellys Barker says: "Adult males receive 3 to 3.5 c.c., adult females 2 to 2.5 c.c., children over ten 1 c.c., small children 0.1 to 0.5 c.c. of the prophylactic injected subcutaneously. The reaction varied greatly in different individuals; as a rule, there was slight fever, malaise with local swelling and edema for twenty-four to forty-eight hours. Ten days later, a second, larger dose might be given, the size varying according to the reaction following the first dose." The protection afforded by the prophylactic was not absolute. When repeated several times it afforded a relative immunity for some months. "Four to 20 per cent. of the inoculated contracted the disease and from two to eight per cent. died." Passive immunization by means of sera derived from animals in whom an artificial immunity had been created, had been used prophylactically and therapeutically. The immunity produced by immune sera was said to last but a few days. Aside from the specific treatment the management of a case of plague was entirely symptomatic. Treatment was inaugurated with a brisk calomel purge, followed by a saline. The patient must be, of course, kept in bed in a well-lighted, well-ventilated room. The diet throughout the acute stage should be liquid, principally milk and water, with the addition of alcohol in cases where there was great prostration. Later a soft bland diet was permitted. In convalescence regard must be paid to the probability of change having occurred in heart muscle and in the kidney. The buboes must be dealt with surgically. As to the treatment of pneumonic plague, the authorities contented themselves with the vague suggestion that expectorants might prove useful. They laid much more stress upon the high degree of contagiousness of pneumonic plague and the great care with which these patients and their sputa must be handled in order to prevent the spread of the disease.

Resolutions.—The following resolutions were offered, referred to the Council, reported back to the Association, and adopted:

To President-elect Wilson, asking his support for the bill establishing a Department of Public Health.

To Congress, asking for the creation of a commission for the investigation of malaria, with a view to the recommendation of practical means for the extirpation of this disease.

To the press, asking its aid in the education of the public in matters of hygiene and sanitation.

Against fee-splitting, urging State and county medical societies to oppose the practice and to discipline any of their members who may be guilty of giving or receiving any fee or commission of this kind.

Officers.—The following officers were elected for the ensuing year: *President*, Dr. Frank A. Jones, Memphis, Tennessee; *First Vice-president*, Dr. Stuart McGuire, Richmond, Virginia; *Second Vice-president*, Dr. J. D. Love, Jacksonville, Florida; *Secretary-Treasurer*, Dr. Seale Harris, Mobile, Alabama.

Lexington, Kentucky, was selected as the place for holding the next annual meeting.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

249th Regular Meeting, Held October 11, 1912.

Dr. J. W. Brannan, President, in the Chair.

Heart Murmurs and Patients.—Dr. B. R. Robinson read this paper (see page 1076).

Dr. A. A. Smith said he would gladly indorse a great deal of what Dr. Robinson had said, but he questioned if a patient suffering from organic disease could be protected by being told that he could not hear what his disease was. He quite agreed that the patient should not be told in a brutal way that he had heart disease. Patients had a particular aversion to hearing this. The physician disliked to say it. What should be said to the patient was

a difficult subject. He could not, however, take the broad ground that Dr. Robinson had taken and should answer the question himself in a different way. Serious harm might be done by allowing the patient to remain ignorant of a heart lesion. He would like to ask Dr. Robinson whether he had been able to convince people of his judgment by saying that he would not tell them anything about the diagnosis, and whether he had not left them in more doubt and anxiety by not telling them. If cardiac functions were properly performed the situation could be explained.

Dr. MEARA said he was not depreciating a cardiac murmur, but he would like to inveigh against the amount of importance that was placed upon cardiac murmurs. The importance of physical diagnosis was magnified to a great degree. When a fourth year student was given a cardiac condition for examination he always made a diagnosis in terms of a cardiac murmur and quite forgot the heart in the murmur, and the patient in the heart. The patient at once thought that a cardiac murmur was synonymous with disease. The student exaggerated the murmur and got no idea of cardiac efficiency. The physical signs were considered but rarely the physical efficiency of the heart, and indeed it was relatively a rare thing for even practising physicians to study the efficiency of the heart. Should a patient with a cardiac murmur fall into the hands of insurance companies he would be excluded from the risk because of the murmur, though his heart might be efficient; while another patient would be passed with a marked degree of cardiac deficiency, but no murmur.

Dr. CONNER said he could indorse what Dr. Meara had said as to the exaggerated importance so often given to auscultation in the examination of the heart. It seemed to him that it might have been better for our patients and for ourselves if the stethoscope had never been invented. In regard to Dr. Robinson's remarks as to the undesirability of telling patients of the existence of heart lesions, the only safe rule seemed to him the application of common sense. One patient you could tell, another not. Some patients were better for not knowing. On the other hand, as Dr. Smith said, serious damage could sometimes be prevented by a frank and tactful statement of the matter to the patient.

Dr. BRYANT said that the question seemed one of common sense and not of hard and fast method. Some people you could reason with, some you could not. It was unwise to draw conclusions and lay down rules in advance in matters relating to present and prospective human welfare and comfort. The protection of the patient from himself seemed quite as proper in this contingency as in those related to specific infections and the sequelæ of other human infirmities.

Dr. PARK said that certain people could be told the truth about their hearts without disadvantage.

Dr. ROBINSON said it was within the last few years that he had come to this conclusion. He told the patient, "I will examine you; I will do the best I can for you, but I shall not tell what I find except to your own physician; if my method displeases you, you can go elsewhere." He had seen too many people made unnecessarily unhappy by telling them of heart murmurs. He was indifferent as to what the other man said to his patient. A practical illustration of his procedure was the case of a man who had come to him last spring for examination. He had been told of his heart murmurs and was in pretty wretched condition in mind and body. He told him he would examine him and do the best he could for him, but would not tell him what he found. That man was now in better shape than he had been for a long time. It took weeks and months to find out his exact condition. His heart now functioned all right. It would have been wrong and worthless to tell this patient that he had a murmur. He did not care if the patient had one or not. He meant every word he had said in his paper.

The Sanitary Control of Local Milk Supplies through Local Official Agencies.—Dr. ERNST J. LEDERLE read this paper (see page 1063).

Dr. DANA asked how much it cost per quart to pasteurize milk; if it added to the expense per quart; if it was possible to have central plants for pasteurization, and if the 6,000 grocers still selling milk made a living.

Dr. MEARA asked what Dr. Lederle meant by "farmers complying with 75 per cent of the B. O. H. regulations"; if "vital regulations" had a value that did not permit the farmer to disregard them; if, aside from theoretical considerations, pasteurization of first-class milk produced a cleaner milk and gave a better milk than the original milk complying with 60 per cent of the B. O. H. regulations; if infant's milk, grade A, complied with the tuberculin test; how rigidly the tuberculin test was insisted on; if carrying out the infant's milk supply had not really involved the principle of paternalism; if the Dairy Demonstration Company was a business or philanthropic enterprise; and if cream was richer in bacteria than milk.

Dr. CONNER asked if pasteurization of milk was done in the city, on the farm, or at the creameries; where would be the best place; and what effect pasteurization had upon the bacterial count.

Dr. BRYANT said that in the 70's he was connected with the department of inspection and was often required with others to inspect milk. They had to ascertain its condition with reference to its properties, especially fat content, reaction and cleanliness. The bacterial count, for obvious reasons, never entered into the question. As to the manner in which the inspection was conducted the inspectors would carry round a canton flannel bag in which was a urinometer and a glass milk holder of suitable size. They went to milk stores and inspected dipped milk. The inspectors had to do a definite number of inspections per diem and turn over the results to the Department. In the light of modern methods he could not see that these inspections were of any other use than to provide the inspectors themselves with $100 a month, and the Department with an occasional fine or suit against milk vendors. However, it was the beginning which led to the present advanced state of affairs. The B. O. H. did the very best it knew how at the time. Those who sold milk either did their best, or, as now, tried to deceive the public. Those brought up on the farm could recall how, by the taste and odor of the milk, they could always tell if the cows had been in the pasture or not. He asked if giving the child top milk gave it more bacteria.

Dr. ROBINSON asked Dr. Lederle if pasteurization impaired the nutritive value of milk.

Dr. BRANNAN asked Dr. Lederle what had been the effect in increase in price of milk; he added that the price paid at Bellevue Hospital was now 6 cents per quart. Three or four years ago the price paid ranged from 6¾ to 7 cents, but in 1910 the specifications were changed so as to require only 12 per cent. solids, instead of 12½ per cent., and 3½ per cent. butter fat in place of 4 per cent., and the price since then has ranged from 6 to 6⅛ cents per quart. The loss in butter fat was made up by the addition of cream, when needed, for babies and young children. Up to ten years ago there had been, he thought, no bacterial examination of the milk at Bellevue or in any of the city hospitals. At that time, he thought, at the suggestions of Dr. Park, specifications were prepared limiting the number of bacteria to 50 or 60 thousand per c.c. in the winter and 100 thousand per c.c. during the summer weather. This regulation had prevailed ever since, the B. O. H. making examinations of samples of the milk supplied the various hospitals two or three times a week. It was Dr. Park's idea that our action would help the Department of Health in raising the general standard of milk in the city. The change in percentage of solids and butter fat to which he referred was made under instructions from the Committee on Standardization of the Finance Department, which was endeavoring to standardize the milk and other supplies for all the public institutions of the city. He asked Dr. Lederle what effect, if any, the regulations which he had described had had in increasing the price of milk for general consumption in New York.

Dr. LEDERLE, replying to Dr. Dana, said that most of the dealers had found that they were able to sell the pasteurized milk at the same price as the raw, the commercial advantages secured by pasteurization being sufficient to offset its expense. Central plants for pasteurization would require too many different pieces of apparatus. Milk came into the city at different times. A supply should be pasteurized immediately. Milk coming in at midnight must be pasteurized and sent out early in the morning. The large dealers had been able to raise capital to pasteurize milk, and if some means could be found for the small dealers to do so it would be of great benefit to the city. Municipal pasteurization had been suggested as a solution of the problem, but he was of the opinion that the dealers should do it themselves. In regard to groceries selling milk he said that if there were a smaller number of stores it would be possible for groceries to sell milk at a profit. Most of them sold milk to oblige customers. The smaller stores could sell bottled milk. In the poorer sections the sale of bottled milk was increasing rapidly. If loose milk dealers would pasteurize and bottle milk they could keep the trade.

In reply to Dr. Meara Dr. Lederle said that every item as to equipment and method was clearly specified and a copy of the findings was left with the farmer. He was advised as to the theoretical value of every point. His

dairy was graded, and if his scoring fell below in any point he was advised what he must do to raise it to the average. As soon as he came up to the requirements he obtained a permit. Creamery inspection was not a difficult thing to regulate from the city. The proper inspection of 45,000 farms, however, was almost impossible. It was thought at first that with farm inspection the milk regulations could be carried out, but the greater the experience the more doubtful this became; that was the cause of the desire of the B. O. H. to introduce general pasteurization. Even after that was accomplished they felt that they must still further insist on a cleaner milk supply. Proper pasteurization produced a cleaner milk, provided that the milk was not reinfected in the handling. Ideal pasteurization, however, would be in the bottle, and it was hoped that it would eventually be done that way. Raw milk classified under grade A complied with the tuberculin test. In the case of pasteurized milk it was not required. The amount of grade A milk coming under the tuberculin test requirement was comparatively small and was almost all certified and guaranteed. At present certified milk came from farms certified by the Milk Commission of the County Medical Society. Personally he believed in the necessity of *all* grade B milk being pasteurized.

The infant's milk supply did involve the question of paternalism at the start. They were really carrying out a great object lesson. Milk stations were the centers of education for mothers. Eventually he hoped that the grade of milk sold there would be generally sold throughout the city and that the stations would become purely educational centers. Here the element of price came in. Last year the milk stations sold milk for 7 cents a quart, which was probably no higher than the cost of production. This was made possible by the generosity of one of the dealers in the city. The following year dealers refused to bid and the Dairy Demonstration Company received the contract. They were trying to demonstrate that a safe, clean milk could be produced without large increase in cost. This milk was sold for very little more than ordinary milk. They were now selling milk in our stations for 8 cents a quart. The Dairy Demonstration Company was part of the work of the New York Milk Committee.

Replying to Dr. Conner Dr. Lederle said that some of the pasteurization was done in the country at the creameries; that theoretically the better time was before it left the farm, but there were many practical difficulties in the way of that. It required considerable skilled labor. The process was easier to control in the city. Pasteurization was not total sterilization, but Dr. Park told him that under the conditions of pasteurization which the B. O. H. required there was practical elimination of bacterial organisms. This required skillful management, and that brought up the question of requiring a definite bacterial standard. Pasteurization depended very much upon machinery. The whole subject of pasteurization upon a large scale was a new one. They had hesitated to make legal bacterial standards. If the bacterial content of grade B was too high the dealers received a warning.

In reply to Dr. Robinson Dr. Lederle said that he thought that the feeling that harm was done by pasteurization was dying out. The ill effects supposed to be due to pasteurization were really caused by sterilization. Sterilization had been practised abroad for a great many years. Many cases cited of infants having been harmed by pasteurized milk had, in fact, used sterilized milk. He said it was not so very long ago that the milk sold in hotels and restaurants and that used in hospitals was considered the poorest on the market, but a great improvement had taken place. More attention was now paid to hospital milk, and hotels and restaurants were now required to have a permit from the Department of Health which allowed the sale of grade A or B only in these places. Only last week he had addressed a meeting of the Association of International Hotel Stewards to explain the milk regulations, the system of grading and the best methods of keeping milk. Replying to Dr. Brannan, Dr. Lederle said that the increase in price had not been more than the natural increase in price as with other commodities. The increase could not be traced to the efforts of the Health Department to obtain clean milk.

Dr. Lederle said that the question of regulations for cream was not yet settled. The Health Department had intended to include cream with milk in the grading plan, but finally decided that milk was such an enormous problem that they would try to put that on a solid basis before going further with the cream regulations. A great deal of pasteurized cream came to the city. From the public health standpoint as stringent regulations should be made in the case of cream as in the case of milk. The flavor of cream depended on conditions of the green fodder. When cows were out to pasture in spring many weeds were in the grass that affected the flavor of the cream and lowered its value. Pasteurization tended to eliminate these flavors. From a commercial standpoint pasteurization of cream was an advantage. Such cream kept much better. It would interest the Society to know that cream for use on the 4th of July was gathered as early as March or April. Cream should be pasteurized. It was inconsistent to have milk pasteurized and not cream. Now that grade C milk had been degraded it would be used for making cream. Cream used for ice cream should also be pasteurized, as freezing was not a safeguard. There was a special grade of butter made from pasteurized milk called nursery butter. Another problem was the use of skim milk. The Board of Health did not permit the sale of skim milk in the city, even if so labeled. There was no other place in the world where this was done. Because of this restriction the commercial use of skim milk was for making a glue substitute. The casein was used and the whey was used in the preparation of milk sugar. A valuable food product had thus been diverted to other uses and that helped to keep up the price of milk. Some time he was sure the value of skim milk would be recognized in this city and it would be largely used.

Dr. Park said that he and Dr. Lederle were so closely connected that they had much the same point of view. It was in 1901 that this certified milk movement was begun. It was thought that the city should have a certified milk taken care of by the Health Department laboratories. Up to that time they thought that they could have the dealers place on their milk "certified milk" and "inspected milk," but the inspected milk never took. People asked, "What is the other milk you are selling?" Competitors would say, "Our milk is as good as yours," and people were not interested enough to find out the difference between inspected and certified labels. Inspected milk has been on the market since 1902 and is used by diet kitchens, hospitals, etc. Dr. Lederle took up this question to force the dealers to put on true labels. It was found that better class dealers wished to get a good clean milk. There had been tremendous pressure that Dr. Lederle had had to fight against to get this labeling done. The difficulty was to see if the labeling was true. Men would have all sorts of schemes to make their labels look right. This question was, however, up to the people as well. The Health Department would have done their share of the work if the people were able to know what they were buying. This was one of the greatest steps in advance if the public could be sure of what they were getting. As to pasteurization, besides the question of convenience to the city, he thought it was better to have one million dead bacteria than five thousand live ones. Even if the milk was shipped through thoroughly iced the city was the best place to urge for pasteurization. He said that pasteurization caused less change in milk than did sterilization. It was not so much sterilizing milk but keeping it after it had been sterilized that did the harm. An Englishwoman, Dr. Claypon, working here under the direction of the London County Council, had come to the conclusion, the more she studied this question in London and Paris, that no harm had come from the use of boiled milk. The Rockefeller Institute and the Good Samaritan Home used boiled milk and the results seemed just as good as with raw milk. Replying to Dr. Brannan he said that pasteurized milk would never catch up with raw milk in bacterial count. Bacteria occurred in any milk, pasteurized or raw, but pasteurization could bring 100,000 count down to 3,000. If the milk was not properly iced bacteria would occur, but 1,000,000 would come down to 30,000 or 40,000 under pasteurization and it would be delivered under 100,000. Replying to Dr. Meara he said that cream had as many bacteria as all the rest of the milk put together. In reply to Dr. Bryant he said the top milk gave a child more bacteria, but unless they were harmful bacteria there would be no harm done.

THE PHILADELPHIA PEDIATRIC SOCIETY

Stated Meeting, Held November 12, 1912.

THE PRESIDENT, DR. THEODORE LE BOUTILLIER, IN THE CHAIR.

THIS was a joint meeting of the Philadelphia Pediatric Society with the New England Pediatric Society, the Section of Pediatrics of the New York Academy of Medicine, and the New Jersey Pediatric Society. The meeting was held in Thomson Hall, College of Physicians, and was largely attended.

The Treatment of Hemorrhagic Disease of the New-

born.—Dr. Beth Vincent of Boston read this paper. He stated that but little progress had been made with the problem of the etiology and treatment of hemorrhagic diseases of the new-born during the past year. The use of serum therapy seemed to mark a distinct advance in the treatment of this condition. This treatment had been applied in the form of blood transfusion and by the subcutaneous injection of animal serum, human serum and whole human blood. While the number of reported cases was not large the results showed such a high percentage of recoveries as to justify the assumption that the employment of these various methods was of therapeutic value in this disease. A review of cases showed that in 11 cases treated by transfusion the immediate effect of the procedure was to check the bleeding and correct the anemia. Eight of the eleven cases treated by transfusion were cured. Of the three cases which terminated fatally, one died of diffuse peritonitis which was probably present before the transfusion, the second died of syphilitic infection about one month after the transfusion, and the third was moribund at the time of the transfusion. Four additional cases not treated by transfusion received injections of whole human blood and all terminated fatally, but the fatal result which occurred in all of them could not be taken as evidence that this method was ineffectual, since three of the cases were moribund at the time of the injections and in the other the injections were not repeated as prescribed in this form of treatment. Several cases in this series received animal serum subcutaneously without apparent result and were subsequently cured by transfusion. This agreed with the experience of other observers. While this experience did not justify the statement that animal serum was altogether ineffective, it confirmed the opinion that human blood or its derivatives was more valuable in the treatment of these hemorrhagic diseases. The good results obtained by Schloss, Cominsky and others who had used the human blood serum was sufficient evidence that these measures were effective in checking the disease. If the bleeding in many of these cases of hemorrhagic disease was due to a defect in the infant's blood, which was apparently improved by any of the three methods of treatment, it would seem that transfusion was the ideal method because it restored directly to the infant's circulation all the elements needed for coagulation. In addition, transfusion possessed the advantage of correcting the anemia by replacing the cellular elements which had been lost by hemorrhage. Transfusion was the only method from which results could be expected in the severe types of the disease in which the patients had been exsanguinated by continuous profuse bleeding. The uniform success which had attended the injection of whole human blood, blood serum, and the transfusion of blood would lead one to believe that the best line of treatment to pursue in these cases was a rational combination of all three methods. In cases in which the bleeding was rapid and profuse and which were usually quickly fatal an immediate transfusion was indicated. Where the disease began with trivial hemorrhage and was seen early, the easier and more simple methods of blood or serum injections were in order. Assuming that these two methods gave equally good results, it would be advisable to make the first injection of whole blood to save delay and at the same time to collect enough blood to furnish serum for further treatment. This treatment should be continued if the bleeding stopped or seemed to be diminished and the infant's condition remained good. Cases which did not follow so favorable a course, or were not seen until the patient was exsanguinated, were more safely treated by transfusion. When transfusion was once done the case might be left, with the assurance that the infant was in no immediate danger, which was of no small advantage where the case could not be kept under constant observation. There were two forms of hemorrhagic disease in which transfusion or any other method could not always be expected to effect a cure. The first class included those cases in which the underlying cause of the bleeding, as bacterial infection, syphilis, and ulcers of the stomach, or duodenum, was such as to be fatal in itself, while the second form comprised those cases with hemorrhage in the brain, adrenals, kidneys or liver, in which the location and not the extent of the bleeding was the vital factor. With these exceptions their experience seemed to show that by the proper application of one or a combination of the methods under discussion they could cure a large percentage of cases in this hitherto fatal disease.

Pyloric Obstruction, with a Comparative Study of the Normal Stomach of Infants.—Dr. Godfrey R. Pisek and Dr. L. T. LeWald (radiologist), New York City, presented this paper. They stated that their object in presenting the paper was to indicate how we may add, in an efficient manner, to the diagnostic resources already at hand. The controversial theories as to the etiological factor were still unsettled and little had been gained from them in the establishment of a definite form of treatment. By the use of Röntgen rays and bismuth one could determine, by the degree of positiveness, whether a given case should or should not be operated upon. Modern apparatus with the intensifying sheets securing instantaneous exposures made this study possible. The paper was illustrated with numerous lantern slides, showing the stomach and alimentary tract of infants with pyloric obstruction, taken at short intervals, the series in each case being completed at the end of approximately twenty-four hours. Comparative studies were made in a similar manner, using normal infants, breast and artificially fed. It was soon evident that the accepted conception of the shape and activity of the infant stomach needed revision. Heretofore these facts have been obtained mainly at the autopsy table and from the embryologist. The study showed that the normal stomach began to empty itself within a minute or two after the intake of food, and this fact was used to differentiate cases of pyloric obstruction in which the food, in cases of true stenosis, escaped very slowly and through an extremely narrow lumen, while in cases of pylorospasm it took twenty minutes to half an hour before the bismuth food passed into the duodenum. As a result of their findings they prophesied that in the future every suspected case of pyloric obstruction would be subjected to a radiographic study before a plan of treatment was determined upon, just as to-day no surgeon would think of putting up a fracture without the use of the rays.

Dr. Edwin E. Graham of Philadelphia said he was especially interested in the reference to the fact that a small portion of the stomach contents passed into the duodenum within one or two minutes after the bismuth meal had been introduced. He would like to know whether a sufficient number of cases had been examined to decide definitely as to whether this was the invariable rule. Was it possible that in these cases the amount of fluid introduced into the stomach was excessive? If this was the rule the portion so leaving the stomach could scarcely be appreciably affected by any gastric secretion.

Dr. Fritz B. Talbot of Boston said that anything that could assist them in the diagnosis of pyloric stenosis was very important. In some cases it was impossible to get these babies *x*-rayed and in these cases he was accustomed to give the baby subnitrate of bismuth by mouth. Subnitrate of bismuth was a crystallizable substance and if it passed through the intestinal canal could be readily observed microscopically in the stools. Absence of typical bismuth crystals from the stools meant that no food was passing through the pylorus.

Dr. Harry Lowenberg of Philadelphia reported one case of pyloric obstruction in which the bismuth shadow did not show beyond the spinal column. He also showed charts of two cases in which the daily and weekly gain was recorded; these were cases of partial obstruction. A point which he considered important and wished to bring before his audience was the diagnostic and prognostic value of the administration of charcoal. If this substance passed through the prognosis was hopeful, whether there was present a hypertrophy or spasm or a mixed condition. Dr. Lowenberg reported another case of a baby sent to him for pyloric obstruction. The patient had persistent vomiting and obstinate constipation. The *x*-ray was interpreted as demonstrating a large twist in the sigmoid which probably accounted for the constipation. The vomiting was probably reflex. The *x*-ray showed that the bismuth meal passed to the right of the spinal column and appeared within two minutes, showing that there was no pyloric obstruction. The dangers of the stomach tube should be emphasized; in this case he believed that the stomach had been perforated, as he could palpate the end of the catheter in the right iliac fosa, but an *x*-ray picture showed that the tube had pushed the lower border of the stomach down.

Dr. Henry L. Coit of Newark, N. J., spoke of the etiology and prevention of pyloric obstruction and believed that the abuse of the saturated boric acid solution, so generally used for washing out infants' mouths, was sometimes, if not often, to blame for the occurrence of pyloric spasm, stenosis and even gastric ulcer.

Dr. J. Finley Bell of Englewood, N. J., said that he had reported a case in 1889 which had been operated upon successfully. The absence of tumor at the pyloric region did not necessarily indicate that there was no obstruction present.

Dr. Walter Lester Carr of New York said that many of those cases of pouched stomachs in which the peristaltic wave appeared to the left of the median line were found in infants that were artificially fed and could not be classi-

fied as cases of pyloric spasm or pyloric obstruction, although showing a reversed peristaltic wave.

Dr. Godfrey Pisek of New York, in answer to Dr. Graham, said that in the normal stomach the contents invariably began to pass through in a short time within a few minutes from the time of ingestion. In the cases of pyloric tumor the meal remained for some time and this was a very helpful point in diagnosis.

In cases of pyloric obstruction in which there was no tumor felt it might be found that there was no bismuth extruded for a half hour; then suddenly, in pyloric spasm, it would gush through. This aided in making a diagnosis between true tumor and spasm and in making a prognosis as well. If there was a fair amount of bismuth in the small intestine soon after the test meal the prognosis was good. The cases to which Dr. Carr referred were introduced to show an effect produced by the *x*-ray. In artificially fed babies the stomach contents appeared to pass readily through the pylorus. Dr. Talbot's point regarding the use of bismuth subnitrate was very good, but of course this would only show that something could pass through the pylorus.

An Objective Method of Teaching Food Values and Food Requirements.—Dr. Clifford B. Farr of Philadelphia read this paper, presented lantern slides, and demonstrated his exhibit. He said that in teaching the principles of dietetics to the medical students, nurses, and to the general public, he made use of charts, graduated cylinders containing colored fluids and permanent specimens of foods preserved in graduated containers. The charts were worded as tersely and emphatically as possible, covering for example, the definition of foods and foodstuffs, the principal foodstuffs and their functions, the principles of the conservation of energy as applied to metabolism, the explanation of the use of the calorie as a unit of food (energy) values, the caloric requirements at various ages with special reference to weight and body surface. Cylinders graduated in cubic centimeters and containing colored fluids, with explanatory labels, were used to show the amounts of the chief foodstuffs (protein, fat, carbohydrate, water, and salts) needed at different ages, the composition of special dietaries and in a somewhat analogous manner, the relative cost of important foods from a caloric point of view. The permanent museum consisted of one hundred or more graduated bottles and jars, each containing a quantity of the food represented sufficient to produce one hundred calories (method of Irving Fisher). These were fully and distinctly labeled and formed into groups as follows: foods rich in protein, foods rich in fat, foods rich in carbohydrates, foods chiefly valuable for the salts contained, percentage mixtures and preparations used in infant feeding, diet for a child after weaning, various forms and preparation of milk (3) of equivalent food value, etc.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON SURGERY.

Stated Meeting, Held November 1, 1912.

Dr. Lucius W. Hotchkiss in the Chair.

Hypernephroma of the Kidney.—Dr. Charles Goodman reported this case. The patient was a man, forty-two years of age, admitted to Beth Israel Hospital on June 20, 1912, with a diagnosis of calculus of the right ureter; he gave a history of having had typhoid fever twenty-two years ago, and had been troubled with constipation for a number of years. He denied ever having had any venereal trouble. Six weeks previous to his admission to the hospital he had frequent micturition with bloody urine for three days; five weeks later he had a similar attack accompanied with pain in his right side. The day before admission he again suffered pain in the right flank, was nauseated, vomited several times, felt chilly, and again passed some blood-tinged urine. He had also some discomfort in the left testicle for about two weeks. Upon admission to the hospital, with the exception of some tenderness over the right flank, an enlarged spleen, and a slightly enlarged left epididymus, the physical examination was negative. He had a temperature of 99.4° F. and a pulse that varied from 80 to 100. There was a slight trace of albumin in the urine, some red and white cells, but no tubercle bacilli. The blood examination showed a white count of 9,800 leucocytes with 77 per cent. polynuclears. On June 25 cystoscopy revealed nothing abnormal about the bladder. He catheterized the ureters and injected .006 ings. of phenolsulphonephthalein into the muscles of the loin and made the following observations: During the first hour several c.c. of urine were obtained from the right catheter which microscopically showed a few red blood cells. There was a positive guaiac test. From the left catheter only a few drops of clear fluid were obtained, which showed nothing microscopically and which was also negative to the guaiac test. The fluid obtained from the right catheter showed a calorimeter estimation of 55 per cent. of phenolsulphonephthalein (equal to the normal output in the one hour of two kidneys). The fluid from the left catheter showed no phenolsulphonephthalein reaction whatever. On July 3 the ureters were again catheterized and practically the same results were obtained as on the previous examination with the exception of a slight diminution of the output from the right kidney. Several radiographic plates made of the case failed to show the presence of calculus anywhere in the urinary tract, and, although the patient was relieved of pain by his rest in bed, and his urine upon chemical and microscopical examination was now negative, he was induced on account of the phenolsulphonephthalein findings to explore the left kidney, in spite of the fact that the subjective symptoms were referable to the right side. On July 3 he explored the left kidney through a left lumbar incision and found it very much enlarged, hardened throughout the greater part, and firmly adherent to the vault of the diaphragm and spleen. In attempting to separate the tumor from the surrounding structures some large tortuous veins were injured producing a profuse hemorrhage, and in order to facilitate the delivery of the tumor he converted his incision into a "T" incision and made a rapid resection of the twelfth rib. The pedicle, which was found to be very short, was ligated and the kidney and tumor removed. The tumor showed that the function of the kidney was almost completely destroyed by the hypernephroma. Three weeks later an irregular temperature occurred (from 102° to 104° F. in the evening) and pain was complained of in the right upper quadrant of the abdomen. The blood culture was negative, the Widal test was negative, and the examination of the urine showed only a few red and white blood cells. Under local anesthesia he made an incision through the upper portion of the right rectus muscle and with the aid of nitrous oxide made an exploration. The right kidney on palpation appeared to be enlarged; otherwise nothing abnormal was noted and the wound was immediately closed. Strange to say, the day subsequent to the operation the temperature dropped to normal and two weeks later the patient was discharged from the hospital. Dr. Goodman saw this patient a few days ago and found him feeling well and able to work at his trade. The phenolsulphonephthalein injection made its appearance at the end of 11 minutes, with 50 per cent. output the first hour, 20 per cent. in the second hour, a total of 70 per cent., which showed that the functional activity of the right (compensatory) kidney equaled that of two normal kidneys. The urine upon a most careful examination of a centrifuged specimen was found to be negative.

This case emphasized the value of ureteral catheterization, and particularly the value of phenolsulphonephthalein in determining in cases of this kind the advisability of operative procedures. The results obtained showed that the right kidney was performing the function of two kidneys, while the left had no functional activity at all. Had he been guided entirely by the history of this case and the subjective findings he would have been led to operate upon the right side rather than the left.

Dr. Otto Kiliani asked Dr. Goldman what were the indications for operation, and whether *x*-ray photographs and other methods of diagnosis were used. It struck him as being rather strange that a tumor of the size presented could not have been easily and readily felt.

Dr. Goodman, in answer to Dr. Kiliani's remarks, said that he thought that he was dealing with an enlarged spleen, the symptoms referable to the right side misleading him. He recalled an instance that happened some years ago in his practice; a woman was admitted to the hospital with the diagnosis of appendicitis and with symptoms referable to the kidney. The radiograph showed a calculus in the right ureter and several large calculi in the parenchyma of the left kidney. The injections of phenolsulphonephthalein showed that the left kidney was only functionating about one-half of what the normal kidney should and that the right kidney was not functionating at all. He exposed the right ureter and removed the calculus that was causing the obstruction. The kidney was very much distended and contained purulent urine. He, therefore, did a nephrotomy. The result was that the function of the remaining kidney was restored to normal. On the second day after the operation an injection of phenolsulphonephthalein was given and it was followed by a large return. The right kidney within

six weeks appeared to be perfectly normal. Three weeks after the right ureterotomy and nephrotomy he operated upon the left kidney and removed three large calculi buried in its parenchyma so that the greater portion of that organ was destroyed. Had he been led to operate upon this kidney first instead of restoring the function of the right the patient could not, in his opinion, have survived. The use of this drug was very helpful in determining whether or not the kidney was doing the work that it was called upon to do.

Reversal of Circulation by Arteriovenous Anastomosis of Femoral Vessels.—Dr. CHARLES GOODMAN presented this case. The patient was thirty-five years of age, a storekeeper, and had had excruciating pain and an impending gangrene of the leg, for which amputation had been advised. He had had similar trouble with the right foot three years previously for which an amputation below the knee had been done. The history of his present trouble extended back a year, during which time he had suffered acute pain, particularly at night, and in spite of large doses of anodynes and hypnotics he had obtained very little sleep. About six months ago an ulcer appeared on the tip of the great toe; the toe became very much swollen, and the entire tip appeared gangrenous. Shortly afterwards an ulcer appeared on the shin. These ulcers refused to heal. He gave the history of cigarette smoking so common to this class of patients. Elevation of the limb was immediately followed by blanching of the foot, and when the limb was suspended it would become very red and mottled. Pulsation could not be felt below Scarpa's triangle in either the popliteal, tibial, or dorsalis pedis; there was no edema. The urine was negative, and also the Wassermann test. The radiograph did not reveal a calcareous condition of the vessels. It was decided to give the patient the benefit of a conservative operation. He was admitted to Beth Israel Hospital on July 12 and five days afterwards was operated upon. The femoral vessels were exposed at the lower angle of Scarpa's triangle, and the femoral artery and vein severed about 1 centimeter, respectively, above and below the point of anastomosis. The proximal end of the femoral artery was then anastomosed to the distal end of the femoral vein, with a continuous circular Carrel suture; the free ends of the vessels were ligated. After the anastomosis was completed and serrefines removed, the vein became distended and could be seen pulsating synchronously with the heart beat. The wound was closed with catgut for the deeper cutures and silkworm gut for the skin. A long splint was applied. During the first twenty-four hours after the operation the temperature was 100° F. and the pulse varied from 80 to 100. The second day after the operation the patient said he was more comfortable than he had been for a year. On the fourth day the dressings were opened, and to their satisfaction they found that the ulcer on the shin had taken on a healthy appearance and was healing. At the end of ten days this ulcer which had resisted all forms of treatment had become completely cicatrized. The swelling of the great toe was diminished and it had taken on a more healthy appearance. Two weeks after the operation a slight edema was present and the limb became mottled in appearance. On August 10, nearly three weeks after the operation, it was found that the operative wound, which had only apparently healed by primary union, showed evidence of fluctuation, and the introduction of scissors was followed by a gush of clear serous fluid, which must have caused pressure on the vessels, for after it was evacuated the edema disappeared and the toe began to heal. The toe was now almost healed and the patient was able to get about without discomfort, and to sleep without anodynes or hypnotics. For the last three weeks he had been getting light massage and an emolient ointment to the toe. There was a distinct thrill and bruit heard over the area of the anastomosis. It was fair to presume that in this case the relief of the pain and the healing of the wounds which had resisted all other forms of treatment were evidences that the circulation was reversed by the anastomosis and that the general trophic condition of the limb was improved. The possibility of the reversal of the circulation had been questioned by such men as Gallois, Pinatello, Coenen, and Hauke. They based their contention on experiments performed on the cadaver. Dr. Carrel and Dr. Guthrie, on the other hand, had shown that in an end-to-end anastomosis of the femoral vessels in a dog the resistance offered by the valves was overcome and the circulation reversed in the course of three hours. The results obtained in a living human being spoke louder than the results of any number of experiments on the cadaver. The following points in the technique might be emphasized: 1. The operation should only be undertaken in carefully selected cases, and under absolute asepsis. 2. The wound in the vessels should be clean-cut and freed from adventitia. 3. The edges of the wound should be approximated without tension. 4. The vessels must be very delicately handled and this was only acquired by plenty of previous experimental work on animals and with the cooperation of a well-trained assistant. Dr. Goodman said that in his twenty years' experience in Beth Israel Hospital, Mount Sinai, and the Montefiore Home he had come in contact with almost every case of this kind in the city at one time or another. He had seen every therapeutic means imaginable used, and yet every one of these cases would sooner or later come to an amputation of either one or both limbs. This seemed to be the experience of every surgeon who had had the treatment of this class of patients.

Dr. RICHARD LEWISOHN said that he had watched this case presented by Dr. Goodman with a great deal of interest, having observed the case for many weeks after operation. He could not agree with Dr. Goodman in all that he said, although he thought that the report of this case was a very important and instructive one. When Dr. Lewisohn saw the patient on August 1 (one week after operation) the limb was still blue and there was no pulsation in the popliteal or dorsalis pedis vessels. This blue condition, together with excruciating pains, persisted until the end of August. The pains were of such severity that the question of amputation arose, and he was very glad that this was not done. The result obtained by Dr. Goodman he considered very good, indeed. There was one point which he considered to be of great interest and importance—in looking up the history he found that the femoral vein was clotted, at least two-thirds of it being taken up by a clot. He doubted whether the operation performed cured the man. There had been employed a conservative treatment for at least four months.

Dr. WILLY MEYER said that they had all seen patients with sometimes one side and sometimes both sides afflicted and there was the persistent excruciating pain day and night. In cases of diabetic gangrene not infrequently it was possible to preserve the foot and leg by exposure to hot air. A number of cases had been reported by men abroad where excellent results were obtained from this same operation. Dr. Meyer believed that the man had been much benefited by the operation, more so than he would have been from any other known procedure. He believed that by means of this anastomosis the patient had been cured. In his hospital service he would not hesitate to have recourse to this nice and impressive operation.

Dr. LUCIUS W. HOTCHKISS said that he had seen many of these cases and had himself amputated several extremities. In one case a study of the amputated leg showed an advanced neuritis as well as the vascular lesion, and there was such a terrific amount of pain that amputation was gladly accepted. He said he was much impressed with the operation done by Dr. Goodman and with his results. Many cases were met with at Bellevue Hospital, all Russian Jews, and were very hard to deal with.

Dr. COHN asked if anything had been done to determine the patency of the vein. In the cases with which he had dealt and where amputation was done changes were found in the veins as well as in the arteries. In the veins there occurred a thrombophlebitis.

Dr. KILIANI asked what good, assuming that the vein was occluded two-thirds, would result by anastomosing the artery and vein when the blood would not pass through.

Dr. LEWISOHN called attention to a case that had been reported by Davis in which there was a distinct pulsation in the popliteal vein.

Dr. WILLIAM HENRY LUCKETT said he failed to see why the blood flow was reversed for he did not believe it could be reversed all the way. Again, he could not see what the influence of cigarettes had on the production of this condition. Vaseline could be introduced into the tissues without any serious effect, or serous exudate being produced.

Dr. GOODMAN closed the discussion. He said the pathologists told them that, in these instances, the arteries were first involved and later the veins. When he severed the vein he found in front a large valve complicating the operation more or less. He cut off a little less than 0.5 cm. of tissue, which the pathologist reported to be a thickening of the wall of the vein. No clot was removed. With regard to the circulation, Dr. Goodman said he would not attempt to state with any positiveness what took place when the femoral vein and artery were severed and united. However, if this was done, why should the limb be alive to-day? In this patient all forms of therapy had been employed and without any relief; after the failure of medicines, a surgical procedure was employed and to-day the man felt very comfortable. With regard to injections of vaseline, sometimes this would cause trouble in spite of statements to the contrary. As to the reversion of the circulation, having no pulse below Scarpa's triangle, how else

could he get circulation without doing what he did? There was no possible collateral circulation because the arteries had become obliterated. During the nineteen years that he had come in contact with these cases he had tried every known form of therapy that had been suggested. He had kept these patients in bed; he had tried the use of hot air, he had tried various other methods, but none were of avail. Every case ultimately came to amputation. This patient he did not present as a cured case. However, it had been four months since the operation and the wounds had healed and the man was without pain.

Angulation of the Junction of the Hepatic and Common Ducts After Cholecystostomy, Simulating Common Duct Obstruction.—Dr. De Witt Stetten presented this case. The patient was nineteen years of age, married, and had a child five months of age. For two months previous to her admission to the German Hospital on July 20 she had had frequent attacks of cramp-like pain in the right hypochondrium radiating to both sides and to the right scapula. The severe attacks were accompanied with nausea and vomiting. She had lost considerable weight during the past three months; her appetite was poor and bowels constipated. Examination showed great tenderness and some rigidity of the right hypochondriac region. There was a slight subicteric line to the conjunctiva. The temperature was 100.2° F., pulse 84, and respiration 20. The diagnosis was subsiding cholecystitis and cholelithiasis. On July 24 an incision was made through the rectus muscle. The gall-bladder was slightly congested, but not thickened. It was opened and found to contain three stones, which were removed. The ducts were carefully palpated and found empty. An attempt to bougie the choledochus was unsuccessful. As the gall-bladder was not much diseased a cholecystostomy was done by inverting the opened fundus of the gall-bladder over a drainage tube by means of a Lambert pursestring suture. The gall-bladder was then fixed to the abdominal wall by several sutures. Gauze drainage was inserted below the gall-bladder. On August 1 the tube was removed and the bile drainage stopped promptly. There was a mucopurulent discharge. From August 9 to 16 the patient had attacks of colicky pain and became slightly jaundiced. On August 17, the gall-bladder was reopened and a profuse biliary discharge was found. This continued together with clay-colored stools, and a diagnosis of common duct stone was made. On August 24, the old wound was reopened and the contracted gall-bladder freed down to the cystic duct. There were no stones in the gall-bladder or ducts. The gall-bladder was removed and then the kinking of the hepatic choledochus angle was found. Through the stump of the cystic duct there was a split into the hepatic and common ducts. A probe could easily be passed into the duodenum. The hepatic ducts were probed and found to be free. A tube was inserted into the hepatic duct for drainage. Gauze drains were placed to the ducts, the wound closed, and the angulation of the junction of the hepatic and common ducts was dilated and also the hepatic duct. There was some reaction after the operation, which was followed by a prompt recovery. There was poor drainage through the tube, but the dressings were saturated with bile. On August 30, the tube and drainage were removed, the stools were well-colored, and the wound was healing well. The wound was closed by September 17 and on September 28 the patient was discharged cured.

Dr. Hermann Fischer reported the case of a woman who came into the German Hospital with an acute cholecystitis with an empyema of the gall-bladder due to biliary calculi. As the patient was old and rather decrepit a cholecystotomy was done with removal of the stones. The patient made a good operative recovery, but the biliary fistula did not heal, and acholic stools persisted. She also complained of pain. It was thought that a stone in the common duct was responsible for the condition. On performing laparotomy again it was found that the common duct did not contain stones, but a kink was found in the common duct, a condition almost identical with that described by Dr. Stetten. Although her condition seemed to be a rare one, one must be on the lookout for it.

At a meeting of the New York Surgical Society last spring a case was shown of rapid recurrence after interscapulo-thoracic amputation for sarcoma, and in the discussion it was stated that practically every case of interscapulo-thoracic amputation for sarcoma showed a recurrence or metastasis within one or two years. Dr. Douglas therefore wished to report this case as one free from recurrence of the sarcoma for six years, the patient dying as a result of operation for carcinoma of the stomach.

Dr. Lucius W. Hotchkiss believed that in these cases it was unnecessary to attach the gall-bladder to the parietal peritoneum. He spoke of one case in which he thought he had to deal with a kidney stone, which a radiograph clearly showed. He opened the pelvis of the kidney and found nothing there, and had then opened the gall-bladder through the same incision and there he found a stone. In this case as there was practically a normal gall-bladder, after removing the stone he had closed the incision and dropped it back into place.

Dr. Stetten closed the discussion and added that he did not lower the operating table because it never occurred to him that in this case there could be any question of tension on the gall-bladder and ducts. As to using the tube method and dropping the gall-bladder back into the abdominal cavity, he did not think that this was a method of choice, as there might be leakage and the possibility of contraction, though much diminished, was by no means entirely absent. He understood, however, that the Mayos used this method and were satisfied with it. He had always felt that stitching the gall-bladder to the parietal peritoneum was considered the most approved method of performing cholecystostomy.

Sarcoma of the Shoulder.—Dr. Otto Kiliani presented this case. The patient was a woman, thirty-one years of age, who was admitted to the German Hospital and Dispensary September 10, 1912. Her chief complaint was a painful discharging growth on the right shoulder with lumps in the arm-pit. Her present illness commenced five years ago with swelling at the junction of the right arm and shoulder. It was not painful, tender, or inflamed. After three months she went to Mount Sinai Hospital, where the tumor was removed. Here she received *x*-ray treatment, during which she sustained a slight burn. After three years there was a recurrence in the same place. She went to Bellevue, where this tumor was removed. She was then free for a year, when ten or twelve months ago a mass appeared in the axilla. About three months ago an open wound appeared over the tumor in the same location as the former *x*-ray burn. Communication with Mount Sinai Hospital elicited the fact that in June, 1908, an osteosarcoma of the right subdeltoid bursa was removed and that the patient left the hospital in a relieved condition. Physical examination was negative except for signs of a thickened pleura at the right base. Local examination showed at the base of the right shoulder a cauliflower-like mass about 4 cm. in diameter and raised about 3 cm. The surface of the growth was ulcerated and discharging. The entire axilla was filled with a large soft mass, hot and non-fluctuating. Just above this a smaller mass was continuous with it. Over the insertion of the short head of the biceps was another mass about the size of a hen's egg and slightly tender. All of these masses were slightly reddened and the surrounding tissues somewhat indurated. The upper end of the humerus was felt to enlarge gradually towards the head and was slightly tender on pressure. The spine of the scapula was also made out and found to be thickened. The diagnosis was osteosarcoma of the humerus and scapular with axillary metastases. At the operation on September 16, 1912, an incision was made along the clavicle and continued in front and behind the shoulder to a point in mid-axillary line about the level of the eleventh rib. The clavicle was divided at the junction of the inner and middle thirds and turned out. The axillary vessels were ligated and cut. The brachial plexus was injected with a 2 per cent. solution of novocaine and suprarenin and severed. The pectorals were cut away. A small extension of sarcomatous tissue was found in the pectoralis major. The muscles of the back were cut and the arm scapular and clavicle were removed *in toto* with the tumor. The skin was closed with silkworm gut, no plastic being necessary. The operation lasted one hour and ten minutes. The convalescence was uneventful except for slight temperature for about eight days, at no time going above 102.2° F. The pathologist's report showed that the growth was a spindle-celled sarcoma of the shoulder. The specimen consisted of a right arm amputated between the scapula and the thorax. In the upper extremity occupying the muscle and the greater part of the axilla the limb was much enlarged by a nodular growth which everywhere was covered by skin except at one place over the apex of the shoulder where it was ulcerated and protruded as a blackened polypoid mass. The parenchyma of the tumor was soft and crumbling; it appeared to infiltrate the fascial planes diffusely, rendering dissection of the parts impossible. The cancellous portion of the humerus, corresponding to the greater and lesser tuberosity was almost entirely eaten away, there remaining only a shell of bone on the outside. The spine of the scapula was also extensively eroded. The microscopical examination showed a small spindle-celled sarcoma. The cells were closely crowded together and separated by a minimum

amount of granular and, in some places, fibrillar intercellular substance. The nuclei were dense and chromatic and the cytoplasm scanty. Scattered throughout the tumor were found hemorrhages and diffuse areas of degeneration and edema.

Dr. CHARLES GOODMAN said that four years ago he presented a similar case in which he had obtained a brilliant cosmetic effect. Unfortunately at the end of eleven months the patient developed sarcoma of the lung and died four or five weeks later. Up to that time the patient had done very well, and had had an artificial limb applied. It had been his experience that sarcoma of the long bones, when operated upon, was almost invariably followed by sarcoma of the lung or some other viscus within a year after the amputation.

Dr. JOHN DOUGLAS said that he had reported a similar case five or six years ago and practically the same operation as performed by Dr. Kiliani was done. The patient had a sarcoma of the scapula. Two years after the operation there appeared a lump under the clavicle, a neurofibroma of the brachial plexus, which was removed. Two years later, four years after the original operation and amputation, the patient had an alcoholic gastritis which was followed by the vomiting of much blood. Last spring he returned, giving a history of having had occasional vomiting and difficulty in taking large quantities of food. The examination by means of the *x*-ray showed an hourglass stomach. At operation there was found a large, very hard callus on the posterior wall and lesser curvature of the stomach, the result of an ulcer. This was adherent to the pancreas and to practically all the tissues about this organ. The ulcer, which was believed to be malignant, was resected with a good part of the stomach; this called for quite an extensive operation as a result of which the patient died three days later. The pathologist reported that what was removed was a carcinoma. Six years later the patient died of a recurring sarcoma.

Dr. WILLY MEYER said that the case reported by Dr. Stetten was a very important one. In order to avoid such kinks it seemed avisable always to have the patient placed flat on the operating table again by lowering the lifter before stitching the gall-bladder to the abdominal wall. If it proved too small and short and ectomy was not indicated Gopper's inverting method around the tube was preferable. He always adhered to this method. If the gall-bladder walls appeared normal the ideal cholecystotomy was a commendable procedure. He had done this immediate closure of the gall-bladder by suture after the removal of the stones in three cases and had been very well satisfied with the result.

Dr. W. H. STEWART said that he made a diagnosis of osteosarcoma in the case presented.

Dr. KILIANI believed that he had obtained very good results in his case and that they should always have in mind the possibility of a recurrence of the sarcoma in the lungs.

Demonstration of Methods in the Treatment of Simple and Complicated Fractures of the Jaw.—Dr. H. J. KAUFFER presented eight cases of fracture of the jaw, demonstrating the methods of treatment with splints on plaster casts and lantern slides showing *x*-rays and photographs of the patients. The interdental cap splints exhibited were worn in all cases where the fracture was in the mandible forward of the last remaining sound tooth in the lower jaw. Where the fracture was in the body of the bone, distal to the last remaining tooth, in the ramus or condyle, and immobilization of the temporomaxillary articulation became necessary, inter-wiring or intra-wiring according to the essayist's method was employed.

CASE I.—This patient was a male, 24 years of age, who had suffered a gunshot wound. The bullet entered in the region of the temporomalar canal on the right side, passed through the superior maxilla, and out through the left cheek at a place that could be described by a circle, the diameter extending from the distal border of the cuspid tooth to the maxillary tuberosity. *X*-ray plates showed that the bullet, being one of large caliber, mushroomed out as it passed through and deposited numerous splinters of lead throughout the entire tract, carried away about two-thirds of the superior maxilla, and destroyed more than half of the roof of the mouth. A plastic operation almost restored the roof of the mouth, and at the same operation all lead was removed, as shown by the *x*-ray plates. Considering that there were no solid bony segments with a fixed facial attachment in the upper jaw to which to fasten a splint, and that the period of cicatrization lasted over three months, the apparatus which he had devised for this case was unique in its simplicity and hygienics; it did not immobilize the temporomaxillary articulation; it held all the fractured segments in their proper anatomical relation, so that when osteogenesis was complete there was no deformity; the contour of the face was normal and there were no appreciable scars. The apparatus also being within the mouth, the patient was able to go about without embarrassment during the period of cicatrization.

CASE II.—This patient was a male, 34 years of age, who had suffered a fracture of the mandible at the symphysis. The *x*-ray showed comminution of the bone at the point of fracture, which necessitated the removal of the bone for the width of and including two incisor teeth. The interdental cap splint used in this case permitted the free use of the jaw and a semi-solid diet. The *x*-ray showed a good line of union, teeth articulating, and contour of the chin normal. The patient presented no facial deformity.

CASE III.—This patient was a girl, 4 years of age, who had sustained a fracture of the mandible. The crepitus was appreciable, but there was no displacement. The *x*-ray showed that the fracture extended through the mental foramen. The periosteum being only slightly torn held the fracture in apposition. No surgical interference was indicated and union took place without splint or bandage. Later the patient presented herself with an induration in the chin. The *x*-ray disclosed that a germ of an incisor tooth which was dislodged at the time of fracture was growing in the soft part of the chin. This case was cited as a curiosity.

CASE IV.—This patient was a boy, 12 years of age, who was run over by an ice wagon and sustained a fracture of the mandible between the cuspid and first bicuspid tooth. The interdental splint was inserted and the *x*-ray showed that good union took place with the teeth in good articulation. Deep laceration severed the malar and infraorbital branches of the temporofacial division of the facial nerve. The ultraviolet ray was employed and nerve anastomosis followed so that the patient now presented a cure.

CASES V, VI, and VII presented fractures of the mandible distal to the last remaining sound tooth. They were treated by wiring sufficient lower teeth to upper ones to secure fixation. Union took place with the teeth in normal articulation and there were no deformities.

CASE VIII.—This patient was a woman, 42 years of age, who had a multiple fracture of the mandible and superior maxilla. In the upper jaw the incisor teeth with a large segment of bone were fractured away from the body of the maxilla. The fractured portion was displaced outward and upward. There were seven fractures in the mandible. The incisor teeth with the alveolar process were torn away from the body of the bone. A fracture extended through the symphysis, there were two distinct fractures in the region of the second molar tooth, and one at the angle on the right side. On the left side there was a fracture through the angle and one which separated the condyle from the ramus. This case was treated by intra-wiring. Only one hole was drilled through the bone. The *x*-ray showed that there were two wire sutures passed through this hole, looped and twisted around the upper and lower teeth in such a manner that all the fractures in the upper and lower jaw were brought into apposition. Union took place without the slightest deformity; all the incisions for wiring were made inside the mouth.

Dr. KAUFFER expressed his appreciation of the *x*-ray work done for him by Dr. W. H. Stewart.

Dr. WILLY MEYER said that he admired Dr. Kauffer's perseverance and ingenuity in the treatment of these cases of simple and complicated fractures of the jaw; much time and much work had been spent by him on the study of these fractures and the result was that the patients had been left in such good condition; in short, the results obtained were fine. In complicated cases the surgeon could make an incision over the edge of the mandible and wire the fragments. Personally he would send these cases hereafter to Dr. Kauffer.

The "Gwathmey-Woolsey" Nitrous-Oxide and Oxygen Apparatus for General Surgical Work.—Dr. J. T. GWATHMAY presented and described this apparatus.

Arthritism and Anaphylaxis.—J. Galup defines arthritism as an anaphylactic diathesis caused by slight repeated intoxications chiefly of alimentary origin. Arthritism may be transmitted in the direct or collateral family line. It includes a large number of morbid phenomena. It manifests itself in definite modes of tissue reaction, such as nervous hyperexcitability, the response occasionally to minimal causes, the paroxysmal character of the attacks, and their interchangeability in the same subject. Other characteristics of this diathesis are the tendencies to congestions and to sclerosis.—*La Presse Médicale*

THERAPEUTICS, MATERIA MEDICA AND PHARMACY. By SAMUEL O. L. POTTER, A.M., M.D., M.R.C.P. 956 pages; cloth; price $5.00 net. Twelfth Edition. P. Blakiston's Son & Company, Publishers, Philadelphia.

INTERNAL MEDICINE. By DAVID BOVAIRD, Jr., A.B., M.D. 618 pages, with 109 illustrations in the text and 7 colored plates; cloth; price $5.00. J. B. Lippincott Company, Publishers, Philadelphia.

MAKING GOOD ON PRIVATE DUTY. PRACTICAL HINTS TO GRADUATE NURSES. By HARRIET CAMP LOUNSBERY, R.N. 208 pages; cloth; price $1.00 net. J. B. Lippincott Company, Publishers, Philadelphia.

DER KOHLEHYDRATSTOFFWECHSEL UND DIE INNERE SEKRETION. By Dr. PAUL HOCKENDORF. 120 pages; paper; price 2.40 M. August Hirschwald, Publisher, Berlin.

SELECTED PAPERS ON HYSTERIA AND OTHER PSYCHONEUROSES. By Prof. SIGMUND FREUD. Second Edition. 215 pages; paper; price $2.50. The Journal of Nervous and Mental Disease Publishing Company, Publishers, New York.

Miscellany.

Shakespeare's Allusions to Syphilis.—Sir Henry Morris states that there is ample evidence that during the Tudor and the Stuart and Commonwealth periods of English history syphilis was rampant in England as well as in France and Italy. It is sufficient for proof to quote Shakespeare in regard to the first, and Wiseman in reference to the latter periods. The word pox reminds one of the frequent use Shakespeare made of it. It occurs at least four or five and twenty times collectively, in fifteen of his plays. He used it as a curse, or an imprecation of impatience or evil. Thus, Iago says to Roderigo, who talked of drowning himself: "A pox on drowning thyself." Sir Andrew in "Twelfth Night," referring to a certain knight who was a celebrated fencer, says: "Pox on't, I'll not meddle with him." In "Measure for Measure," Barnardine in his prison exclaims:

"A pox on your throats! Who makes that noise there?"

In "Love's Labor Lost" we find even ladies of quality—ladies in attendance on the Princess of France—making similar exclamations, such as, "A pox of that jest!" In "All's Well That Ends Well" a French lord in a camp near Florence says of a soldier: "Let him fetch off his drum"; and he is answered by another French lord:

"A pox on't, let it go, 'tis but a drum."

In "Two Gentlemen of Verona" the servant of one of the gentlemen says to him of the other: "A pox of your love letters." In "Henry IV," in "Hamlet," in "Cymbeline," in "The Tempest," and other plays there is similar employment of the word, which is equivalent to the "Damn," or "Damn it" of the present day. This use of the word seems to prove conclusively that syphilis was very common in Shakespeare's day, and that the constitutional and local symptoms of the disease must have been quite familiar to the man in the street and to the ordinary person in society. It is quite obvious from the context of several of the passages in which the word occurs that it was the great-pox and not the small-pox which had given it currency and to which allusion was made. For example, in "Pericles, Prince of Tyre," the virtuous Marina, the daughter of Pericles, who had been taken captive by pirates and sold to a brothel keeper, is cursed in the following manner by a Pander of the Bawd, for not yielding her honor on the solicitation of the customers: "Now the pox upon her green sickness for me!"; and the Bawd replies to him: "Faith, there's no way to be rid on't but by way to the pox." Shakespeare was quite alive to the pains of periosteal nodes, to tendon gummata, to ozena, to the loss of hair, to the voice changed by syphilitic laryngitis, and to the sallow, withered look of the skin of the face in late syphilis. He speaks of "a pox of wrinkles," and the makes Timon tell Phrynia and Timandra, in language which shows a considerable knowledge of the characters of secondary and tertiary syphilis:

"Consumption sow
In hollow bones of man; strike their sharp shins,
And mar men's spurring. Crack the lawyer's voice,
. . . . . down with the nose;
Down with it flat; take the bridge quite away
Of him, that his particular to foresee
Smells from the general weal; make curl'd-pate ruffians bald;
And let the unscarred braggarts of the war
Derive some pain from you. Plague all;
That your activity may defeat and quell
The source of all erection."

—*Proceedings of the Royal Society of Medicine*, October, 1912.

The Successful Doctor in the Seventeenth Century.—Bernier, in his *Histoire Chronologique de la Médecine* (Paris, 1695), gives a summary in verse of the whole duty of medical man. The doctor who aspires to success, he says, must not be modest, but must do all he can to push himself forward, talking confidently with his brethren. He need not bother about further study, but should use every effort to establish useful connections. For introduction into families women are useful. Fashionable ladies, devout women, coquettes—all should be conciliated. Every one, even the meanest servant, should be cultivated. The young doctor should bring all his science to bear on satisfying fools. Let him remember that what one says of him another will repeat, and it is from this gossip that celebrity springs. To get the reputation of having much business he must take care not to be found at home; when he is in bed, let his servants say that he has been called out to a case. Let him give out that he has to be up whole nights; that the longest days are too short for him; that he is called everywhere; in short, that the practice so much sought for by others comes to him against his will and overwhelms him. Even when his trouble is poorly paid, he should speak of the big fees that are forced upon him for a visit. This hint scattered among good friends may wake up those who are asleep. The young doctor should dress as much like a man of fashion as possible that he may gain the good graces of the ladies. In the street he should bow to one side and the other, courteously saluting every one he passes. He may ride in a chariot or be carried in a chair; two carriers in the street attract much attention. Let his successes be attested by dukes and marquises. Everything, it is urged, that can advance one's interest is legitimate; even self-praise is allowed. If some parts of this exhortation remind one of the arts of Mr. Robert Sawyer, late Nock'emorf, one has the satisfaction of knowing that at the present day the arts which were considered necessary to success in medicine in the seventeenth century are extinct. The puff, direct and oblique, self-assertion, subtle detraction, intrigue, and the whole art of scheming to attain the lofty ideal *monstrari digito et dicire, Hic est*—of course all these things are unknown in this age of professional probity, or at any rate are condemned by all high-minded practitioners as obsolete and dishonorable.—*British Medical Journal*, November 23, 1912.

Rich Man's and Poor Man's Gout.—F. W. Langridge notes that in talking of cases of arteriosclerosis and cardiac pain associated with the toxemic conditions which give rise to heightened arterial tonus, Alexander Morison says: "It calls for treatment by the recognized diet and regimen. The wealthy, overfed, and idle might do worse than follow Abernethy's advice to such a patient, namely, to live on sixpence a day and earn it, with a little balneological treatment thrown in by way of consolation for their temporary and exemplary self-denial! 'Poor man's gout' is usually a consequence of the excessive imbibition of malt and other alcoholic liquors, taken to enable him to cope with the excessive labor which is generally his lot, or to procure for him a transient exhilaration and oblivion in his struggle for existence. The treatment of this condition is educational and political rather than medicinal, although in *statu anginoso* the measures which are found to relieve Dives will also be of benefit to Lazarus. A touch of colic makes the whole world kin.'"—*The Clinical Journal*, September 11, 1912.

MARGINAL SOUNDS IN THE DIAGNOSIS OF PULMONARY TUBERCULOSIS.

By G. E. BUSHNELL,

COLONEL MEDICAL CORPS U. S. ARMY.

MARGINAL sounds are sounds heard at the base of the lung during deep inspiration. The writer has already discussed the subject in a previous paper[1] which, so far as it relates to marginal sounds, is to be considered as a preliminary study to the present communication. Reference is made to that paper for an account of the work of other writers. Before considering marginal sounds in the diagnosis of tuberculosis, it is desired to submit some anatomical and physiological facts which have a bearing upon the theory as to the causation of these sounds, and also for the convenience of the reader, a brief résumé of some of the experimental results which were reported in the earlier paper as well as two hitherto unrecorded experiments.

The following account of the anatomy and physiology of the pleural sinus is condensed from Gerhardt.[2] The lower margin of the lung forms a line running at nearly equal height about the thorax. At the mammillary line it is at the upper border, at the axillary line at the lower border of the seventh rib. Between the lower lung margin and the bottom of the pleural sac the pleura diaphragmatica and the pleura costalis lie in contact with one another over a surface which, according to Luschka, amounts to 2 cm. in the parasternal line, to 4 cm. in the mammillary line, to 9 cm. in the axillary line, and to 3 cm. beside the spine. This complemental space, as Gerhardt has named it, is filled in deepest inspiration so that the lung margin thrusts itself between the leaves of the pleura to their point of transition in front and behind; in the axillary line, however, only when the subject lies horizontally upon one side and breathes as deeply as possible does the lung margin (of the upper side) descend to the lower limit of the pleural sac, fill completely the complemental space and give a clear, full sound on percussion to within 2½ cm. of the costal arch.

According to Leichtenstern, quoted by Gerhardt, the excursion of the lung margins from the position of rest may be increased in expiration above that of inspiration, but often only after repeated practice. Usually there is greater mobility for inspiration than for expiration. The importance of active expiration for the production of maximum differences between expiration and inspiration is not always appreciated. Persons who have acquired great mobility of the thorax accomplish this by learning to increase the force of expiration. Men whose occupations require vigorous and continued use of the respiratory organs learn instinctively to expel the air forcibly in expiration. The wood chopper breathes out with an audible grunt as his axe descends upon the log, and is able to continue his exertions indefinitely, while the tyro is breathless after a few strokes. Becker has shown that the capacity for maximal emptying of the lungs is more than usually well developed in the players of large brass instruments.

Donders assumed a perfect elasticity of the lungs. Tendeloo,[3] however, has shown that the lung, not being a homogeneous organ, is not perfectly elastic. It returns only after an interval to its position of rest after maximal distention. It results from this fact that repeated distentions of the lung lead to an increase in its volume, temporary if the distentions are few in number, more lasting if the distentions are frequently repeated over a considerable time. Raither[4] quotes Durig, who found an increase in lung capacity immediately after a mountain trip, which disappeared in two days, and Hasselbach, who caused his servant to practice with the spirometer daily, determined the lung capacity and found that it was increased by 500 c.c. after a half-year, but that it soon returned to normal after discontinuance of the exercises. Similar observations have been made on men training for athletic exercises.

The object of the complemental space manifestly is to permit expansion of the lungs, not only temporarily during violent exercise, but during the continuance of conditions that put a strain upon the respiratory apparatus for periods of some length, the increase in lung volume being necessary to provide the larger respiratory surface requisite for the increased needs of oxygenation.

It follows from the foregoing that continued deep respirations will result in a distention of the lung unless the individual actively employs the expiratory muscles and thus equalizes the force of the two portions of the respiratory act.

Hofbauer and Holzknecht,[5] studying by means of the *x*-ray the changes of position and extent of the excursions of the diaphragm in various postures of the body, found that the arch of the diaphragm stands the highest in the dorsal decubitus, the lowest in sitting, and in standing has an intermediate position. Also that the excursions of the diaphragm are the greater the higher its position. When the subject lies upon the side, the half of the diaphragm upon the dependent side has a maximum elevation and makes large excursions. The upper half has a maximum depression and makes almost no excursion. This they explain by the fact that since the abdominal organs on account of their movability practically obey the laws of hydrostatics, their weight exercises a pressure upon the diaphragm in the dorsal decubitus which disappears in the erect position. This pressure varies for the two halves of the diaphragm in the

lateral recumbent position, being very large for the lower, very small for the upper half. The excursions of the diaphragm are the greater the more it is pressed passively upward, because the dome is the insertion of the muscle, and the movable insertion of a muscle acts with the greater amplitude of movement and greater force the farther it is removed from the point of origin.

Marginal sounds are best studied over the flexible thorax of a young and vigorous man. Mark the level of forced expiration and of deepest inspiration at the anterior axillary line. Instruct the subject to inspire deeply, but not very rapidly, and to breathe out as forcibly as possible in expiration. During inspiration numerous crackling sounds or sounds of a moister quality resembling closely medium sized or smaller moist râles are heard over the entire surface between the levels determined. The sounds are heard at the beginning of inspiration immediately below the line of forced expiration, at the close of inspiration immediately above the line marking the level of fullest inspiration. They are heard but once at a given level during a single inspiration. They follow the shadow of Litten downward and are heard only as this shadow is passing the point of auscultation, and may be obtained simultaneously along the line of this shadow by two observers over different intercostal spaces.

Attach the bell of a stethoscope to each of the two rubber tubes of a binaural stethoscope, and closing the free arms of the bells with the thumbs place the bells over the pleural sinus, one bell slightly below the level of expiration, the other slightly above the level of inspiration. Auscultate during a deep inspiration, and if marginal sounds are present and the inspiration is not too rapid it will be distinctly apparent that the crackles are heard first by the ear connected with the upper bell and only a moment later by the other ear.*

These observations establish beyond doubt the fact that the marginal sounds are developed only in a single line advancing from above downward during inspiration. Since they are never heard above the expiratory level and continue down nearly if not quite to the inspiratory level of the lung, the place of their production can be no other than the inferior margin of the lung. If the subject succeeds in following instructions so that the force of expiration equals that of inspiration, the sounds continue indefinitely with their original force. More usually, however, they become more and more faint and finally disappear. In this case, if the levels of inspiration and expiration are determined as before, it will usually be found that both the level of inspiration and of expiration have descended. Direct the subject to breathe out as fully as possible and to breathe in as little as possible, and it will be found after a few respirations of this kind that the former levels have been regained and that when deep respirations are again resumed the marginal sounds have returned. These results can only mean that the production of marginal sounds is dependent upon a free movement of the diaphragm and ceases when a preponderance of inspiration over expiration has caused the lung to become over-distended so that the diaphragm can no longer move freely. In other words, marginal sounds occur in the healthy lung during every deep inspiration if efficient contraction has taken place in the preceding expiration. Marginal sounds may be heard at all points around the base of the lungs. They are heard with more regularity over the base of the right lung because a distended stomach may interfere with the free movement of the diaphragm on the left side. They are loudest in the axillary line, the reason of which, of course, is that the complemental sinus is here deepest.

*The writer is indebted to Dr. E. H. Bruns, U. S. Army, for this experiment.

The marginal sounds when perfectly developed constitute a striking phenomenon. But it must not be expected that the results described will be readily attained even in all athletes. Stupidity and nervousness often constitute a barrier to effective breathing during examination. It may be of assistance to cause the subject to blow noisily during expiration or to cough at the end of the expiratory act. But we shall always find, among sick and well persons, a certain proportion of poor breathers who breathe the worse the more their attention is directed to the act. In such cases the marginal sounds may not be heard at all, or if heard cannot be brought back after disappearance. The absence of marginal sounds, therefore, in cases in which they might be expected, is of no value in diagnosis.

It remains to inquire how marginal sounds are affected by posture. A subject upon whom marginal sounds have been demonstrated while standing is caused to lie upon a high couch provided with an aperture so placed that the dependent portion of the thorax is accessible from below when the subject lies upon his side. Determine the level at rest of the base of the lung upon the superior side. It will have descended one-half to one inch below the level previously marked in the erect position, while the inferior lung will have ascended approximately half an inch. This demonstration is only successful when the body is not bent laterally. If the thorax is permitted to descend to fill the aperture of the couch, the relation of the parts is so changed that alteration of the lung level cannot be made out. The findings on the superior side are less affected by slight changes of posture. When the subject takes a deep inspiration the level of the base of the lung descends about two inches lower on the superior than upon the inferior side, and the complemental space is resonant almost to the costal arch. Examine for marginal sounds on the superior side and it will be found that they have, as a rule, disappeared, being present only in the most vigorous breathers and in them much diminished in loudness, while examination of the dependent side shows that they are present with sometimes increased intensity. If the subject turns to the other side the findings are reversed, the marginal sounds disappear in the formerly inferior now superior side, they are present in a marked degree on the other side.

Morrison[6] describes these peculiarities of the marginal sounds in the lateral recumbent position under the name of "reversible crepitations." He considers the cause of the crepitations to be a passive hyperemia of or an exudation into the alveoli and smaller bronchi dependent upon weakness of the heart. Our results, however, were obtained with exceptionally vigorous young men.

The fact that marginal sounds may be increased in intensity on the dependent side agrees with the observation of Hofbauer and Holzknecht already cited, that the dependent half of the diaphragm is pushed up by pressure of the abdominal viscera, for the greater separation of the insertion of that

muscle from its origin pointed out by him affords a better opportunity for the efficient contraction which is requisite for producing marginal sounds most distinctly. The abdominal viscera doubtless fall toward the inferior side in all cases. Whether they exert much or little pressure on the lower half of the diaphragm will, it is thought, depend upon the degree of relaxation of the abdominal wall and upon the precise position of the subject. Holzknecht states that the pressure of the abdominal viscera upon the upper half of the diaphragm is very small. But our observations show an actual descent of the margin of the superior lung. This can only be accounted for by the supposition that the viscera in their descent toward the lower side of the abdomen exercise no pressure upon the upper half of the diaphragm, but instead a suction which causes the low level of the diaphragm noted by Holzknecht, and the descent of the lung margin determined by us by percussion. The superior lung is passively distended to fill the vacuum produced by the displacement of the viscera. Though capable of filling the complemental space, the superior lung in its respiratory inflation moves through a comparatively small distance and marginal sounds are producible with difficulty or usually not at all. The "reversible" marginal sounds of the lateral position thus furnish an interesting corroboration of the theory advanced to explain the phenomena attendant upon their production in the erect position. They are present if the lung can expand freely in inspiration, absent if it cannot.

As for the causation of marginal sounds, being a physiological phenomenon and strictly confined to the extreme margin of the lung, the only possible explanation of their production is that they are in some way connected with the progress downward of the lung margins. It has been shown in the preceding paper that marginal sounds generally occur with Litten's phenomenon. Sahli's[7] explanation of Litten's phenomenon is undoubtedly the correct one. "As the diphragm in its descent begins to peel off from the thorax it exerts a suction upon the intercostal spaces just below the margin of the lung. This produces the shadow." The fact that the soft parts of the thoracic wall are depressed during inspiration, thus producing the shadow of Litten, proves that, as might be expected, the apposed moist surfaces of the diaphragmatic and costal pleura offer some resistance to their separation. The "peeling off" of the diaphragm tends to create a vacuum which the pressure of the atmosphere fills by indenting the soft parts of the intercostal spaces. But the resistance soon gives away and sounds are produced as the moist surfaces are torn apart which are the marginal sounds. It is evident that the more suddenly and forcibly the separation of the pleural leaves is effected, the more marked will be the preliminary depression and the louder the marginal sounds. This is corroborated by the fact that the production of Litten's shadow and of marginal sounds both depend upon a vigorous inspiration.

Marginal sounds in the vigorous breather resemble rather loud, dry crackles. In persons who breathe less forcibly they are more like moist râles, fine or medium coarse. While other writers may not make just this distinction, it is evident that variation must exist in the quality of these sounds, for they have been likened to dry crackles, moist râles, crepitant râles, and friction sounds. Cabot states that after the age of forty-five it is unusual not to find marginal sounds. It has appeared to the writer from examination, it must be admitted, of comparatively few cases of persons beyond that age that the sounds are relatively dry, resembling crackles rather than moister sounds. This would be most obviously explained by a relative dryness of the pleural surfaces resulting in a slight "tackyness," and hence a crackling sound when those surfaces are pulled apart. But the same quality has been noticed in the young if the inspiration is forcible. Is there any relation between rapidity of separation of the pleural leaves and the "dryness" of the resulting sounds? This question, in the writer's judgment, may be answered affirmatively, for the following reason: The pulmonary margin must, of course, always remain closely applied to the angle formed by the free portion of the diaphragm with the costal pleura and must, therefore, in rest have the same amount of lubricating moisture. Now, the great expansion which takes place in the lower lobe during deep inspiration leads to a relative dryness of its pleura because the same amount of moisture is necessarily distributed over a much more extensive surface. The margin of the lung, therefore, becomes drier as it expands, and being constantly drier because constantly expanding drinks up, as it were, the moisture at the juncture of the pleural leaves which would otherwise permit the separation of the apposed surfaces with sounds resembling moist râles, and produces instead a series of drier, more crackling sounds. Hence, the more powerful the inspiration the drier, and, therefore, the louder the sounds, and the more they resemble as respects quality those produced in the chests of persons of advanced years.

Marginal sounds have been interpreted in every conceivable way, but almost without exception as a morbid phenomenon. They have been considered a sign of tuberculosis of the bronchial glands, of apical tuberculosis, of dry pleurisy, of marginal pleurisy excited by an accumulation of infectious fluids which escape from apical lesions and collect in the pleural sinus, as relics of former pleurisies or influenzas, as due to the presence of mucus aspirated into the lung margin from above, as a sign of atelectasis, which atelectasis has been ascribed to compression of the base of the lung by the bending of the body forward, as in mechanics, or to disuse of the lung margins in the obese and the bed-ridden. The uncritical way in which these sounds have been declared without adequate examination or proof to indicate this, that or the other morbid condition is a rather melancholy exhibit. Many of the items of the above no doubt incomplete list need not be taken seriously. The one unanswerable argument against all these suppositions is that marginal sounds are best elicited in the most vigorous specimens of mankind. Still something may be gained by a consideration of these sounds in connection with the diagnosis of pulmonary tuberculosis, the allied condition of pleurisy and the supposedly allied condition of atelectasis of the base of the lung.

It has been held that marginal sounds bear some direct relation to early apical tuberculosis, and that they are heard only on the affected side. The experience of the writer, however, convinces him that in small apical lesions, whether those of initial or arrested tuberculosis, marginal sounds are produced practically to the same extent as in health.

But when the disease involves any considerable portion of the upper lobe, it is found that while present on the healthy side, the marginal sounds are often heard more easily over the base of the affected lung, and, moreover, that they are generally evanescent.

According to von den Velden[8] the anatomical cause of what he calls "a fine, small equal râle very similar to crepitations (Knisterrasseln)," occurring at the base of the lung at the end of inspiration is a pure marginal atelectasis. Citing as extreme cases the atelectases demonstrated by Traube as the result of upward pressure from abdominal affections, von den Velden goes on to say that "there is a series of gradations which depend on a more or less restricted power of excursion of the ribs and diaphragm. If this excursion is wanting or lessened the inspiratory expansibility of the lungs suffers, especially those parts affected by the first respiratory widening of the thorax, *i.e.* the margins. Clinical observation finds them (the atelectases) between the mammillary and axillary line because this part normally has the greatest capacity for mobility and accordingly must first become atelectatic." He finds the marginal sounds absent in patients with strong and frequent cough in which cases "there is ventilation of the margins," also in "the so-called compensatory emphysema of the lower lobes." He finds marginal sounds present in 60 per cent. of cases of apical tuberculosis. He thinks the sounds depend upon a pure marginal atelectasis and that their cause is a diminished activity of the diaphragm. Aside from the superficial breathing of the phthisical, the reflex arrest of the movement of the affected side and stomach and intestinal troubles as causes for defective breathing, marginal sounds in apical tuberculosis of the same side are, he says, in many cases to be regarded as the auscultatory equivalent of Williams' phenomenon. De la Camp could only demonstrate an exactly measurable inspiratory retardation of the diaphragm in one-third of his cases, whereas von den Velden's 60 per cent. of cases with marginal sounds shows, he thinks, the marginal sounds the finer test. Williams' phenomenon is defined by Oestreich and De la Camp[9] as a sign of incipient phthisis, consisting in diminished or absent excursions of the diaphragm of the affected side in inspiration, the diaphragm of both sides appearing alike in the position of expiratory rest. That is the diaphragm of the diseased side lags in inspiration. De la Camp ascribes the phenomenon to paralysis or paresis of the phrenic nerve implicated in pleuritic processes where it passes over the dome of the apical pleura. The more usual explanation of Williams' phenomenon is that it is due to loss of elasticity of the lung through disease of the upper lobe. When the upper lobe is the seat of a fairly well-marked tuberculous lesion or is more or less fixed by pleural adhesions it has lost a material portion of its elasticity, it no longer expands as readily as the healthy lung. Hence, during ordinary respiration, the healthy lung assumes part of the work of the diseased lung. This is, therefore, habitually more distended and the diaphragm may occupy a lower level on this than on the diseased side. But if the lower lobe is not involved in the disease and there are no pleural adhesions over it, the diseased lung is still capable of fairly full expansion, though such expansion is only possible with greater effort than formerly and takes place chiefly at the expense of the lower lobe. The lower lobe having an excessive function to perform quickly becomes over-distended during deep breathing as ordinarily practised. The diaphragm which at first descended fully during inspiration and in so doing was instrumental in producing marginal sounds abundantly, soon finds its movement checked, the over-distention, the temporary emphysema, of the lower lobe prevents the collapse of the lung in expiration which is necessary if the lung is to move freely in the succeeding inspiration, and marginal sounds are no longer producible. Hence the initial abundance of the marginal sounds and their speedy disappearance. On the healthy side, the lung being relatively over-distended at the beginning of the examination, is capable of producing marginal sounds, but with less distinctness than the diseased lung at the outset because the lung has a larger volume at the beginning of inspiration. The law of production of marginal sounds in the condition under consideration is thus seen to be the same as in health. That lung is best capable of producing marginal sounds which can expand most freely in inspiration. Marginal sounds then are the equivalent of Williams' phenomenon in so far as the presence of disease of the upper lobe tends to diminish the use of the lung in ordinary respiration and thus make certain that when it is called upon for deep inspirations there will be no over-distention to prevent its free expansion.

The correctness of the view set forth above can be easily demonstrated, for the marginal sounds of the tuberculous lung may be brought back after their disappearance and the marginal sounds of the healthy lung may be increased in distinctness by the same expedient as that already described, *i.e.* by causing the patient to exhale during several expirations more strongly than he inhales. This procedure is not, however, to be recommended in the presence of active and extensive tuberculosis.

It has been said that marginal sounds are absent in advanced tuberculosis. They will, however, be found present more frequently than is generally supposed, if they are sought for at the beginning of the examination; in other words, they are often evanescent rather than entirely wanting. But excessive coughing, if it leads to a distention of the lung margins, prevents the occurrence of marginal sounds, and they are, of course, absent in the case of pleural adhesions over the lower lobe or of advanced tuberculosis of that lobe, conditions which prevent the necessary free expansion of the lung. On the other hand, the presence of marginal sounds is a proof of the absence of extensive adhesions and of advanced tuberculosis of the base.

For those who consider all sounds resembling râles as pathological there exists the manifest danger that marginal sounds may be interpreted as evidence of an extension to the base of a tuberculous process in the upper lobe. And the opinion which has been expressed that tuberculosis of the lower parts of the lung occasionally runs a benign course probably arises from the misinterpretation of marginal sounds. It is well known that sparse miliary foci occasionally become fibrous in this location, and it seems to be true that tuberculosis of the lower lobe of greater extent pursues at times a sluggish (hardly a benign) course, provided that the lung is restrained from movement by pleural adhesions. Tuberculous lesions of the base of any considerable extent are never benign if such adhesions are absent or are inadequate to check respiratory movements. The diagnosis of a benign

tuberculosis of the base in a case in which the lung margin is freely movable should, therefore, be looked upon with suspicion. If the auscultatory signs are due to marginal sounds they may be recognized as such by the aid of the criteria already mentioned. On the other hand, if the lung is bound down by adhesions, sounds heard at the base are not marginal sounds. The accurate determination of the mobility of the lung margins and of the range of the respiratory movements is, therefore, of much importance in the study of early basal tuberculous lesions.

Pleural friction sounds are distinguished from marginal sounds by their occurrence above the level of forced expiration in the individual case, by their presence in expiration as well as in inspiration, usually by the character of the friction sound. In pleurisy there is to be expected a lessening in the vigor of the inspiratory movements. The pleural friction sounds will usually be heard in cases in which the respiratory excursions are slight, the marginal sounds in cases in which they are ample. The marginal sounds are evanescent, but may be brought back by deflation of the distended lung, pleural friction sounds are more constant. Attention to the position of the lung margin at the time when the sounds are heard will often serve to discriminate marginal from friction sounds. Thus sounds heard toward the close of an inspiration at a point above the position of the lung margin at the moment cannot be marginal sounds. In short, what might be called the obedience to fixed laws of the marginal sounds affords the best criterion by which to distinguish them from signs of disease.

Koll[10] has described a sinus pleuritis in which the symptoms were abdominal, the signs thoracic, the latter consisting in a fine friction sound heard "during the second half or at the height of a deep inspiration and at the beginning of expiration" and limited to the pleural sinus. The diagnosis was in no case confirmed by autopsy, and the friction sounds as described by him are practically identical in their mode of occurrence with marginal sounds. It is interesting to note that at the beginning of his investigations Koll raised the question whether the sounds heard were not physiological sounds, and even considered the hypothesis that they might be due to the unfolding by the intruding lung surfaces of the damp pleural surfaces which lie upon one another in ordinary breathing. But he rejected this idea after examining a large number of other patients because though he sometimes heard fine "pleural crackles" they always disappeared after one or two deep breaths, the evanescence of the marginal sounds in poor breathers thus proving as misleading to him as it has to many other investigators.

In the pleural sinus localized pleurisy is not as often seen at autopsy as elsewhere in the pleural cavity. It is not uncommon to find but partial adhesions in the sinus in cases in which the lung is firmly fixed to the chest wall by old universal adhesions. It is to be expected from the pathological law that localized pleurisies develop over local pulmonary lesions, that, at least in tuberculosis, pleurisies of the complementary space would be of less frequent occurrence than pleurisies of the pulmonary pleura. Dry pleurisies limited to the pleural sinus do occur however. Those recognized by the writer have presented friction sounds quite different in their quality from marginal sounds.

Von Ziemssen[11] has described a rare form of dry pleurisy which he designates as circumscribed indurating pleurisy. It is characterized by its unusually long duration and the extraordinary intensity of the pleuritic friction, inflammatory and febrile symptoms being absent. The harsh friction perceptible to the physician as well as the patient by palpation may continue for many weeks with undiminished intensity but without pain. The disease usually has its seat in the anterior and lateral portions of the complementary space.

True râles often, no doubt, mistaken for friction sounds are the râles from atelectasis dependent upon a pleural effusion. According to Lichtheim[12] it is not necessary that the effusion shall be large enough to actually compress the lung. A smaller effusion permits the retraction of that part of the lung which lies beneath the surface of the fluid. No longer following the respiratory movements the affected portion of the lung loses its air completely by absorption and becomes of a leathery consistency, but may still be capable of expanding during deep inspiration with the production of râles which, according to Janowski,[13] may even be heard through the effusion if the layer of fluid is not too thick. If edema supervenes, according to this author, there may be heard in addition to the fine crackles from the expansion of the atelectasis which occur only on inspiration very numerous small, moist râles in both expiration and inspiration.

Writers on physical diagnosis recognize the fact that friction sounds may simulate râles. It is not desired to deny this absolutely, at the same time, however, the frequency with which marginal sounds are taken to be evidence of pleurisy and the very markedly different quality of the unmistakable pleuritic rub justifies the question whether the supposed friction sounds which simulate râles, if they are not of the nature of the râles just mentioned, are not really after all usually marginal sounds which persist during the early stage of pleurisy, and when the diagnosis has been confirmed by other signs, are considered to be proved thereby to have been a sign of early inflammation of the pleura, *i.e.* friction sounds. Certainly sounds like râles occurring in the pleural sinus should not be regarded as a sign of pleurisy in the absence of other signs of that disease.

While the notion that marginal sounds are due to an atelectasis of the base of the lung, complete or incomplete, has been widely accepted, it is unnecessary to say that such an explanation in the absence of pleural effusion, of certain rare pulmonary conditions or of extreme abdominal distention has no anatomical facts in its support. No one, it may be confidently affirmed, would have anticipated that atelectasis could occur from slight causes in the part of the lung which is most used in respiration. The interpretation of marginal sounds as the râles of an expanding atelectasis has simply been accepted for the lack of a better explanation of this, at first sight, puzzling phenomenon.

Recalling the phenomenon of the reversibility of marginal sounds in lateral recumbency, we may point out that in the absence of competent organic causes for the condition atelectasis of the pulmonary margins is unlikely to occur in the recumbent individual, however weak or obese, provided that he is able to turn in bed, for every change from one to the other side brings with it the passive inflation of the margin of the superior lung. The

possibility of the origination of atelectasis from disuse of the pulmonary margins would, therefore, seem to be excluded in cases in which the lateral decubitus is possible.

The expert clinician learns by experience to attach no importance to the marginal sounds, whatever his theory of their causation may be. Perhaps marginal sounds were in mind when Janeway[14] said, "we may hear fine crepitation which does not mean anything much," and when Lawrason Brown[15] adopted the rule that "physical signs at one apex should be considered as due to tuberculosis until the contrary is proved: physical signs at one base should be considered non-tuberculous until the contrary is proved."

But for many physicians the marginal sounds have constituted a veritable stumbling block, to the removal of which it is hoped that the investigations here reported may in some small degree contribute.

FORT BAYARD, NEW MEXICO.

THE MECHANISM OF THE HEART BEAT, WITH A CONSIDERATION OF SOME OF ITS FUNCTIONAL DISTURBANCES.*

BY WALTER R. STEINER, A.M., M.D.,

HARTFORD, CONN.

VISITING PHYSICIAN, THE HARTFORD HOSPITAL.

THE mechanism of the heart beat has been of absorbing interest since the earliest time. In the sixteenth century the pious Fracastorius, unable to solve it, dismissed the question, saying God alone could understand it. Since then the pia mater of many a distinguished physiologist and clinician has been stretched more than once to the aching (to borrow a quaint expression from Sir Thomas Browne) in the effort to explain it. In the last century the neurogenic theory was long in vogue, which considered the nerves to be responsible for the origin and transmission of the heart beat. Later, in the myogenic theory, this function was assigned to the muscles, and the solution of the problem is not yet in sight. However, if we remember, as Lewis emphasizes, that the walls of the heart are composed of a syncytium of muscle fibers closely interwoven with nerve fibrils and ganglia, and if we speak of these fibers as in full functional connection with the nerve elements surrounding them, then it is immaterial to the subjects considered and to the conclusions arrived at, whether one or other view is held.

It has long been known that in the lower vertebrates the origin of the heart beat was in the sinus venosus, which is in them a distinct and well-defined chamber. In the mammalian heart, on the other hand, the sinus and auricles are fused into one cavity which is designated by the latter's name.

According to Keith, the auricles and ventricles are merely outgrowths from the primitive cardiac tube of the embryonic state, and are formed as pouches from the tube after it becomes bent upon itself. When the tube ceases to exist as such, remnants of its primitive tissue are found in the auricles in isolated masses, at the superior cavo-auricular junction, where it is known as the sino-auricular or sinus node, in the vicinity of the coronary sinus, in remnants in the auricular septum, in the valve of Eustachius, and at the mouths of the pulmonary veins. The tissue which unites the auricles with the ventricles and is known as the bundle of His or the atrio-ventricular bundle is thought to belong to the same system. It represents that portion of the heart muscle which is most irritable or that in which rhythms are most readily developed. These fibers differ from the cardiac muscle elsewhere, having a fusiform character and a great structural similarity. They seem, also, to have a remarkable glycogen content.

The sinus node, above referred to, is normally, as Keith has well shown, the pace maker of the heart or the site where cardiac impulses to contraction first normally arise. It lies at the junction of the superior vena cava and right auricle, and has generally a length of 2 cm. in man and a thickness of 2 mm. Keith's work has been amply confirmed by Lewis, Lewis and Oppenheimer, and Cohn and Kessell. Unfortunately the pathology of this node has not been extensively investigated, but in the type of arrhythmias to be described later and known as perpetual, or termed auricular fibrillation, Koch and Draper have reported extensive sclerotic changes.

In 1892 Kent published an imperfect account of a muscular connection in the mammal between the auricles and ventricles. A year later His, Jr., independently described this muscle bundle and Retzer, Braeunig, Tawara, Erlanger, and other investigators have subsequently much amplified their work. The auricular fibers join at the base of the auricular septum, near the coronary sinus, a specialized structure known as the auriculo-ventricular node. It is situated at the posterior and right border of the septum. At this node the bundle of His, or the atrio-ventricular bundle, commences and is directed at first almost horizontally forward and to the left. Then pursuing a course directly to the right of the central fibrous body of the heart, it goes to the pars membranacea of the ventricle, being ensheathed in a fibrous canal throughout its whole course. At the anterior part of this membrane, the bundle divides at a point a little in front of the anterior end of the attachment of the median or septal segment of the tricuspid valve, the left division perforating the membrane while still ensheathed upon the upper border of the muscular septum. It then enters the sub-endocardial space of the left ventricle immediately beneath the union of the anterior and right posterior cusps of the aortic

*Read before the Franklin District Medical Society, Greenfield, Mass., January 9, 1912.

valve. Subsequently it continues its course downward and under the endocardium until it undergoes arborization upon the septum, where it distributes its main branches to the papillary muscles of the mitral valve. The right branch is also directed downwards and subendocardially entering the so-called moderator band or its representative and going thence to the papillary muscles, where it begins its arborization. These arborizations on both the right and left sides of the heart are directly continuous with the complex network of Purkinje fibers, by which it comes in direct communication with the ventricular muscle fibers. The junctional tissue thus described has a different histological structure in its several divisions, for first there is a diminution in the size of the fibers, especially at the sinus node, then an increase, especially in the network of Purkinje, and finally a decrease. The fibers of the bundle are conspicuous on account of their pallor.

The impulse to contraction then normally has its origin at the sinus node and is transmitted from it to the auricular fibers. These contract and carry the impulse to the auriculo-ventricular node from whence it is, in turn, conveyed to the papillary muscles of the ventricles by means of the muscle of His, and consequently the ventricles themselves finally contract. This represents the normal course of the mechanism of cardiac contraction, but impulses leading to pathological contraction may arise in the irritable primitive tissue located, as I have above described, in other areas of the heart's musculature. From their onset irregularities in the rhythm or arrhythmias arise. Formerly these were classified according to the five cardiac functions of rhythmicity, excitability, contractibility, conductivity, and tonicity, for any interference of these properties was thought to cause them; but more modern knowledge considers any such abnormality insufficient to differentiate precisely the functional disturbances of the heart. At times more than one of the functions is at fault. We shall consider briefly heart block, extra-systole tachycardia, auricular fibrillation, respiratory arrhythmia, and alternation. Other forms of irregularities also exist, but are less frequent and consequently less deserving of mention.

For a separation of these different forms, a study of the pulse both arterial and venous is most necessary. The arterial pulse was the first recognized, but no instrument was made to study it by tracings until Vierordt devised a sphygmograph for this purpose in 1855. Since then Marey, Dudgeon, and Jaquet have invented excellent instruments to accomplish this. Our knowledge of the venous pulse, though more recent, is yet of antique date for venous pulsations are referred to in the writings of Lancisi and Morgagni, in the eighteenth century. Later, in 1865, Friedreich took the first venous curves from pathological subjects and Potain, two years later, obtained simultaneous tracings of the apex beat, carotid, radial, and jugular pulses from his sister. But the first impetus to the scientific study of the venous pulse was given by James Mackenzie, now of London, who, in 1893, published his first investigations upon this subject. His scholarly book on "The Study of the Pulse" appeared nine years later, and stands as a wonderful example of the work a general practitioner can do to advance the science and art of medicine. For as he states in the preface of that book, he had seldom opportunity in the midst of his busy everyday practice to devote an hour's uninterrupted study to its preparation. In spite of this difficulty in its composition, it stands to-day unrivaled, for it yet remains the standard book on the study of this subject. The tracings from the venous pulse show the time of onset of the auricular systole, while tracings from the arterial pulse reveal that of the corresponding ventricular contraction. By a study of the tracings from both, the onset of contraction in each is given, as well as their time relationships.

The venous pulse is recorded by Mackenzie's special attachment to the Dudgeon sphygmograph, by Mackenzie's ink polygraph, by Jaquet's or Uskoff's polygraphs, or by other instruments. The tracings in both man and animals are very similar and show, like the auricular curve, three main elevations and three main depressions so that similar factors are concerned in the production of both of them. In addition to the above-mentioned instruments for the study of the pulse, the electrocardiogram first introduced by Einthoven, in 1903, should be mentioned, for it can also register the human heart beats. It consists of a single conducting strand between the poles of a powerful magnet. The movements of the string are observed by projecting its shadow upon a screen. The string is connected with a carrier at the upper and lower ends of the cleft between the magnetic poles and through it communicates with the two wires which transmit the current to be examined to and from the instrument. The readiness with which it can be used and the absolute reliability of the curves predict for it an extremely useful and important future. Its cost, however, is a serious drawback.

1. *Heart Block.*—By heart block we mean atrio-ventricular allorrhythmia or independent auricular beats without corresponding ventricular contractions. This irregularity has been known since the time of Harvey, the illustrious discoverer of the circulation of the blood, but it was not experimentally produced until recent years. In 1895 Graupner apparently destroyed, with success, the muscle of His in a rabbit's heart, obtaining a dissociation in the rhythms of the auricles and ventricles. Later the investigations of Hamblet, Hering, Retzer, Tawara, Erlanger, and his associates, Tabora, Briggs, Cohn, and Trendelenburg have extended our knowledge of this condition so that we can now safely affirm that the muscle of His or the atrio-ventricular bundle is the path of the conduction of impulses from the auricles to the ventricles. If the dissociation of the normal sequence of ventricular contractions following those of the auricles is complete then both upper and lower chambers of the heart will contract absolutely independently of one another, for the ventricles have a dormant, inherent rhythm of their own, which is called into action, when they can no longer receive impulses from the auricles by means of the muscle of His. If, on the other hand, the block is incomplete, that is, if some of the impulses can pass through the muscle of His, the dormant ventricular rhythm is not aroused and we get two or more auricular systoles to one ventricular or in other words we have two to one, three to one, four to one ratios, etc. (a ventricular contraction at different regular intervals). In the still lighter forms, the transmission of the stimulus to contraction may be merely delayed through this muscle, and be manifested, in a jugular tracing, by the prolongation of the intersystolic period (the interval between the con-

traction of the auricle and the contraction of the ventricle, which normally is fairly constant and one-fifth of a second in duration). This arrhythmia does not necessarily result from tissue destruction, for it may ensue from a stimulation of the vagus nerve, be due to the injection of poisons (especially digitalis, aconitine, adrenalin, muscarine, and physostygmine) and occur directly from asphyxia.

The first case of clinical heart block was observed in 1875 by Galabin, who reported at this time a case of slow ventricular action (25 to 30 per minute) and stated in his paper "we have here a heart, the auricle of which sometimes contracted twice in the interval between two ventricular pulsations and sometimes singly in the midst of a long pause instead of just before the systole of the ventricle." He made this diagnosis from his study of the case by auscultation and by cardiac apical tracings. Chauveau, Wenkebach, His, and Mackenzie have subsequently advanced our knowledge of this subject, and during the last few years many cases have been published. In them the radial pulse is slow with forcible beats and a high blood pressure. Occasionally an indication of auricular contractions may be observed in the radial tracings, while by auscultation distant sounds, due to auricular contraction, may be detected, as in one of Osler's cases. By venous curves we find waves from the contraction of the right auricle distributed frequently and uniformly in the tracings, exhibiting a 2, 3, 4 or more rhythm as compared with the ventricular contractions. If the block be partial, some ventricular contractions are preceded by those of auricular origin, but if the block be complete there are regular auricular contractions without corresponding one on the part of the ventricles. The electrocardiographic tracings, however, are the best means to show the block, for the separate systoles of the auricles and ventricles are here most readily revealed and their time relationship to each other most easily distinguished.

Lewis has recently collected fifty cases of clinical heart block, in which the bundle has been carefully examined and in none of them has it been shown to be absolutely intact histologically. The findings have varied from gummata, circumscribed areas of fatty degeneration or fibrosis (the latter being frequently combined with calcareous degeneration), anemic necrosis, ulceration, atheromatous degeneration, lymphocytic deposits, calcareous nodule on the bundle's path, or a stretching and subsequent obliteration of this muscle. The fatty and fibroid changes in the myocardium may show a peculiar predilection for the specialized tissues. Some of these cases exhibited slow pulses, associated with syncopal or epileptiform seizures. They form a comparatively small yet distinct clinical group which has been included under the term Adams-Stokes syndrome. I have seen five such cases and reported three of them before the Hartford County Medical Association, April 3, 1906. These patients present nervous symptoms as shown in attacks of a vertiginous, syncopal, or epileptiform nature, which are accompanied by a slowing or standstill of the ventricular rate. The nervous symptoms thus seen are due to an anemia of the brain, as has been substantially proven by experimental observations, while the cause of the ventricular slowing must be in the heart itself or in its nervous connections. If the duration of this slowing continue only for from two to two and a half seconds, then little or no nervous disturbances will follow; if a longer period of from three to five seconds be seen, then unconsciousness will ensue; if the standstill period lasts fifteen to twenty seconds, epileptiform phenomena will occur, while an absence for ninety to one hundred and twenty seconds rarely results in recovery. The epileptiform seizures are more frequent in partial than in complete heart block and seem to be due in the former to some alterations in conductivity, resulting in a slowing of the ventricle; while in the latter it appears to result from some factors which influence the pace-maker of the ventricle, situated in the immediate neighborhood of the lesion producing the dissociation. A partial block may be increased by (1) a sudden increase in the auricular rate and (2) vagal inhibition. Heart block from the use of digitalis or vagal stimulation appears to be due to the result of the drugs or nerve action upon tissues already deficient in the power of conduction.

The prognosis of Adams-Stokes disease is always grave, yet need not be immediately fatal, but when death does occur, it is most apt to be sudden. One of Osler's patients had a slow pulse for thirty years. There is no specific treatment. In the younger patients, where a syphilitic taint may be present, the iodide of potassium should be employed. Its use has apparently cured a number of cases.

The milder forms of depression of conductivity occur in infectious diseases, especially influenza and acute rheumatic fever. Their appearance should be a warning against the further use of digitalis, if this drug is being administered, as its further employment might lead to the production of a severe heart block.

When there is a complete dissociation between the auricular and ventricular systoles, then, after an interval, which varies with the rapidity of the block's onset, the ventricle will contract spontaneously for it possesses a dormant, inherent rhythm of its own (the idioventricular rhythm). Its rate is slower than that caused by the sinus node, the normal pace-maker of the heart, as it is thirty to the minute against seventy-two of the latter. This former rhythm is also termed physiological or homogenetic. It seems to be especially connected with the so-called primitive cardiac rests, which are the seat of the rhythmic discharges. The cardiac muscle can also respond to external causes of irritation, and when such stimuli have ceased to act, can resume again its homogenetic rhythm. These external causes, which are pathological, may give rise to a premature beat or to contractions which are rhythmically repeated in a series of beats. They are always different from those of a homogenetic type and have been designated heterogenetic. They are not seen at regular intervals, as the idioventricular beats, but are haphazard or premature in their time of occurrence so that the interval between their onset and the preceding systole is customarily very short, and the subsequent pause of diastole long, generally exceeding the distance between two beats of the sinus rhythm. The homogenetic types differ from the heterogenetic in that that the former "signals the birth of the impulse which promotes the idioventricular contraction, while the latter actually initiates the premature beat or promotes its special impulse." Again, the former are associated with the normal nutrition of the heart, while the latter result as a consequence of a gross disturbance of this nutrition. They also

differ in their rates, for the homogenetic rate is slow, while that of the heterogenetic is rapid, rarely being less than one hundred and thirty and sometimes surpassing four hundred to the minute. If the increase in beats comes on gradually, the new rhythm is probably identical with the old, except for its more rapid rate. If the rate rises suddenly and those before and after this increase are constant, then some new factor must have appeared.

2. *Extra-Systole.*—By extra-systole we mean that type of cardiac irregularity in which there are additional contractions of the heart which accompany those of a normal cardiac rhythm. By tracings we find a contraction occurring before its time, followed by a pause (the compensatory pause). Knoll has shown that the distance from this premature to the preceding and succeeding systoles is equal to the distance occupied by two whole cycles of regularly beating ventricles, while Engelmann explains it as having arisen independently of an auricular contraction. The auricular impulse succeeding the extra-systole, he thinks, reaches the ventricle when in systole and consequently in the so-called refractory period. As a result, the ventricle fails to respond to this impulse and waits for the next one, so the long pause is produced. If, however, the heart rate be slow and the premature contraction be sufficiently early, then no response may be missed and the extra beat may be merely interpolated. This irregularity may be of ventricular or auricular origin or arise in the auriculo-ventricular node (nodal extra-systole). Experimentally it may be produced when pressure in the ventricle is abruptly raised by clamping the aorta, by rendering the heart muscle anemic, by deliberate obstruction of the vena cava, by ligation of a branch of the coronary artery, or by the injection of certain poisons (digitalis, adrenalin, aconitine, muscarine, and physostygmine). It occurs when all nervous connections between the heart and the central nervous system are severed, and is seen in isolated and perfused hearts.

Clinically, ventricular extra-systoles are characterized by the presence of a full compensatory pause and the absence of permanent dislocation of the spacing in the recovered rhythm. The venous and arterial tracings proclaim them to be of the ventricular type, and by the electrocardiagram a further localization in the walls of the ventricles may now be made.

Premature auricular contractions are recognized by the relative shortness of the pause which follows them, although this pause is relatively longer according as the seat of the disturbance moves from the pace-maker or sinus node to the ventricle. In addition to the general absence of the compensatory pause we have also a permanent dislocation of the spacings of the succeeding systoles. Unfortunately we do not know their method of production.

Premature beats arise in the junctional tissues when simultaneously a premature contraction is seen in both auricle and ventricle. The systoles are thus more or less coincident but there may be considerable variations in the relation of one to the other. The measurement of the interval between the onset of the systoles in the auricles and ventricle will aid in the differentiation of this variety of premature contractions.

Extra-systoles are seen in neurotic individuals as well as in those who suffer from rheumatism, cardiosclerosis, dyspepsia, or tachycardia. They have no specific treatment.

3. *Tachycardia.*—Increased frequency of the heart beat occurring periodically, as a common clinical phenomenon. It is caused normally from stimuli arising at the pace-maker or sinus node under the influence of emotion or exercise; and is also seen in persons who exhibit an instability of their nervous system, as well as in those whose myocardium is involved in a disease process, as in tuberculosis. But apart from these varieties it occurs in a specific form, which is a grave and not infrequently fatal malady. It is characterized by the abrupt appearance and disappearance of the attacks and is brought on in a haphazard manner. It is due to pathological or heterogenetic contractions which occur rhythmically in a series of beats. Experimentally it may be produced by induction shocks or mechanical stimuli as well as by the other methods employed to cause single premature contractions. It may be of ventricular or auricular origin. If the latter, it is consequently of ectopic origin and the rate proclaims it as pathological. Fully established, it may be of a few minutes' duration or continue for half an hour or more. Eventually the heart generally recovers and the pace-maker's rhythm becomes dominant again. The tachycardia, however, may become progressive in rate so that finally the ventricles may no longer beat coördinately and death follows. The paroxysms appear to be formed in the heart wall as a result of local disturbance. They are of rare occurrence and their foci of origin can be identified by the knowledge we have of the type of electric curves resulting from the experimental stimulation of various portions of the ventricular walls. Each series of premature contractions is apt to be followed by a pause of considerable length.

Tachycardias of auricular origin are almost due to heterogenetic contractions arising in the auricle. They are more common than those of ventricular origin and may last from a few seconds to an hour, several days or weeks or months. They are identical in their paroxysms, however they may vary in duration, and are recognized by polygraphic tracings.

The third type arising in the vicinity of the auriculo-ventricular node, now designated as nodal rhythm, is the rarest of the three.

Lewis has classified the tachycardias upon their clinical pathology as follows:

(*A*) Homogenetic tachycardias, the result of alterations in the rate of physiological impulse formation at the site of the old pace-maker.

(*B*) Heterogenetic tachycardias:

I. Regular tachycardias springing from single foci of the musculature.

(*a*) Arising in the pace-maker (as yet unobserved).

(*b*) Arising in the central regions of the auricular tissue.

(*c*) Arising in the neighborhood of the auriculo-ventricular node.

(*d*) Arising in the right ventricle.

(*e*) Arising in the left ventricle.

II. Irregular tachycardia probably springing from many foci in auricular musculature.

4. *Auricular Fibrillation.*—Instead of a return of the tachycardia to a normal pulse rate, a still higher grade of disorder may be seen, characterized by a perpetual and absolute irregularity of the arterial pulse. This is designated as auricular fibrillation or auricular delirium. In this condition, the auricle is in the diastolic position and its mus-

cle is in an extremely active condition of movements or is fibrillating. The auricular tissue appears to be broken up into a variable number of small areas, which can originate, independently and spontaneously, heterogenetic impulses.

This condition is the most common of all the causes of persistent cardiac irregularity, being met with in about fifty per cent. of all such cases. It has been called the mitral pulse, pulsus irregularis and perpetuus, and has been attributed to delirium of the heart. Formerly the pulse in this type was characterized with the adjectives irregularis, inæqualis, deficiens, and intermittens. A prominent systolic pulsation is also seen in this condition, which has been considered as due to tricuspid incompetence. The irregularity has been long known, but the chief progress of our knowledge concerning it dates from the appearance of Mackenzie's book on "The Study of the Pulse," which appeared in 1902. At that time he considered it due to auricular paralysis and correlated the two chief phenomena in this type, viz., gross irregularity of the heart and the systolic venous movements, which he called the ventricular form of venous pulse. For, in venous tracings of these cases, the auricular wave is missing and the pulse is of the so-called ventricular type.

Later Hering described its arterial pulse and included this class of functional disturbances under the title pulsus irregularis perpetuus, and the subsequent introduction of the electrocardiograph has fully substantiated its specific nature. Finally Mackenzie found evidence that the auricle in these cases was active, for (1) at autopsy the hearts were found to be hypertrophied and (2) in certain instances the normal rhythm reasserted itself. In 1904 he published a paper in which he located the seat of this rhythm in the junctional tissue lying between the auricle and ventricle, which has been termed the auriculo-ventricular node and which we have previously described. Consequently he designated this irregularity nodal rhythm, thinking that it originated from the simultaneous contraction of both auricle and ventricle. This view, however, has not met with favor and has been generally abandoned, even by Mackenzie himself.

In this irregularity the pulse may present many variations. It may be fast or slow, averaging between 30 to 200, although the faster type is the more frequent of the two. The heart rate in the latter is double the normal, varying from 110 to 150, and presents a most disorderly character, for we see in the tracings an absolute irregularity and an absence of a definite and continued relationship between the strength of a beat and the length of the pause which precedes it. Many of the beats do not reach the wrist, so the radial pulse is but a poor index of the rate of the ventricular contraction. The electrocardiograms also yield specific findings.

5. *Respiratory Arrhythmia.* — By respiratory arrhythmia we refer to the arrhythmia which occurs as the result of vagal influence, in which we get a variation in the length of the diastolic period. It occurs in normal respiration when the pauses increase in length in expiration and decrease in inspiration. It may be experimentally abolished by section of the vagi or saturation with atropine. In children this type is the rule, and on this account it has been termed by Mackenzie the youthful or infantile type of arrhythmia. By a jugular tracing, the right auricle and ventricle show an irregularity similar to that seen in the radial pulse. It is a true intermission and disappears with an increased pulse rate. Pathologically it is seen in convalescence from acute fevers, in neurasthenia, in brain disease, and in meningitis, and may be recognized by the continually changing pulse rate, although the beats are the same.

6. *Alternation.*—In 1872 Traube described a condition which he termed pulsus alternans, in which we have large and small beats alternating, with or without a higher rate. It varies much in degree, so much so in fact that the smaller beats may be imperceptible in the arteriogram. According to Traube the interval separating large and small beats was greater than that separating small and large beats, but subsequently the incidence of the beats has been shown to be perfectly regular. This arrhythmia occurs in overtaxed healthy heart muscle, especially in paroxysmal tachycardia, and in hearts whose muscle has previously been seriously affected, being especially frequent in progressive fibrosis of the heart. It may also be produced by the injection of certain poisons (digitalis, antiarin —a closely allied body—aconitine, glyoxyl, and hemolytic serum), and is frequently accompanied by anginal pain. It indicates both structurally and functionally a precarious cardiac condition. Unfortunately its pathology is still wrapped in mystery.

These recent advances in our knowledge of cardiac irregularities, thus briefly outlined, promise much for our better understanding of them. We should all avail ourselves of this knowledge, for it will enable us to treat our patients with these functional difficulties more efficiently and intelligently.

4 Trinity Street.

SELECTION OF FEMALE RISKS IN WHOM HYSTERECTOMY AND OVARIOTOMY HAVE BEEN PERFORMED.*

By P. H. INGALLS, M.D.,

HARTFORD, CONN.

ASSISTANT MEDICAL DIRECTOR, THE ÆTNA LIFE INSURANCE COMPANY.

The improvement in modern surgical methods, and the wonderful results obtained in operations within the abdominal cavity, have been the means in recent years of admitting to the class of operable cases many persons who before were considered hopelessly incurable, and not only have these persons been successfully operated upon, but have been restored to health with all that this term implies.

We have considered at these meetings in previous sessions applicants from whom the gall bladder has been removed and have formulated ideas of what treatment should be accorded them in the field of life insurance applicants.

We are receiving applications, oftener than one would believe possible, from persons in whom one kidney has been removed and before long, experience will demonstrate to what extent their vitality and power of resistance has been lowered by the loss of that organ.

And we have also taken up and thoroughly discussed the subject of appendicitis, operated and not operated, and have been able to form definite ideas of what treatment should be accorded applicants in this class.

*Read at the twenty-third annual meeting of the Association of Life Insurance Medical Directors of America, October 10, 1912.

Operations on the female genital organs have for many years played a very important part in the field of surgery, and it is for a brief consideration of this class of cases that, at the suggestion of the president, I have ventured to submit this small contribution to the proceedings of this association.

For many years now I have been devoting my attention in private work to this class of cases and, while the whole field of gynecology is a very wide one and has no part in the questions which I intend to outline in this paper, I am going to ask your consideration of those applicants for life insurance on whom the operations of hysterectomy and double ovariotomy have been performed. When I began work in the life insurance field I found that my seniors promptly rejected all female applicants of this class, and reference to their applications shows that in many cases they had applied to other companies and had also been rejected by them.

The surgeons in our large centers who so often only see their cases just before operation, and as soon as their convalescence has been completed have them drop out of sight and go to their homes, scattered all over the country, have not as good an opportunity to observe the ultimate results of their work as those of us who operate in the hospital which draws its patronage from territory adjacent, and who have to follow up and look after the cases for a long time subsequent to their operation, and as for over twenty-five years I have been following this class of work in one of our smaller hospitals and have been able to see and live in a community with a fairly large number of this class of cases, I came to the conclusion that many women were being denied the privileges of life insurance who could safely be taken and would make good and profitable risks.

What are the undesirable features of this class of cases?

The most prominent characteristic, and the one which I think has been the greatest bugbear, is the disturbance to the nervous system owing to the fact that in all these cases we bring about a premature and forced menopause. True it is that this is an important condition and sometimes leads to distressing and even permanent nervous instability. The modern operation for hysterectomy in which the ovaries are left in position has relieved to a very marked extent this class of symptoms, while they still persist in the cases of double ovariotomy—but with the exception of a very small majority of cases these symptoms all disappear within a year or eighteen months after the operation. I can recall personally but one of my own cases in which any permanent nervous disability has resulted from the operation while, like every other surgeon with much experience in this class of work, I have had some rather disturbing manifestations within the first few months following the operation.

Malignant degenerations have not appeared in any of the cases where we were satisfied that such degeneration did not exist at the time of the operation.

Changes in other organs of the body have not been observed. The effect on the general health has been one of steady and gradual improvement and no fear need be had on that score.

Hernias are no more apparent than after any other abdominal section and need have no part in any objection to these cases by the time they are accepted.

Much was written in years past about the great changes in personal appearance, mental characteristics and changes in temperament as a result of the so-called unsexing of women. Gynecologists the world over have given this matter their painstaking and careful consideration, and I feel that I can say with great positiveness that this is an objection which need not receive any serious consideration, that no such condition is found to exist, and that it is not possible to pick out from any observable change in physical or mental characteristics those women who have had these operations performed. I have not attempted in this article to obtain any vast number of statistics from various operators, but from my experience in our special medical societies I know that my own experience is an average one and that statistics obtained from many operators as to the ultimate results would not change the results of my own observation. Neither have I asked for a tabulation of experience from other companies as to their results with this class of applicants. I have felt it would be fairer to state my experience and deductions as a basis to bring this matter before you for discussion, and maybe we will all be agreed on the general principles with which to regulate our selection in this class of applicants.

I must confess that when I went through the papers in our own office I was rather surprised that I did not find more of the cases on which to base my deductions, but I have tried to be careful in selection, as I will demonstrate later, and as a result a very small number appear on the books.

In the last ten years we have taken thirty-four cases which come under this classification. This does not include any cases of myomectomy or single ovariotomy, or plain removal of tubes, ventral fixations or suspensions. I have limited the observations here absolutely to those women in whom the uterus and ovaries—the uterus alone or the ovaries alone—have been removed.

We have twenty-three cases of double ovariotomy and ten cases of hysterectomy representing a total exposure in the thirty-three cases of 167 years. These exposures are subdivided as follows:

10 years	3 cases
9 "	2 "
8 "	4 "
7 "	3 "
6 "	4 "
5 "	2 "
Less than 5 "	15 "

Strange as it may seem, I find but one death in this class of cases, and as that was so manifestly a case of fraud and has so many peculiarities about it I will give that special consideration later on. It may be that the particular requirements which have been insisted on in accepting these cases has had something to do with the good mortality record, but I am not yet ready to advise any greater liberality in the acceptance of this class.

In the first place, we have taken all pains at our command to find out that no malignancy was suspected or found out in all the cases operated on.

Secondly, that no complications were found in the operative work.

Thirdly, that at least two years had elapsed from the time of operation until the acceptance of the risk, and that in that time there had been no evidence of any return of the growth or symptoms referable to the conditions, and that all symptoms, nervous or general, due in any way to the operation, had abso-

lutely disappeared, and naturally, we insisted that the applicant was up to the required standard in all other physical characteristics.

The one death which occurred in our series of cases presents to my mind enough of peculiar characteristics to warrant a brief outline of the circumstances attending the issue of the policy and the investigation of the death record.

This applicant was 49 years of age and applied for insurance May 16, 1911. She had had one child with normal labor in 1884 and had never miscarried. The medical examiner made statements that eight years before he had performed a complete hysterectomy for fibroids. The recovery was complete and she had enjoyed the best of health since the operation and he had kept the case under observation personally. She was accepted and the policy was issued June 12, 1911. On October 11, 1911, she died and the certificate of death, from a neighboring town, gave the cause of death as cancer of the uterus and the duration of the illness three months. I immediately wrote to the doctor who examined her and he said she had been under his observation and always had told him that she had been in good health, and distinctly told him at the time he examined her for insurance that she had been in good health and was in good health on that date.

By various tracings of her proceedings in the year previous we unearthed the fact that she had applied for admission in July (two months after taking her insurance) to one of the large hospitals where she gave a history that six years following the operation she had pain in the lower abdomen. One year before, *i.e.* July, 1910, she had to wear a napkin on account of the discharge, and six weeks before that, *i.e.* early in June, had a hemorrhage from vagina and was admitted with diagnosis of cancer of cervix and bladder wall.

Subsequent investigation showed that she had put herself under treatment for pelvic discharge and pain in November, 1910, and that the doctor who treated her did not tell her that he suspected cancer although he affirms that he did inform her husband of the fact.

This was so evidently a case of fraudulent representation that our adjuster had no difficulty in denying the claim, and a compromise was made for a very small sum.

This case would seem to indicate that the general rules we have been following in the selection of these risks would not stand the test of time, but it is sufficiently peculiar and out of the ordinary to be classed as a notable exception. In the first place, I do not recall any case in my operative experience where malignant disease appeared at so long an interval after the operation, and I am forced to believe that she might have had cancer any way. In all my work where cancer has been found or suspected all returns have been noted within eighteen months—and in the second place, this applicant was so crooked in making her application that we might have been deceived at any date subsequent to operation. This is one of the risks every company runs in dealing with applicants who are willing to make fraudulent statements to procure insurance.

The matter then resolves itself into the question: Can we safely write these risks and under what circumstances? I believe we can if we follow out a few simple rules.

1. A sure and accurate knowledge that no malignancy was expected or found at the time of operation.

2. That the operation did not reveal any abdominal or other complications existing.

3. That sufficient time has elapsed—at least two years—to be sure that all nervous and physical disturbances as a result of the operation have entirely disappeared.

4. That the applicant is up to our required standard in all other respects.

This may involve some correspondence and special investigation concerning each application. The number of cases is bound to be small, and will make no large difference in the volume of the business written, but my point is,—cannot we grant to these women desired insurance without running any greater risk than we do in many other classes now accepted by us?

SACRAL KIDNEY SIMULATING ACUTE APPENDICITIS.

By M. S. KAKELS, M.D.,

NEW YORK.

ATTENDING SURGEON TO LEBANON HOSPITAL, CONSULTING SURGEON TO ROCKAWAY BEACH HOSPITAL.

While anomalous situation of the kidneys must be considered of moment to the general practitioner, and especially to the surgeon when making a diagnosis or operating for some obscure tumor in the abdominal cavity, a congenital misplaced kidney must still be regarded more or less as a curiosity. Although recent literature records numerous cases of anomalies in number, form, and size one does not see reported many cases of dystopia of this organ.

Formerly most of the anomalies were discovered only after death, but now that operations upon the kidney are of more frequent occurrence more instances are being observed and therefore more interest has been shown in the subject from both the surgical and from the pathological standpoint. From the literature of the cases reported one learns the fact that a misplaced kidney seldom gives rise to serious symptoms and generally escapes observation during life, and therefore is rarely diagnosed.

Most frequently, if not attended by mobility and not encroaching on important neighboring organs, an abnormally situated fixed kidney is discovered only accidentally in making a physical examination of the abdomen. Furthermore, when a fixed displaced kidney does give rise to symptoms it does not as a rule point to the displaced organ, but generally to the neighboring organs upon which it may lie. Grave symptoms and serious complications may arise especially when pressing upon the bladder, rectum, or uterus.

Munroe (*Boston Med. and Surg. Jour.*, 1910) relates of having seen four cases of renal ectopia, in none of which were the symptoms referable to the urinary tract. One of the cases was discovered at an operation for acute appendicitis.

The more pronounced displacements are rather rare, and when anchored in the iliac fossa or situated on the promontory of the sacrum are most likely to cause serious complications. Especially in females, when lying over the sacroiliac synchondrosis, are they apt to cause error in diagnosis for the reason that they are readily mistaken for a pelvic or abdominal tumor arising from the genital organs.

Of the frequency of misplaced kidney Henry

Morris states that "out of nearly 13,000 post-mortems there were found 13 instances of misplaced kidney, thus averaging one out of every 1,000 bodies examined." The peculiarities in the origin, number and distribution of the blood-vessels, and the course and length of the ureter, as is found in these fixed malpositions, favors the theory of the congenital nature of the displacement.

As the renal ectopia is a condition which takes place prior to birth, during the process of fetal development, the presumption is that the gland does not ascend but becomes fixed in its abnormal situation owing to the shortness of the ureter and vessels, although the latter (blood-vessels) have been found of normal length in some instances, when springing from the aorta and not from the iliacs. Thus anchored in its position it does not become unduly movable. If not submitted to undue pressure from neighboring organs, and there is no interference with its blood supply and no impediment to the escape of urine, the natural conformation of the kidney is preserved, but on the other hand any interference or impediment to the vessels or ureter or any undue pressure upon it during the progress of growth may cause a malformation of the organ to ensue.

Newman in his "Monograph on Movable Kidney and Other Displacements and Malformations," classifies displacements of the kidneys without mobility into (1) congenital displacements without deformity, (2) congenital displacements with deformity and (3) acquired displacements.

Morris ("Surgical Diseases of Kidney and Ureter") states that "fixed displaced kidneys have seldom been diagnosed *intra vitam*, as they rarely give rise to symptoms or even inconvenience during life."

Ectopic kidneys have frequently simulated many other conditions in the abdomen and given rise to errors in diganosis and disagreeable surprises. Because they are so frequently mistaken for abdominal or pelvic tumors, the surgeon, gynecologist, and obstetrician may be brought face to face with unexpected obstacles. One can readily imagine the varied complications of diagnosis which a diseased kidney placed in an anomalous position might give rise to, and furthermore it is plainly evident that such complications would be greatly increased if the right kidney should be so anomalously situated.

Hochenegg (*Wiener klinische Wochenschrift*, 1900, No. 1) reports a case of an obscure tumor pressing upon the rectum, causing for many years obstinate constipation and distress with psychic disturbance, the true nature of which was only revealed at operation (by the sacral route) as a congenital dystopia of the kidney.

Israel ("Nieren Chirurgie," 1901) diagnosed a resistant mass in a woman, producing pronounced intestinal symptoms, as an ectopic kidney. This mass, from the symptoms and the physical signs, had been previously diagnosed by others as a carcinoma of the cecum. This case is, so far as the casual perusal of the literature shows, the first one correctly diagnosed *intra vitam* before operation.

Cragin (MEDICAL RECORD, 1898) reports a case of vaginal nephrectomy for a congenital pelvic kidney obstructing the parturient canal which had in previous confinements been the cause of dystocia.

That an ectopic kidney should simulate an acute attack of appendicitis is rare and unusual, although Newman (*Scottish Med. and Surg. Journal*, Vol. I, No. 1, p. 53) reports a case of fixed displacement of the right kidney above Poupart's ligament simulating a perityphlitic abscess. "The patient was admitted to the Glasgow Royal Infirmary in 1894, complaining of pain in the right iliac region with a previous history of pain with more or less persistence since 1890. He noticed a swelling in the abdomen about seven months before admission to the hospital. There was a slight fullness of the abdomen in the right iliac and lower lumbar regions and a rounded swelling was felt. It appeared to be fluctuant. There was dullness on percussion over an area of about two inches in breadth running parallel with Poupart's ligament. The swelling was cut down upon and as soon as the muscles were cut through the sense of fluctuation was lost. The incision was then enlarged, when the swelling was found to have a rounded outline with a distinct hilum toward the inner and upper aspect, and being semielastic but firm immediately suggested a displaced kidney.

In a casual search of the literature of reports of true ectopia of the kidney I have found no instance in which the displaced organ simulated, from the objective and physical signs, an acute attack of appendicitis. I feel, therefore, prompted to place on record the following case which came under my observation, especially as it illustrates an unusual error and a rare form of ectopia of the kidney. Furthermore, the report of the case may put others on their guard when dealing with an indefinite abdominal mass.

Sadie J., age 19, born in Italy, married two months, was admitted to my service in the Lebanon Hospital on the evening of June 19, 1912, with the following history.

Four days before admission she was seized with general abdominal pain, cramp-like in character, and radiating toward the right side. There was constipation, but no nausea or vomiting. The following day the pain localized itself to the right iliac fossa, where it remained, increasing in severity till the time of admission to the hospital. She had been having chilly sensations since the beginning of the attack. Her past history had no bearing on the present condition. Her menstruation was regular, without pain, the flow lasting four days; the last menstruation was eighteen days ago.

Her family history was negative. The patient looked acutely ill. The head and chest revealed nothing abnormal. There were marked rigidity and tenderness over the whole of the right side of the abdomen, and an indistinct mass, tender to pressure and intolerant to careful manipulation, was palpable in the right iliac fossa. Nothing could be felt per vaginam. The temperature was a little less than 101°, pulse 96, respiration 22. The blood count showed: White cells 14,800, polynuclears 73 per cent. The urine showed a trace of albumin, few epithelial casts, no blood, no sugar; in fact, nothing in the urine to give a clue as to the diagnosis.

The clinical picture and subjective symptoms of sudden colicky pains extending over the entire abdomen and radiating to the right side, in conjunction with the other signs such as rigidity and an indefinite mass, tender on pressure and intolerant to careful palpation, led us to believe we had to deal with a case of acute appendicitis.

Accordingly the patient was submitted to operation. A Kammerer incision was made, and only after the abdomen was opened and a slightly congested appendix removed was the true nature of the mass revealed. By pushing the coils of intestines

aside a retroperitoneal mass was exposed to view situated over the right sacroiliac synchondrosis a little to the right of the median line. An incision into the posterior parietal peritoneum was made when the kidney was recognized fixed, congested, rather small in size, with its hilus directed toward the median line and apparently not diseased. Exploration in the abdominal cavity with the hand showed that the right kidney was not present in its proper site, but that the left kidney was. We thus had to deal with a sacral kidney.

The condition of the patient precluded any further dissection of the ectopic organ in order to demonstrate the nature of the vessels and ureter, although the pelvis of the kidney was not felt to be enlarged. Consequently the organ was left *in situ*.

The posterior parietal incision was sutured with a runing catgut suture and the abdomen closed without drainage. The patient made an uneventful recovery, with no rise of temperature, and was discharged July 1, 1912, twelve days after her admission.

The history and the symptoms were the usual ones that pointed to an acute attack of appendicitis; consequently, this rare and unusual error in diagnosis affords considerable interest and is, to say the least, instructive.

Taking into account the rarity of sacral kidney and all the evidence at hand the error in diagnosis was excusable. A subsequent careful inquiry elicited the fact that the patient suffered from a slight frequency of urination before she entered the hospital. This may have some bearing upon the cause of the symptoms which simulated an attack of appendicitis. Other than this acute illness the patient was never cognizant of the fact that she had a mass in her abdomen, nor did she suffer any inconvenience from the location of the same. Only after the operation was she made aware of the existence of an abnormally situated kidney.

We do not presume to be able to explain positively the pathological condition of the kidney which produced such symptoms as were evidently mistaken for appendicitis, as a free exposure of the kidney at the time of operation was not made. We can only conjecture that the patient may have had a renal colic in an ectopic kidney, due to calculi, with an acute congestion of the kidney with reflected pain and spasm of the abdominal muscles and rigidity of the same. This surmise may be more than reasonable and not seem so strange when one considers how often the passage of a calculus through the ureter from a normally situated kidney, especially on the right side, has been mistaken for an acute attack of appendicitis.

The recording of this case may cause one to bear in mind, in diagnosing acute abdominal conditions, the possible existence of an ectopic kidney.

71 East 66th Street.

THE POST-OPERATIVE TREATMENT OF LAPAROTOMY, WITH COMPLETE WOUND CLOSURE.

By RUSSELL S. FOWLER, M.D.,

BROOKLYN, N. Y.

CHIEF SURGEON, FIRST DIVISION, GERMAN HOSPITAL OF BROOKLYN; SURGEON, METHODIST EPISCOPAL HOSPITAL OF BROOKLYN.

General Considerations.—The post-operative treatment of all acute abdominal conditions and many chronic ones begins when the patient is first taken ill, and consists in early recognition of the possible need of surgical intervention and the intelligent pre-operative treatment of the condition. This is particularly true in perforations and acute infective processes. The so-called operative mortality can be very materially lessened by the observation by the medical attendant of a few simple rules. In acute conditions of the abdomen all feeding by stomach is contraindicated. Nothing, not even water, should be given, for the reason that the ingestion of anything in the stomach results in peristalsis with its accompanying spread of whatever infection is present. However, the tissues must not be deprived of water, as the possible operative procedure might otherwise have a disastrous effect upon the general metabolism. *Fluid* is given by rectum either by slowly administered, frequently repeated enemata or by the Murphy proctoclysis or, in urgent cases, by hypodermoclysis. Morphine must be withheld until a diagnosis is reached. If these three rules are followed out, an earlier diagnosis is possible and if a surgical operation is indicated the patient is in the best possible condition for it.

The general after-treatment of operations on the abdomen differs but little from the after-treatment of operations in general. The difference depends upon two or three underlying principles which, if understood, simplify the after-treatment to a great extent. Removal of a patient from the operating table to the bed is done with the usual care that no additional injury be inflicted or strain put upon the operated part. The treatment of shock is as for other operations and the treatment of the wound itself is as for wounds of a similar nature in other parts of the body. It is to be noted, however, that kidney complications and lung complications occur more frequently after laparotomy than after operations on other parts of the body, and that shock is a more frequent complication. For these reasons it is best to give saline solution by the rectum following all laparotomies. Either repeated enemata or the Murphy proctoclysis may be used.

Our knowledge of these cases has so increased of late years that the three main complications, shock, nephritis, and pneumonia, are rarely met with. With care in the preparation of patients, with the anesthesia, and with proper technique and speediness in operating, they will become less and less common. In former years the complication of intra-abdominal hemorrhage and of postoperative intestinal obstruction and peritonitis in various forms were the commoner complications. Nowadays, because of earlier diagnosis in inflammatory lesions, better technique at the operation and of increased care in the handling of tissues these complications are seldom met with.

The lesser complications of vomiting and distention are still frequent, but not so common as formerly. Careful anesthesia precludes the one and an efficient preoperative preparation excludes the second in most cases.

Given a *clean laparotomy* in which no operation has been done upon the intestinal canal and in which the abdominal wound has been properly made and sutured, the after course should be as uneventful as an operation upon any other part of the body. Irrespective of what operation has been done intra-abdominally there is usually no complication. The postoperative treatment is the same as in operations elsewhere. The patient is kept quiet for twenty-four hours or until the anesthetic

nausea has ceased and may then sit up or be propped up in bed. Wound quiet is maintained by the use of a tight-fitting abdominal bandage of adhesive plaster after the method of Boldt, reenforced by a snug fitting abdominal binder. The intraabdominal pressure acts in conjunction with the extra abdominal support to maintain rest of the wound. Abdominal tension is relieved by placing pillows beneath the knees. The period of rest in bed depends almost entirely upon the patient's general condition. If the patient has lost a large amount of blood at the operation, or is anemic from long-continued illness, general conditions which affect wound healing, it is best to keep him quiet in bed until such time as the blood examination showed rapid improvement in the blood condition. It is well known that wounds in anemic persons do not heal with the rapidity of wounds in robust persons. Such a wound would need support and rest for a longer time. Barring this complication, however, there is no reason why such patients should not be allowed up in bed at the end of twenty-four hours, out of bed in a chair in two or three days, and to take a few steps on the following day. The size of the wound does not contraindicate this, providing the wound has been suitably made and sutured and properly supported to insure rest. In hundreds of laparotomies treated in this manner I have not had one untoward symptom. In fact, convalescence has been hastened and wound repair made more rapid. If infection occurs it will occur irrespective of the position of the patient. Should infection occur it is treated on general wound principles and the patient is kept in bed until the infection has cleared up. When the wound has reached the condition when it can be strapped the ambulatory treatment can again be initiated.

Diet in this class of cases should be brought as rapidly as the condition of the stomach will permit to the normal diet. For the first twenty-four hours the diet is as in all postanesthesia cases; following this the diet is rapidly increased. It is to be remembered that the stomach is in a weakened condition following the use of any anesthetic and that feeding must not be forced. Nor should the ingestion of large quantities of fluid at one time or at frequent intervals be allowed, as this is apt to result in a dilatation of the anesthetic weakened stomach.

Bowels.—The bowels should be moved daily for the first few days by a copious enema of soapsuds and water. After the first few days some form of pill may be given, preferably containing aloin, belladonna, and strychnine in just sufficient doses to produce evacuation without purgation. Distention is not apt to occur in these cases except in debilitated subjects or in elderly people, or in cases in which very large intra-abdominal growths have been removed. In such cases distention is carefully watched for and its relief by enemata initiated before great distention has occurred. In the case of large growths a preventive consists in filling the abdomen with saline solution after removal of the growth. In this and in the other two cases mentioned above the distention is due to a paretic condition of the intestine. Of all the drugs which act in this regard atropine is the best. Atropine sulphate gr. 1/50 given hypodermically will aid in toning up the afferent intestinal nerve impulses. Opium or any of its derivatives should be avoided in these cases. If the distention does not subside following an ordinary enema of soapsuds and water an efficient enema is one quart of warm water in which one ounce of alum has been dissolved. This enema will succeed in bringing away the gas unless paresis is complete or unless a mechanical obstruction exists.

Pain in the first few hours following the operation is due to distention or to the traumatism inflicted at the operation, either to the wound itself or to the retraction of the abdominal muscles during the operation. In the former event the pain is relieved by enema; in the latter event one dose of one-quarter of a grain of morphine may be administered hypodermically. One does not like to use morphine because of its after effect in favoring intestinal distention. If, however, the enema fails to relieve the pain one-quarter of a grain of morphine sulphate and 1/150 gr. of atropine sulphate may be given. This dose should not be repeated except in rare instances.

Operations upon the gastrointestinal canal should be treated as above except as regards diet and catharsis. In general it may be said that following intestinal resection, repeated small doses of magnesium sulphate, one dram of saturated solution every hour or two may be given in order that the contents of the intestinal canal may be kept liquid and that impaction at the site of the Murphy button or suture line may not occur. Active cathartics should not be administered before the ninth day, at which time intestinal wound healing is complete. Intestinal wounds are supported for the first three days by the sutures; on the third to the fifth day, which is the weakest time, the sutures loosen somewhat and the parts are held together by weak union; from the fifth day on the union is firmer, until by the ninth day it is complete. During this period no cathartics should be administered which will act in a forceful manner on the musculature of the intestine. Following appendectomy, on account of the nature of the intestinal wound, this rule is not so important; it is a good plan, however, to employ enemata for the first ten days even in these cases. The diet should not be forced in intestinal resection cases but the patient should be kept on fluid and farinaceous diet until the ninth day.

Posture in Operations upon the Upper Abdomen.—Following all operations upon the upper abdomen, if the patient is placed in the semi-sitting posture or in the elevated head and trunk posture a smoother after course will be noted than if the patient is kept flat. There is distinctly less reaction following the operation, the stomach emptying itself more easily into the intestine, breathing is easier, pulmonary complications are not so frequent, and the patient is very much more comfortable.

301 DeKalb Ave.

MISTAKES IN THE DIAGNOSIS OF TYPHOID FEVER.*

By CHARLES EDWARD NAMMACK, M.D., LL.D.,

NEW YORK.

VISITING PHYSICIAN TO BELLEVUE AND TO ST. VINCENT'S HOSPITAL; PROFESSOR OF CLINICAL MEDICINE IN CORNELL UNIVERSITY MEDICAL COLLEGE AT NEW YORK.

THE average patient expects a physician to make a correct diagnosis of his ailment at the first professional visit. The younger the physician the more insistent is this demand, and an honest acknowledg-

*Read before the Williamsburgh Medical Society October 14, 1912.

ment by the doctor of his inability to comply with the demand at this time often results in his involuntary retirement from the case. An older physician may be pardoned for his honesty and permitted to continue his observations, especially if he is one of the diplomatic brethren whose clients are frequently told that they are "threatened" with a serious disease. When the "threatened" calamity does not subsequently develop, its defeat is then attributed to the superior methods of treatment adopted. But typhoid fever, at its outset, is so protean in its manifestations, and shows so many variations in its symptoms and course, and is simulated by so many different febrile and inflammatory affections that its immediate diagnosis at the bedside may be impossible. It is only by keeping its possibility always in mind that the chances of overlooking it, of mistaking it for other diseases, or of mistaking other diseases for it, will be minimized. The typical text-book case will usually be promptly recognized, but the typical case is usually found in the text-books rather than at the bedside. A recital of some of the mistakes, my own as well as those of others, that I have encountered, may serve to fasten the differential points in your memory as they have in mine. Many of these mistakes would not occur in a well-equipped hospital with excellent laboratory facilities, but we have not yet become sufficiently paternalized in this country to be able to afford to relinquish all our typhoid patients to the care of the well-endowed hospitals and laboratories. The careful clinical observations of a qualified practitioner, corroborated by the simpler laboratory blood tests and blood counts which every recent graduate is taught to make, will steer us aright in most cases. It is only their neglect which serves to emphasize the truth of the old remark, that nine-tenths of the mistakes in differential diagnosis are made by not looking, and only one-tenth by not knowing. Blood cultures, which need an elaborate laboratory equipment, are rarely necessary. The Widal reaction, available after the seventh day, and the differential leucocyte count, available on the first day, will furnish all we ought to ask—data to disprove the existence of most of the simulating diseases. Given the general picture of a febrile infectious disease, there are only six acute infections in which leucocytosis is absent, to wit: malaria, typhoid fever, influenza, measles, mumps, and leprosy. To these may be added most cases of uncomplicated tuberculosis, except the meningeal form. Let us consider some differential points.

1. *Tuberculosis.*—Acute miliary tuberculosis may present all the symptoms and signs of typhoid fever, even including the rose rash. But the respirations will be more frequent, the pulse will be proportionately rapid instead of proportionately slow and dicrotic, cyanosis will be more apt to appear, the abdomen may be flat instead of tympanitic, the temperature will be irregular instead of definite in type, phonophobia and photophobia will be notable, petechiæ may be present instead of rose spots. Widal reaction will be wanting, and a tub bath will produce a greater drop in the temperature than 2° F. A case in Bellevue Hospital at present also shows tubercles in the choroid, but this is very rare. Lumbar puncture may show tubercle bacilli in the spinal fluid.

2. *Malaria.*—In the past the term malaria has covered a multitude of diagnostic sins, but the present generation hears less of "typhomalarial fever" or "bilious remittent fever" than we did thirty years ago when hematology was an infant science. Still, estivoautumnal fever, with its continued temperature, its septic aspect, and the difficulty of finding the crescents in the peripheral blood, may keep us guessing for some days. At St. Vincent's we get many seafaring men from Southern ports with the estivoautumnal type of fever and are on the watch for it. But it may arise also in our latitude. I have seen cases that originated on the shores of Jamaica Bay, in the Borough of Queens.

3. *Typhus Fever.*—The sporadic cases of typhus fever that we see in this vicinity are of the attenuated type, so well described recently before this society by one of your members. It seems to be more prevalent among certain of your neighbors than with us across the Williamsburgh Bridge. I have seen but two cases in Bellevue in the last two years and none in St. Vincent's. It is easily recognized when once known.

4. *Septicemia.*—Originating after labor or after abortion, this condition is often miscalled "typhoid fever," especially by that class of practitioners who have "never lost a woman after confinement." Leucocytosis and an increase in the polymorphonuclears will assign the proper label to this condition. A fatal case of gonorrheal septicemia with ulcerative endocarditis, occurring in a young man with old rheumatic simple endocarditis, was sent into our wards at Bellevue with a diagnosis of typhoid fever, but leucocytosis suggested and blood culture proved the actual conditon. An additonal reason, if any were needed, why young people with chronic endocaditis should avoid tacking on an acute gonorrheal infection.

5. *Endocarditis.*—As in the supervention of gonorrhea, the addition of typhoid bacilli to the circulating blood of a patient with old endocarditis renders the liability to ulcerative lesions of the heart lining very grave. An undamaged endocardium usually resists their invasion.

6. *Influenza.*—Many cases of influenza are so typhoidal in their aspect at the onset that only the subsidence of the influenzal symptoms in a few days dispels our anxiety. Some cases may require a blood culture to decide.

7. *Febricula.*—Many of the cases of short continued fever formerly classified under this head and some of the so-called "gastric fever" cases would now be demonstrated by the Widal reaction to be mild forms of typhoid.

8. *Intoxication.*—The various autointoxications which for want of more definite knowledge we regard as ptomaine poisoning can usually be differentiated by their suddenness of onset, the violence of their initial symptoms and their reference to an obvoius dietetic indiscretion.

9. *Osteomyelitis.*—A case seen by me was that of a young man who, suffering from a crop of boils, worked at a hand drill all the week, pitched baseball on Sunday, and was taken ill with chill, sweats, high fever, and pain referred to the shaft of the humerus. He was treated four days for malaria, three days for rheumatic fever, three days for typhoid fever, this by four different physicians. The leucocyte count was 26,000 with 89 per cent. polymorphonuclears, and trephining the shaft of the bone at St. Vincent's Hospital confirmed my diagnosis. This case had almost become one of the tragedies resulting from "not looking." Osteomyelitis has been called "bone furunculosis." It is one of the diseases we should always think of in childhood and adolescence.

10. *The Acute Exanthemata.*—Measles, scarlet fever, and variola will soon clear up their own diagnosis and need no description here.

11. *Trichinosis.*—Cases of trichinosis are frequently sent into hospitals with a diagnosis of typhoid fever. Leucocytosis with abnormal eosinophilia will point the way to, and excising a piece of muscle will establish, the correct diagnosis.

12. *Syphilis.*—Secondary syphilitic fever with macular eruption will not be mistaken when associated with sore throat and adenopathy. The absence of the Widal and the presence of the Wassermann reaction will decide the doubtful cases.

13. *Cerebrospinal Fever.*—Leucocytosis and the results of lumbar puncture have recently placed the diagnosis of this condition on much firmer ground. In my earlier days mistakes were common. The same diagnostic procedures will be of much service in the recognition of other forms of meningitis and also in a variety of diseases with nervous manifestations in which fever with more or less stupor are prominent features.

14. *Pulmonary Conditions.*—The initial bronchitis of typhoid fever may be so severe as to concentrate our attention on that condition. Or typhoid may set in with an unmistakable attack of acute lobar pneumonia which may entirely overshadow, or even obliterate, the usual low leucocyte count and slow pulse of typhoid. No amount of care will save us from this mistake, if it can justly be so called. The term pneumotyphoid should not be used for these cases.

15. *Abdominal Conditions.*—An Italian suffering from typhoid fever was admitted to my service in Bellevue who was seized in the middle of the night with violent gastroenteritis after a supper into which green peppers had largely entered. He had been treated for five days by a physician of his own nationality for appendicitis. This was a pardonable error with the given history of sudden onset and violent symptoms. The first typhoid patient of my own upon whom I had mistakenly advised an operation for appendicitis caused me considerable chagrin, although I had only sustained the diagnosis of a man of sufficient experience to be chief of clinic at a college dispensary, and we had both been sustained by the operating surgeon. Study of the literature lessened my shame, when I found that the same error had been often made by the best surgeons. Richardson of Boston emphasizes the most important differential point, to wit: *Muscular rigidity is wanting.*

16. *Renal Conditions.*—A young policeman came to my office one evening complaining of headache, dimness of vision, and scanty urine. I had incised a suppurative tonsillitis for him ten days previously. His urine presented the characteristic physical, chemical, and microscopical evidences of acute desquamative nephritis, and he was sent to Bellevue with that diagnosis. He afterward ran the typical course of typhoid fever. This was one of the so-called nephrotyphoid cases.

17. *Varieties of Typhoid.*—As stated at the outset, age cannot wither nor custom stale the infinite variety of typhoid, and he who studies his typhoid cases attentively will not only acquire a fund of knowledge regarding the working of the acute infections in general, but also a knowledge of the sanitary intelligence of the community in which he resides. Cases may be classified as the malignant, which are usually fatal from cardiac degeneration, severe toxemia, or intestinal hemorrhage and perforation; the mild, which are only dangerous in so far as they may be the means of communicating the disease to others; the ambulatory, which are dangerous to themselves because of their marked liability to hemorrhage and perforation; the hemorrhagic, by which is meant those in which bleeding occurs from various parts of the body, and of which the majority of cases die; the afebrile, which I have never seen; the obese, who, as a rule, do badly.

18. *Paratyphoid Fever.*—The diagnosis of this condition is made only in the laboratory. Symptomatically, diagnostically, or therapeutically, it does not differ from ordinary typhoid, and it need not cause the working practitioner any more doubt or delay than does the particular organism producing a felon on the finger, whose quietus he knows that he can make with a bare bodkin, without calling in a laboratory man to identify the germ.

42 East Twenty-ninth Street.

A NEW GASTROESOPHAGOSCOPE.

By JULIUS LONDON, M.D.,

NEW YORK.

ADJUNCT VISITING GENITOURINARY SURGEON BETH DAVID HOSPITAL; GENITOURINARY SURGEON, O. P. D., LEBANON HOSPITAL; ASSISTANT GENITOURINARY SURGEON, O. P. D., MOUNT SINAI HOSPITAL.

In this article I desire to describe a new gastroesophagoscope which I have devised. It consists of three major parts. The outer sheath is simply a straight, round, metallic tube, 23½ inches long and one-half inch in its internal diameter. It is beveled at its distal end and flattened in one diameter so that the distal opening is oval instead of round, as the proximal one is. This tube is used as an introducer for the other parts, but can also be used as a direct esophagoscope with an external source of illumination, such as a head reflector or a handle reflector, as in the Bruning apparatus.

The middle sheath is oval in shape and 26 inches long. At the proximal end of this sheath are attached two cocks for distention of the stomach and a catch for electric connection. At the distal end of this sheath is a cluster of lights for illumination of the entire horizon and a terminal rubber tip, which acts as an introducer into the pharynx, esophagus, and stomach. The distal end, just described, is connected to the main body of the middle sheath by two slender rods which carry the electric connections.

The inner tube contains the optical system. This is composed of a straight telescopic system and my objective lens, which is placed in front of the telescope and connected to it by two slender rods.

This objective is made in two forms, one the biconvex lens and the other the perfect sphere. One-half of this lens is silvered, the unsilvered portion being nearer the telescope, so that rays of light reflected from the mirrored surface can enter the telescope and be conveyed to the eye. This spherical objective has an angle of vision of 150° in water and 100° in air and it shows the entire horizon in the same field without any rotation of the instrument. This objective has a practical marking near its point of one-quarter of an inch.

763 East One Hundred and Fifty-sixth Street.

Acquired Hemolytic Icterus.—Oulmont and Boidin report a case of this condition presenting the well known clinical and hematological phenomena. Syphilis seemed to be the important etiological factor. A striking manifestation in this case was the marked diminution in the amount of cholesterin in the blood.—*La Presse Médicale.*

VACCINE VIRUS.

IT is strange that the exact form of the germ or poison of smallpox remains unknown, because it, that is the virus, was the first to be used to produce artificial immunity. In the century and a half just passed only two important advances have been made in the methods for obtaining immunity to smallpox. The first was made with the discovery by Jenner in regard to cowpox: this led to an entirely new method which superseded the previous method of direct inoculation with smallpox virus. The second advance, made in a negative way, came with the control of the production of vaccine virus by excluding as far as possible the admixture of other pathogenic germs and the attenuation of the thousands of extraneous germs which are present by exposing them to the action of glycerin for a certain period.

As to the details of the method of vaccination itself and the after-treatment we have not even kept abreast of Jenner if we accept the general practice throughout this country as a criterion; for it does not seem to be generallly known that a single scratch is sufficient for inoculation and that it is perfectly proper on the fifth day when the vesicles appear to apply any of the mercurial ointments just as Jenner did, and thereafter to treat the local inflammation with a view to curing it. From the widespread practice of permitting vaccination shields there would seem to be a general deep-rooted conviction that vaccinia must run its course undisturbed. Such a conviction is not founded on the fullest knowledge of vaccinia, and the practice of leaving the vesicles exposed to infection is the cause of most of the secondary inflammations which have been the real source of developing antagonism to vaccination, on the part of a large portion of the laity.

This antagonism, together with ordinary neglect, has permitted the occurrence of epidemics of smallpox. Every step toward preventing such occurrences is to the honor of medicine; especially any attempt to perfect the method and to remove the dangers of vaccination. Recently Teissier, Duvoir, and Gasinel (*Journal de Physiologie et de Pathologie générale*, Vol. XIV, No. 5, 1912) report the results of experiments with vaccine virus introduced into the system by different routes. These experimenters used rabbits. Some of these they inoculated intravenously. By this method they always succeeded in obtaining the development of immunity to subsequent epidermal inoculations. Others were inoculated by subcutaneous injection, intraperitoneal injection, or the administration of the virus by the digestive tract. By all of these methods immunity was developed and in no case was there a generalized eruption. When the virus inoculated in the peritoneal cavity was placed within collodion sacs, the immunity was slower in its developing and much larger doses were required for its production.

Although these results are very striking in experiments upon animals, the authors are of the opinion that they are of only experimental value and conclude in recommending the epidermal as still the method of choice. We have noted their results as they serve to emphasize that much of the diagreeable part of vaccination is due to extraneous infection. It is to be hoped that research along this line will be continued until some material advance over the crudeness of vaccination as new practised is reached. No other infectious process is so accessible to research students, and much work has been done in studying the morphology of the lesions and the biological properties of the virus. The fact that the latter resists some of the ordinary antiseptics, passes through a filter, and acts in extreme dilutions has caused it to be regarded as of the nature of an enzyme by some students, while others have explained its properties by regarding it as a protozoan. Life-cycles have been described for the Guarnieri bodies, the cellular inclusions found in the corneal cells of the rabbit's eye when inoculated with vaccine virus, and for parasites as small as the *Chlamydozoa* of Prowazek.

THE ESTHETIC ASPECTS OF MEDICINE.

IT was Socrates who taught that beauty is one with utility. Whether or not modern philosophers agree with this conception, there can be little doubt that beauty is incompatible with disease. The human form which has appealed to both the plastic and the graphic arts as the highest type for representation depends for its perfection upon the maintenance of health. Whether the artist's ideal is one of strength or of grace, of symmetry or of agility, it is certain that none of these attributes can be delineated apart from the normal organism. If the physicians' highest aim is the guidance of the individual in the preservation of health, then the former becomes, if not the artist, at any rate the honest servant of art.

In spite of the truth of the above statements, it must be admitted that some of the sublimest phases of art that were the product of subtle flights of the imagination were nevertheless the offspring of minds that were not entirely normal. The sparkling reveries of De Quincey or of Coleridge betrayed the narcotic influence of opium, and the enchanting romanticism of Keats or of Stevenson evinced the stimulating effects of tuberculous toxins. These and other instances provide the exceptions that prove the general rule that health and beauty are almost equivalent terms.

In his recent work on "Conduct and Its Disorders" Mercier states that "from the point of view of pure biology—of the preservation of the stirp—the appreciation of beauty, and the considerable department of conduct that is based upon, and prompted by, the appreciation of beauty are not easily explicable. Grace of motion, indeed, means ease of motion. It implies complete and efficient mastery over the movements, so that the maximum of effect is produced with the minimum of effort; and it is clear that this is biologically advantageous. *Cæteris paribus,* graceful movement is economical movement.

"We recognize form by ocular movements, and the application of the term 'graceful' to form as well as to movement rests upon an inarticulate, unexpressed recognition, that the appreciation of both is at bottom the same. Esthetic conduct is no exception to the rule that all conduct is ultimately based upon the motive of reproduction of the race. The earliest glimmerings of esthetic conduct in the human race are exhibited in personal adornment for the attraction of the opposite sex, and whatever esthetic conduct is exhibited in the lower animals, whether in the decoration of their haunts by the bower birds; in the display of their adornments by birds of beautiful plumage; in the exhibition of brilliant colors, or graceful movements or attitudes, by other animals; all are limited to the period of courtship if they are not confined to the actual pursuit of courtship. Esthetic conduct actually owes its origin, in fact, to the motive of sexual attraction, and is the earliest, as it is the most efficient, means of purging the approaches of courtship of their grosser elements or signification and elevating the whole process to a higher plane. Once the value of beauty and the love of beauty as aids to the fundamental function of courtship are established, in process of time beauty becomes, by anticipation of motive, an end to be pursued for its own sake."

One cannot overestimate the importance of certain esthetic details in the physician's *entourage* that contribute an appreciable share to his efficiency. The personality of the doctor should provide the pleasing combination of strength and refinement, of dignity and condescension. No other calling demands from its votaries such studied attention to the correctness of dress and of manner. The person who is ill is more susceptible than any other to the apparently trifling factors of the physician's environment. The orderly appearance of the latter's home, particularly of his waiting and consulting rooms, and the taste displayed in their decoration and furnishing, cannot but impress the patient with the prosperity and good judgment of the physician, and create that ease of mind and that confidence which are important factors in the successful outcome of any form of treatment.

The secret of artistic decoration is to be sought in its unobtrusiveness. Simplicity is to be chosen in preference to elaborate display. The pictures should not suggest any of the painful episodes in the history of medicine nor should there be any ambitious exploitation of the nude in art. Physicians who indulge in the laudable though expensive avocation of collecting art objects frequently convert their rooms into a veritable museum—whether of old mosters, tapestries, Japanese urns, or rare bindings. There is a growing and commendable tendency to banish as much as possible from the consulting room all outward evidences of the physician's calling—such as by concealing surgical instruments behind the stained glass doors of cabinets. Some gynecologists have found that the decoration of, or even the fastening of framed pictures upon, the ceiling, may aid in distracting the attention of the patient upon the examining table. There is, however, nothing that can add to the physician's rooms a cheerfulness as great as that afforded by the presence of fresh flowers, which bring the beauty and the repose of the outer world and help to counteract the mental depression of the ailing individual.

THE MOISTENED TRANSFER SLIP.

THE hygienic aspects of the street-car transfer constitute one of the few subjects that were not discussed at the recent Congress of Hygiene in Washington. There is a growing tendency to minimize the danger of transmission of disease through the agency of fomites of currency, and of books. There is perhaps small likelihood that the street-car transfer may be a means of carrying contagion. Street-car conductors at any rate constitute a healthy group of individuals. Nevertheless, the fact that millions of the little slips of paper daily pass from hand to hand in the larger cities is sufficient basis for the elimination of all danger of thereby disseminating disease, however slight this danger may be.

There is a peculiar irony in the advice printed on the back of transfers issued on some of the car lines of New York: "If you have tuberculosis do not give it to others by spitting in this car." Yet the very transfer that is made the vehicle of this important bit of hygienic information is in nearly every instance moistened with the saliva of the conductor who hands the slip of paper to the passenger. The latter, if careful, may avoid bringing his fingers in actual contact with the ominous moistened area on the paper. The physician with his knowledge of the potentialities of tuberculosis sputum, of the secretion from mucous patches, and of the secretions from throats and mouths that may harbor virulent strains of pneumococci or of other microorganisms, will at least hesitate to accept a transfer saturated with the conductor's saliva.

It would not be a matter of insuperable difficulty to put an end to this evil. The officials of the car lines should prohibit this practice on the part of their conductors. If the pad of transfers were constructed with a beveled edge, the single slip could be easily grasped without the necessity of moistening the finger. Would it not be a distinct advance in public hygiene if all people would avoid the practice of moistening the fingers before taking up articles such as wrapping paper, and if all mercantile establishments would make this a stringent rule with their employees? Both esthetic and hygienic needs would in this way be satisfied.

Chemistry of Cancer "Soil."

The analogy which must subsist between the chemical constitution of tissues disposed to tumor growth and infection with germs on the one hand and that of artificial culture media on the other, has long been remarked. A familiar concrete example is seen in diabetes in which the saturation of tissues with the saccharated plasma may be likened crudely to the addition of sugar to bouillon; in either case certain germs thrive the better in the soil because of the sugar content. In the Freund and Kaminer reaction in which cancer cells are not attacked by the patients' own serum, but are destroyed by the serum of a healthy subject, some definite chemical substance is evidently responsible for this result. At a recent session of the Royal Imperial Medical Society of Vienna (*Berliner klinische Wochenschrift*, November 4) Freund announced that this substance is a fatty acid soluble in ether and containing no nitrogen. The absence of this reaction in the cancerous they impute to the presence of a protective nucleoglobulin. It is by no means impossible, therefore, that this latter substance sensitizes the tissues to cancer. Extirpation of the latter in such a case does not by any means assure the future welfare of the patient even when all the diseased tissues are extirpated. This conclusion is borne out by clinical experience. Freund has experimented with extracts of various tissues, normal, and pathological (in reference to predisposition to cancer). From these experiments he has built up a structure of facts which show that there is a natural defence to cancer in the tissues, and that only when this is lacking can the nucleoglobulin mentioned protect the cancer cell. The presence of the nucleoglobulin is systemic, making a factor of predisposition. But the failure of natural defence is not general but local. The menace of cancer is, therefore, twofold—in the first rank local, in the second general. If it can be shown that this peculiar nucleoglobulin is not resident in a patient's tissues the likelihood of his death from cancer, Freund believes, is at least greatly diminished.

News of the Week.

Clearing House for Defectives.—At a meeting of the Women's Municipal League of New York on December 12, announcement was made of the raising of a fund to make permanent the work of the so-called Clearing House for Defectives, which was organized recently by Dr. Max G. Schlapp in connection with the Department of Charities. The work has heretofore been done entirely by volunteers.

United States Public Health Service.—The Board of Examiners of the Public Health Service will meet in Washington on January 13, 1913, for the purpose of examining candidates for admission to the grade of assistant surgeon in the service. Candidates must be between twenty-three and thirty-two years of age and graduates of a reputable medical college, with at least one year of hospital work or two years of professional experience after graduation. The examinations are: 1, physical; 2, oral; 3, written; 4, clinical. Successful candidates will be numbered according to their attainments and will be commissioned in the same order as vacancies occur. After four years, assistant surgeons are entitled to examination for promotion of higher grades. The salary for assistant surgeons is $2,000, for passed assistant surgeons, $2,400. Further information may be obtained on application to the Surgeon-General, Public Health Service, Washington, D. C.

Nobel Prizes Presented.—The winners of the Nobel Prizes for 1912, including Dr. Alexis Carrel of New York, to whom the prize in medicine was awarded, were guests at a banquet given by the King of Sweden on December 10, when the prizes were distributed by His Majesty.

New Head of the Bureau of Chemistry.—President Taft has appointed by Dr. Carl Alberg to succeed Dr. Harvey W. Wiley as head of the Bureau of Chemistry of the Department of Agriculture.

Hospital for the Ruptured and Crippled.—The new hospital of the New York Society for the Relief of the Ruptured and Crippled was opened on Monday of this week. Addresses were made by the president of the society, Mr. William Church Osborn, and by the surgeon-in-chief, Dr. Virgil P. Gibney. The buildings were thrown open to the inspection of the public on Monday and Tuesday. The new building is on a lot 200 x 200 feet at 303 to 325 East 42d street. It is fireproof, five stories high, and of the Northern Italian Renaissance style. In the basement are the kitchen, laundry, lighting and heating plants, and workshop. On the first floor are the reception rooms, general offices, dispensary, waiting rooms and rooms for special treatment. On the second floor are the living quarters for the staff. There are four wards on the third floor and a large dining-room. The fourth floor contains wards and operating rooms. On the fifth floor are the schoolrooms and a room for luncheon. The sixth floor contains fresh air rooms and a solarium. There are accommodations for 225 children.

Opposition to Foreign Students in German Universities.—A despatch to the *New York Times* says that, under the leadership of undergraduates of the University of Halle, the medical students of Germany's twenty-three universities are organizing a strike against the alleged favoritism shown to foreign medical students at Halle, where one-third of those attending the medical college are foreigners, including many Americans.

New Cancer Home.—St. Rose's Free Home for Incurable Cancer at 71 Jackson street, near Corlears Park, New York, was opened by Cardinal Farley on December 15. The home has accommodations for more than a hundred inmates and is intended to provide medical care and shelter for persons who are suffering from cancer and are without means. Both men and women will be admitted. The institution is supported by private charity.

Report of the Surgeon-General of the Navy.—The annual report of the Surgeon-General of the United States Navy made public on December 11, states that while contagious diseases have markedly decreased among the men in the navy, mental diseases are decidedly on the increase. The greatest number of fatalities among the men, however, was due to drowning, and the Surgeon-General urges that all sailors and officers be compelled to take a course in sea swimming wherever possible, which would seem to be a reasonable requirement. Another interesting statement contained in the report is that an investigation of the records at the Narragansett

Training Station has led to the estimate that 28 per cent. of those enlisting from the Southern States are infected with hookworm, and that of these 50 per cent. come from South Carolina and Alabama. It is estimated, also, that 90 per cent. of the inhabitants of Samoa and Guam carry the hookworm, that 50 per cent. have incipient and active tuberculosis, and that both diseases are on the increase.

Secretary of Medical Examiners.—The Regents of New York State at a meeting on December 12, appointed Dr. Otto von Huffman of New York City as secretary of the State Board of Medical Examiners, to succeed Dr. Maurice J. Lewi, resigned. Dr. von Huffman is a graduate of the College of Physicians and Surgeons, and is at present pathologist to the Sloane Hospital for Women and instructor in clinical pathology at the college.

Babies' Welfare Association.—The permanent organization of this association which has done good work in New York during the past few months was effected at a meeting held at the Academy of Medicine on December 12. The association is made up of seventy different philanthropic and medical societies, and has for its aim the lessening of infant mortality, in which it was very successful last summer. Commissioner of Health Ernst J. Lederle has been elected honorary president of the association.

Hospital Dedicated.—The Seraphic Heights Hospital of Waterloo, Ia., was dedicated on December 4, by the Archbishop of Dubuque. The hospital has been built by the Sisters of the Franciscan Order at a cost of about $200,000.

Nurses Graduate.—Eleven young women received diplomas from the Training School for Nurses of the Beth Israel Hospital at the ninth annual commencement exercises of the school on December 10.

New Tuberculosis Hospital.—The Supervisors of Suffolk County, New York, on December 14, voted to build a hospital for the treatment of tuberculosis. A plot consisting of some forty acres near Holtsville, Long Island, will probably be selected, and a building costing $50,000 erected. Suffolk is the twenty-seventh county in New York State to build such a hospital.

Deaths from Pellagra.—The report of the United States Public Health Service issued in Washington on December 14, places the number of persons who have died from pellagra in the years from 1907 to 1911 at 6,205. During these years a total of 26,000 cases were reported by various physicians and institutions in the Southern States, of which 2,500 were in Tennessee and 1,500 in Texas.

Deaths in New York.—During the week ending December 7 there were in New York City 1,420 deaths, or two more than during the same week last year. For the forty-nine weeks of 1912 thus far elapsed the death rate was 14.08, as compared to 15.09 for 1911.

Letchworth Village.—The plans for the development of the colony for the segregation of the epileptics and feeble-minded in New York State, to be known as Letchworth Village, have reached a point where contracts can be let for ten buildings, and it is hoped that the work of construction will be under way by next spring. This group will comprise four dormitories, an attendants' home, a dining hall, a laundry, a shop, a power plant, and a storehouse, the last four being sufficient for the needs of the entire village when it is completed. Ultimately there will be six groups of buildings, each containing eight dormitories, an industrial building, attendants' home, dining hall and kitchen, and school houses when needed. The total accommodation will be 500, the inmates being divided into three classes: improvable children, able-bodied adults, and infirm adults. In planning the buildings and laying out the village every effort has been made to secure a maximum of administrative efficiency with a minimum of expense, so that it may be demonstrated how economically the policy of segregating mental defectives can be carried out. The buildings themselves will be constructed of the field stone on the site and have been planned with especial reference to the peculiar needs of those who will occupy them.

Medical Missionaries Needed.—The Student Volunteer Movement for Foreign Missions announces the need of a woman physician for the Mary S. Ackerman Hoyt Hospital and Dispensary for Women and Children at Jhansi, India; of a woman physician in the Canadian Presbyterian Mission, working in the northeastern part of the Korean Peninsula, with headquarters at Jen San, about 135 miles north of Seoul; and of five trained nurses in Christian hospitals in Turkey, India, and Ceylon. All inquiries in regard to these opportunities may be sent to Mr. Wilbert B. Smith, 125 East Twenty-seventh street, New York.

Section on Orthopedic Surgery.—The American Medical Association, recognizing the increasing importance and usefulness of this special line of surgical work at its meeting last June, formed a Section on Orthopedic Surgery with Dr. Newton M. Shaffer of New York as chairman. This step was taken partly as a result of the desire of the American Orthopedic Association to limit its membership to a comparatively small number—those devoting their entire time to the study of this branch. The development of orthopedic surgery as a separate field has been rapid. It began about 1860 under the influence of such men as Davis, Taylor, Sayre, Knight, and Bauer; but it was not until the early 80's that the New York Orthopedic Society was formed, and not until 1887 that the national society, the American Orthopedic Association, was organized. In 1890 the International Congress at Berlin recognized orthopedic surgery and assigned it a special section, and at the Congress to be held in London next summer the subject will also occupy an important place. The first meetings of the new section will be held in Minneapolis in June, 1913, and the chairman asks for the cooperation of all those members of the American Medical Association who are interested in this field, in the preparation of a program. Application for permission to present contributions should be sent to the secretary, Dr. John Ridlon, 7 West Madison street, Chicago, Ill.

Personals.—Mr. Richard Lake, F.R.C.S., of London arrived in New York on December 12, lectured before the Section of Otology of the New York Academy of Medicine the next evening, and sailed for home on the *Mauretania* on December 18.

Dr. Jules Constantin of Paris, who was formerly an assistant to Dr. Doyen of that city, but more recently an aviator attached to the Bulgarian Army, was killed while flying in his biplane over the Turkisk Army at Tchatalja. Dr. Constantin had gone aloft carrying bombs to drop into the Turkish intrenchments.

Dr. H. W. Powers has resigned his position as Medical Superintendent of the Kenilworth Sanitarium, Kenilworth, Ill., and has been succeeded by Dr. Sherman Brown, formerly assistant physician of the Kings Park State Hospital, New York.

Gifts to Charities.—Under the will of the late Prof. Morris Loeb of New York University, a bequest of $250,000 subject to a life interest of his widow, is made to the Solomon and Betty Loeb Home for Convalescents.

The will of Dr. John D. McGill of Jersey City, who died last Thanksgiving Day, directs that his surgical instruments be given to St. Francis Hospital, Jersey City.

The Passaic, N. J., General Hospital receives $200,000 as a trust fund in perpetuity, the income to be used for maintenance, and St. Mary's Homeopathic Hospital, Passaic, the income of $20,000 for five years and then the principal, by the will of the late Mr. Peter Reid of Passaic.

The Good Samaritan Hospital of Lexington, Ky., receives $5,000 by the will of the late Mr. James M. Duff of that city.

Medical Society Elections.—The Dallas County (Ala.) Medical Society: Annual meeting at Selma on December 5. Officers: *President*, Dr. Edward B. Ward, Selma; *Vice-President*, Dr. S. B. Allison, Minter; *Secretary-Treasurer*, Dr. B. B. Rogan.

St. Clair County (Ala.) Medical Society: Annual meeting at Odenville on December 5. Officers: *President*, Dr. W. B. Johnson, Ashville; *Vice-President*, Dr. P. G. Dunlap; *Secretary-Treasurer*, Dr. J. P. Hawkins, Ragland.

Morgan County (Ala.) Medical Society: Annual meeting at New Decatur on December 5. Officers: *President*, Dr. John B. Shelton, New Decatur; *Vice-President*, Dr. A. M. White, Hartsells; *Secretary-Treasurer*, Dr. W. C. Bailey, Decatur.

Etowah County (Ala.) Medical Society: Annual meeting at Gadsden on December 5. Officers: *President*, Dr. A. W. Ralls, Gadsden.

Calhoun County (Ala.) Medical Society: Annual meeting at Anniston on December 3. Officers: *President*, Dr. T. J. Brothers, Anniston; *Vice-President*, Dr. S. T. Mehard, Weaver; *Secretary*, Dr. I. P. Levi, Anniston; *Treasurer*, Dr. E. C. Anderson, Anniston.

Jefferson County (Ala.) Medical Society: Annual meeting at Birmingham on December 2. Officers: *President*, Dr. Henry Silas Ward, Birmingham; *Vice-President*, Dr. J. T. Kent, Ensley.

Tuscaloosa County (Ala.) Medical Society: Annual meeting at Tuscaloosa on December 2. Officers: *President*, Dr. George H. Searcy; *Vice-President*, Dr. C. E. Elgin, Searles; *Secretary-Treasurer*, Dr. J. A. Maxwell.

Crisp County (Ga.) Medical Society: Annual meeting at Cordele on December 4. Officers: *President*, Dr. T. E. Bradley, Cordele; *Vice-President*, Dr. M. R. Smith, Cordele; *Secretary-Treasurer*, Dr. A. J. Whelchel, Cordele.

Allen County (Ind.) Medical Society: Annual meeting at Ft. Wayne on December 3. Officers: *President*, Dr. W. O. Gross, Ft. Wayne; *Vice-President*, Dr. D. J. Mercer, Poe; *Secretary*, Dr. Garrette Van Sweringen, Ft. Wayne; *Treasurer*, Dr. E. E. Morgan, Ft. Wayne.

Howard County (Ind.) Medical Society: Annual meeting at Kokomo on December 6. Officers: *President*, Dr. William Scott, Kokomo; *Vice-President*, Dr. F. N. Murray, Center; *Secretary-Treasurer*, Dr. E. M. Shenk, Kokomo.

Madison County (Ill.) Medical Society: Annual meeting at Alton on December 6. Officers: *President*, Dr. J. M. Pfeiffenberger, Alton; *Vice-President*, Dr. E. A. Cook, Alton; *Secretary*, Dr. E. W. Fiegenbaum, Edwardsville; *Treasurer*, Dr. R. S. Barnsack, Edwardsville.

Public Bath.—Plans have been prepared for the erection on Twenty-eighth street, near Ninth avenue, New York, of a four-story public bath and gymnasium to be owned by the city. The cost is estimated at $170,000.

The Late Dr. von Ramdohr.—At a stated meeting of the Medical Board of St. Mark's Hospital of New York City, held at No. 177 Second avenue, in said city, December 3, 1912, the following resolutions were unanimously adopted: *"Whereas,* Time in his unswerving course has removed from our midst Dr. Cæsar A. von Ramdohr, an associate, who was one of the founders of our hospital, knowledge of whom engendered not only respect for his honesty of purpose and indomitable courage of conviction but personal affection because of the uniform kindly courtesy of his deportment; *Whereas,* His faithful services abundantly show his unswerving attention to duty, and these services, eagerly sought by those suffering, made him endeared to every professional and lay member of the hospital, and his counsel was often asked and eagerly accepted, as it was cheerfully given; *Whereas,* In his life he had acted to his professional brethren who were troubled in their career, with the utmost consideration, with unusual kindness and courtesy, and his services were sought and given cheerfully; *Whereas,* His genial companionship, his uncommon charm of manner and courtliness of address, attracted and held the admiration and affection of all with whom he came in contact. Therefore, be it RESOLVED, That the sympathies and condolence of the members of the Medical Board of St. Mark's Hospital of New York City, be and hereby are, extended to the bereaved family, and furthermore, be it RESOLVED, That these resolutions be spread upon the minutes of the Medical Board and published in the principal medical journals.

"(Signed) IGNATZ MORVAY ROTTENBERG, M.D., BENJAMIN T. TILTON, M.D., ANDREW VON GRIMM, M.D."

Obituary Notes.—Dr. EDWARD F. SCHWEDLER, retired, of New York, a graduate of the University of Leipzig, Germany, in 1848, and formerly a visiting surgeon at the German Hospital, New York, died at his home on December 7, aged 90 years.

Dr. ALVIN M. CUSHING of Springfield, Mass., a graduate of the Homeopathic Medical College of Pennsylvania, Philadelphia, in 1856, died at his home after a long illness on December 1, aged 83 years. In 1866 when Mrs. Eddy, the discoverer of Christian Science, was injured in a fall, Dr. Cushing attended her through a rather serious illness. Mrs. Eddy in later years referred to her recovery as "a divine cure" and dated Christian Science from that experience. Dr. Cushing, however, possessed proofs that the "divine cure" was in reality his.

Dr. RICHARD J. BRADY of Hastings, Minn., a graduate of the Jefferson Medical College, Philadelphia, in 1909, died in St. John's Hospital, St. Paul, of typhoid fever, on November 26, aged 28 years.

Dr. CHARLES HENRY THOMPSON of Belmar, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1868, a member of the New Jersey State and Monmouth County Medical So-

cieties, and formerly mayor of Belmar, died at his home suddenly on December 3, aged 69 years.

Dr. H. J. Salley of Salley, S. C., a graduate of the Medical College of Georgia, Augusta, in 1885, died at his home on November 23, aged 52 years.

Dr. William G. Crum, United States Minister to Liberia, a graduate of the Howard University School of Medicine, Washington, and formerly Collector of the Port of Charleston, his appointment to that post by President Roosevelt, in 1903, having met with great opposition, died at his home in Charleston, S. C., from African fever contracted in Monrovia, on December 7, aged 54 years.

Dr. Robert A. Gunn of New York, a graduate of the University of Buffalo, Medical Department, in 1866, died in Bellevue Hospital on December 7, aged 48 years.

Dr. Daniel Stanislaus Harkins of Boston, Mass., a graduate of Montreal University and of the Harvard Medical School in 1888, formerly resident physician in the Boston city institutions on Long and Rainsford Islands, and for two years quarantine physician of the port, and a member of the Massachusetts State and Suffolk County Medical Societies, died at his home of Bright's disease on December 8, aged 48 years.

Dr. William D. Humphrey of Virginia, Ill., a graduate of the Northwestern University Medical School, Chicago, in 1889, and a member of the Illinois State and Cass County Medical Societies, died at his home on December 4 as the result of injuries sustained in an accident some weeks before.

Dr. Toliver Wertz of Princeton, Ind., a graduate of the Bellevue Hospital Medical College, New York, in 1879, and a member of the American Medical Association and the Indiana State and Gibson County Medical Societies, died at the home of his daughter in Altoona, Pa., on December 6, aged 64 years.

Obituary.

ELLSWORTH ELIOT, M.D.,

NEW YORK.

Dr. Ellsworth Eliot of New York died at his home from acute bronchitis on December 9, in the eighty-sixth year of his age. Dr. Eliot was graduated from Yale University with the degree of A.B. in the class of 1849, the class that also numbered Timothy Dwight, later president of the University, among its members, and three years later was graduated from the College of Physicians and Surgeons, New York. After leaving the medical school he entered Bellevue Hospital as an interne on the surgical service and was one of the first graduates of that institution. The breaking out of the Civil War found him enlisted in the Union Army, in which he served with distinction until 1864, when he returned to private practice in this city. His interest in medical education was keen and for many years he acted as a trustee and registrar of the College of Physicians and Surgeons. His other activities were numerous, and he was a member of the American Medical Association, the New York Academy of Medicine, the New York State and County Medical Societies, serving as president of the last in 1872 and 1873, and of the New York Pathological Society, in which his membership dated back to 1855. Dr. Eliot was also consulting physician to the Northeastern Dispensary, New York.

Correspondence.

OUR LONDON LETTER.

(From Our Special Correspondent.)

DEPUTATION TO THE CHANCELLOR—MEDICAL PROBLEMS CONNECTED WITH WAR—SARCOMA OF LONG BONES—THE R. S. M.'S EXHIBITION AND CONVERSAZIONES—DEATH OF MR. TEGETMEIER, THE NATURALIST.

London, Nov. 29, 1912.

The Chancellor of the Exchequer received the deputation of the B. M. A. on Monday and again on Tuesday. On Thursday a report of the conference was submitted by the delegates to the State Sickness Committee. The Council will meet on Wednesday next, December 4, to consider the present position. The Council do not propose to publish the revised and final terms of the Government until next week, but will after their meeting transmit the documents concerning the situation, with their own observations, to the divisions of the association in the United Kingdom. Meantime it is undesirable that any member, or body of members, should negotiate with any Insurance Committee. All divisions in the kingdom will then be called upon to hold special meetings and take a vote accepting or rejecting the revised terms and conditions. Non-members of the association who are qualified practitioners in the districts will be invited to these meetings. It seems a roundabout sort of proceeding, but is in accordance with the constitution of the B. M. A., and so we must await the result.

The medical problems connected with war have naturally of late demanded attention from civilian surgeons, as well as those engaged in the military and naval services. Dr. F. M. Sandwith considered the subject historically in his Gresham lectures from about 450 B. C., and had to note the barbarities which went on for so many centuries before there was any record of a hospital on the field of battle—the first being in 1487. But even in the Crimean war the army medical service broke down as completely as any on account of the divided rule which caused so much confusion.

On November 13, at the United Service Medical Society, Col. Bruce Skinner, M.V.O., read a paper in which he pointed out how much the mobility of an army is influenced by the necessities of the medical units, and how desirable it is that the medical staff should study war in order to be able to grasp the designs of the general commanding and foresee what may have to be provided for. It is a fundamental principle that a field medical unit must not become clogged with sick and wounded. Free evacuation toward the base is, therefore, imperative. The fewer the sick in front the more the supplies for the healthy, and the nearer the hospital to the base the easier become its necessary supplies. Therefore, the true hospitals have to be on the lines of communication and the advanced medical units should consist mainly of ambulance transport. Illustrations from historical battles were given both in hostile and friendly countries. In the latter there would probably be wide lateral dispersion of the wounded, and Colonel Skinner pointed out how the modern voluntary aid societies might supplement the medical units. He suggested that Red Cross detachments should be taught the method of registering the patients entrusted to their care so that reliable records would be available as in the medical units. His conclusions may be

emphasized as: (1) Force without sufficient medical transport loses mobility, and requires additional army service transport; (2) but with sufficient gains in mobility and needless Army Service Corps transport; (3) the necessary evacuating transport must take the form of a medical unit, such as the "Ambulance Column" now proposed for the Indian Army—for in war we cannot rely on another branch or an improvised transport. The sphere of work for this unit is between the field ambulances and the line of communications, working under the Director of Medical Service; (4) the organization of such a system of evacuation forms the *crux* of the medical problem in war.

The Surgical Section of the R. S. M. gave two whole meetings to a discussion on sarcomata and myelomata of the long bones. It was begun by Sir F. Eve of the London Hospital, and continued by other experienced surgeons who gave their opinions on numerous points and reported illustrative cases. Two examples of metastasis in myeloid sarcoma were mentioned as suggesting that such tumors were related to sarcoma, but it would not be desirable so to name them as if they were different forms of one growth. Mr. Gask had endeavored to trace the results of treatment of sarcoma of long bones by investigating as far as possible the after-history of cases occurring at St. Bartholomew's Hospital during ten years, and comparing them with the figures of Butlin's "Operative Surgery of Malignant Disease."

After consideration of various points with a view to obtaining some guidance as to prognosis he submitted the following conclusions: (a) The immediate risk to life is small; (b) the prognosis in myeloid sarcoma is good, particularly after amputation; (c) in all other cases of sarcoma the results are horribly bad. The prognosis can only be made on a microscopical examination. An attempt should be made to improve results by earlier diagnosis and free removal of the disease together with the lymphatic glands. Mr. Bruce showed radiograms of tumors of bones to draw attention to the use of *x*-rays in differential diagnosis. He pointed out that in two endosteal sarcomata the appearances differed from three others of periosteal sarcoma which he showed, as he also did a series of radiograms of conditions which might be confused with new bony growths. Mr. A. D. Reid reckoned the value of *x*-ray examination in these cases as in direct ratio to the duration. It was seldom that the surgeon was called to them in the very early stages, consequently more or less definite abnormalities were often found when at the first consultation. He described these abnormalities, and although *x*-ray examination sometimes afforded assistance there were many cases in which it quite failed. It aided in demonstrating the absence of periostitis which assisted in excluding inflammatory, tuberculous, and specific lesions, but for diagnosis between the various cystic lesions its value was very limited.

Mr. Makins, presiding, remarked that a question which had not arisen in the debate was whether sarcomata ever developed at the site of a recent fracture. A speciman exhibited seemed to suggest that the fracture appeared first in that case. He felt the danger of cutting into a growth, for diagnosis was real, and in such case he was always prepared to complete the operation within the next twenty-four hours; for, he argued, it was necessary to incise to the depth of the growth if microscopical examination was to be made. One could not look without favor on the view that the object of treatment might be fulfilled without amputation.

The Royal Society of Medicine is holding high revels, giving a sort of housewarming in its new home, which, as I informed you at the time, was formally opened by the King. Four conversaziones on four successive evenings, the last to-morrow, comprise the entertainments provided to celebrate the occasion, and at the same time show the profession the advantages the society offers its members. Among the exhibits the cinematographs shown by Pathé Frères included pictures of the circulation of the blood, agglutination, phagocytosis, and development of sea-urchins' eggs. In the optical exhibition of Messrs. Leitz the most notable thing was the latest form of their universal projection apparatus, which makes possible microprojection in both vertical and horizontal positions, can be used for diascopic projection both of opaque and transparent objects, also for episcopic projection, whether the object be illuminated from above or from the side.

An extremely interesting demonstration by Mr. Hewett (librarian) on the epidiascope was of great interest and eminently attractive to every lover of rare books—it was of some of the curious old volumes in this fine library. There was Religio Medici, 1650 edition. Less known, perhaps, but of as much interest or more, was the "Detection and Querimonie of the Daily Enormities and Abuses Committed in Physick," which may almost be looked upon as the earliest work on medical ethics. Curious recipes were thrown on the screen from the "Queen's Closet Opened." One of them was "to make children's teeth come without pain. Proved. Take the head of a hare, boiled or roasted, and with the brain thereof mingle honey and butter, and therewith anoint the child's gums as often as you please." Other equally interesting exhibits were "The Dispensary" (Garth); the "Tabidorum Theatrum" (1656); and the "Organon Salutis" (1657).

The veteran naturalist, W. B. Tegetmeier, died on November 19, at the age of ninety-six. He was educated for the profession and took medals at the University, but soon turned his attention and devoted his remarkable energies to science and literature. He became Davis lecturer to the Zoological Society and assisted Darwin with observations on the variation of plants and animals, and carried out many experiments in breeding. He was one of the oldest members of the Ornithologists Union, and a regular contributor to their journal. He wrote on "Poultry" in the Encyclopedia Britannica, and for forty years he edited the poultry department of the *Field*, all the time furnishing also weekly articles to the *Queen*. Among the volumes of which he was the author are: "The Poultry Book," "Pigeons," "Poultry for Table and Market," "Natural History of Pheasants," "Grouse," and jointly, with Colonel Sutherland, a work on "Horses, Asses, Mules, and Mule Breeding." Twenty years ago he was writing in *Nature* on "Military Pigeon Posts," and his contributions are held to be of permanent value. It was he who, many years ago when he was a comparatively young man, proved the possession of the homing faculty of pigeons by organizing express services over long distances, including from Belgium to the Crystal Palace.

NINTH ANNUAL MEETING OF THE PHILIPPINE ISLANDS MEDICAL ASSOCIATION.

(From Our Regular Correspondent.)

MANILA, P. I., November 4, 1912.

THE ninth annual meeting of the Philippine Islands Medical Association was opened to-day in the building of the College of Medicine and Surgery of the University of the Philippines. The Acting Governor-General, the Hon. Newton W. Gilbert, delivered the address of welcome, in which he felicitated the American medical man in the Islands who had been responsible for the great sanitary progress which has been made here, and more especially for having established a first-class medical school with high standards and for having already graduated young Filipino men and women after taking the whole of the five years' course which is prescribed by the Medical College. His remarks were followed by the presidential address of Dr. R. E. L. Newberne, entitled "Basic Principles of Psychotherapy and the Identity of all Healing Systems." The address gave a resumé of all systems of healing, past and present, and had particular reference to the influence of mind over matter, the unconscious application of the principles of which was, no doubt, responsible for the successful results which were reported from time to time by the exponents of the various cults. He made an earnest plea for the study of psychology by the medical man in order that he might take full advantage of this valuable therapeutic aid and use it as an adjuvant to the drug and other relief remedies which were commonly employed.

The first two papers, namely: "Two Cases of Primary Purpura" and "A Case of Microcephalus with Symptoms of Tetanus," were read by Dr. Maria Paz Mendoza, and were reports upon cases that had been observed in the Philippine General Hospital.

The next paper was entitled "Cutaneous Anthrax, with Report of a Case," by Dr. E. C. White of the United States Navy. This paper gave the history of the case of a seaman on board a United States war vessel, who handled meat which was purchased in Shanghai and which was probably anthrax infected. The man suffered from the cutaneous form of anthrax. After cauterization of the lesions he made a good recovery. In the discussion which followed Dr. Heiser stated:

Dr. White's paper has particular interest for us in the Philippines at the present time, even though the infection was contracted in Shanghai. Anthrax had figured very largely in the statistical reports of the Bureau of Health, but so far as he was aware, there had been no case reported which was supported by reliable bacteriological findings. The frequent reports of anthrax were, perhaps, due to the fact that in the Spanish nomenclature it is customary to refer to carbuncles as anthrax. Just at the present time Dr. Barber of the Bureau of Science was in Buhi, Ambos Camarines, investigating a strange disease which had been reported as occurring among animals and which was alleged to have been responsible for eight deaths in human beings in the last two months, and the symptoms of which, as described by a layman, suggested anthrax.

The next paper was entitled "A Case of True Bilharzial Disease in Porto Rico" by Dr. U. R. Webb of the United States Navy, and was read by Dr. Charles F. Butler of the Navy. This paper gave the history of a case that came under observation in Porto Rico, in which a diagnosis of suppurating kidney was made and in which the right kidney was removed. The patient improved for a time, but soon afterward it was noted that he was still passing blood, a microscopical examination of which showed the Bilharzial parasites. In the discussion which followed Dr. Butler stated that he had personally seen a number of cases of Bilharziosis in Porto Rico, which had been confirmed microscopically.

The next paper was entitled "Korsakow's Psychosis, with Report of a Case," by Dr. Heber Butts of the United States Navy. This paper gave an excellent description of a case of this disease which he recently had at the Cañacao Hospital. The writer pointed out that Korsakow's psychosis is frequently mistaken for and diagnosed as delirium tremens. He further called attention to the fact that practically all of the cases of this disease are associated with alcoholism. The principal points in connection with the differential diagnosis were, that in delirium tremens the patient is delirious, frequently has hallucinations and other symptoms, but which clear up in comparatively a few days, whereas, in Korsakow's disease there is no delirium, no hallucinations, the symptoms never improve, and there is, usually, marked amnesia.

The next paper was entitled "Congenital Varicosities of the Venæ Paraumbilicalæ, Thoracoepigastricæ, and Mammariæ, with Report of a Case," by Dr. A. G. Sison.

The next paper was entitled "Lipomatosis, with Report of a Case," by Dr. Honoria Acosta Sison. This paper gave the history of a child that had been delivered by the author in October, 1910, at which time it was noted that there was a slight enlargement of the right leg, otherwise the child was normal in every respect. Examinations made of the child from time to time showed that the right leg was increasing in size much more rapidly than the left leg. The author stated that the enlargement of the leg was due to hyperplasia of the subcutaneous fat, also, perhaps, to the deposits of fat which, apparently, caused obstruction to the venous circulation.

The next paper was entitled "Bone Lesions in Smallpox," by Drs. W. E. Musgrave and A. G. Sison. In this paper the authors gave histories and showed *x*-ray photographs of a number of cases in which shortening and other deformities of the bones of the extremities and lower jaw had occurred in persons who had suffered from smallpox. The disease only occurred in children or in those in whom epiphyseal ossification had not taken place. In the discussion which followed Major Ashburn stated that it was not clear to him that this condition was necessarily the result of smallpox; that it might well be possible that scurvy or similar diseases might be concerned in its etiology. Dr. Heiser stated that this paper, supported, as it was, by good *x*-ray photographs, gave an excellent account of bone lesions encountered in persons who have had smallpox during infancy, but that he should like to ask Dr. Sison whether he knew of any other diseases occurring in the Philippines in which similar bone lesions are found. In at least 8,000 examinations which he had made of persons who were alleged to be affected with leprosy, bone lesions of the kind Dr. Sison mentioned were often found.

Some of these were in true cases of leprosy; others in yaws and syphilis, and many others were noted in cases in which either smallpox or any of the other conditions mentioned could be excluded with reasonable certainty. Could Dr. Sison give some more direct connection between these lesions and smallpox?

Dr. Wells stated that it seemed strange to him that in view of the many thousands of cases of smallpox that had occurred in Germany, Great Britain, and the United States, the literature did not contain reports of similar bone lesions due to smallpox in those countries.

The last paper of the day was "Glandular Fever," by Dr. A. P. Goff, of the San Lazaro Dangerous, Communicable Disease Hospitals. Dr. Goff stated that on account of the presence of plague in Manila, glandular enlargements were regarded with suspicion, and that many of such cases were sent to San Lazaro for observation. He stated that it frequently happened that a case was admitted with a large femoral bubo, a temperature of 40° C., partial delirium, headache, and without any evidence of injury in the leg or foot below the bubo. The bacteriological findings were always negative for plague, and there had been no mortality among such cases. In the discussion which followed, Dr. Heiser stated that in view of the presence of plague in Manila, all glandular enlargements were, naturally, of the greatest interest to those who were connected with the Bureau of Health. The cases which came under observation at the San Lazaro Hospital might be divided readily into two classes:

1. Those which have enlargements of the glands in specific regions, like those in the femoral region, a case of which Dr. Goff had mentioned in his paper. In these cases not only were the glands enlarged, but there was edema of the surrounding tissues, and the whole appearance was rather suggestive of plague, but, on account of the negative bacteriological findings and the rapid convalescence, plague could usually be excluded with certainty.

2. Those in which practically all of the superficial glands throughout the body were enlarged. In these cases the glands are readily movable, are very hard, and the swelling confined within the capsule of the gland, the surrounding tissue being apparenty unaffected, no edema being present.

Progress of Medical Science.

Boston Medical and Surgical Journal.

December 5, 1912.

1. Heredity: With Special References to the Law of Gregor Johann Mendel, O. S. A. J. M. Connolly.
2. The Teeth and Their Relation to the Body. G. H. Wright.
3. The Treatment of Pulmonary Tuberculosis by Artificial Pneumothorax, According to the Method of Forlanini. G. M. Balboni.
4. A Study of the Blood in a Case of Severe Hemorrhage. J. E. Ash.
5. A Case of Fatal Endocarditis, Due to a Capsulated Gram-Staining Diplococcus, Occuring in Chains. W. H. Smith and R. Kinnicutt.
6. Treatment by Salvarsan During the Past Year. E. L. Oliver.

2. The Teeth and Their Relation to the Body.—G. H. Wright states that there are four distinct periods in the life of a growing child when the tonsils become enlarged, which periods are coincident with the final eruption of the teeth, and at such times these tonsils, although enlarged, are in no manner diseased, inflamed or suppurative. If these tonsils are left alone (except in a few instances in which prophylactic cleansing of the crypts has been advised) they are no longer enlarged or troublesome. These periods of tonsillar enlargement appear approximately at the ages of 2 years, 6 years, 12 years, and 18 years, and these coincide with the eruption of four groups of molars. The author is very confident in his belief that the tonsil (which is histologically a lymphoid gland irrespective of its other possible functions) is sharing in the work of taking care of the normal physiological débris due to the elaboration and eruption of forty-eight teeth and their adjacent membranes. Diseased teeth may be a source of infection and enlargement of glands and tonsils. Tonsils become enlarged without infection or disease whenever (*a*) the first group of temporary molars at two years of age are in process of eruption; (*b*) at six years when the first permanent molars, and at twelve years when the second molars are active in eruption. General practitioners of medicine, district nurses and physical examiners of school children in particular should learn the years when to expect these teeth. Where there has been no previous history of recurrent tonsillitis and the tonsils are simply enlarged, the periodicity of the eruption of teeth should be considered.

3. Treatment of Pulmonary Tuberculosis by Artificial Pneumothorax.—G. M. Balboni notes that the establishing and the maintaining of an artificial pneumothorax is not an indifferent operative procedure, but if the technique proper is followed this procedure does not present any particular dangers. Nevertheless it is not a treatment to be carried out by the general practitioner. This method of treatment is not as a rule to be adopted in the early cases, neither should it be the only treatment adopted in the serious cases. The consensus of opinion among clinicians who have closely watched the effects of Forlanini's method is favorable. In fact, considering that in many cases, as Brauer says, the treatment has been a last resort, the results are very encouraging. The method of Forlanini, namely, the production of an artificial pneumothorax in phthisis, aims directly to eliminate from the lung the destructive and tuberculous process. It has steadily gained ground in the last few years.

2. Spinal Ataxia in the Aged.—C. W. Burr states that in tabes most frequently the symptoms begin to appear in the decade between the thirty-fifth and the forty-fifth year. Ataxia from any cause is not frequently seen in the aged, because those in whom it has developed in the period of maturity die before old age begins, and it is very rare for it to begin in old age. In examining an elderly patient who is ataxic, if one does not know the history and judges simply from the general appearance and the ataxia, one may jump too quickly to a diagnosis of true tabes. If all the classical symptoms are present, and the history of the manner of the onset is that of tabes, there is no escape from the diagnosis, but as a rule the mode of onset of the symptoms in old people is found to be unlike that of tabes, and some or many of the important subsidiary symptoms are absent. The points of resemblance to tabes are the spinal ataxia and the absence of the knee jerks. The things which differentiate it from true tabes are the rapidity of the onset, the absence of pain, the early appearance of more or less palsy, the temporary improvement in the ataxia under treatment, and the final stage, that of a myelitis.

3. Ocular Manifestations of Angiosclerosis.—D. F. Harbridge enumerates these manifestations as follows: (1) A change in the course and size of the retinal arteries, manifested by an undue tortuosity associated with other evidence of disease; an alteration in the caliber of the retinal arteries, which may be a general contraction of one or more branches, or an alternating contraction and broadening in the same artery, or an artery may be practically normal in size, then more or less suddenly become greatly reduced in size, and continue as such out toward the periphery. (2) A change in the course and size of the veins with signs of pressure. The conditions are very similar to those described in the arteries, with the addition of pressure signs, manifested by the obstructed venous flow, a point upon which Gunn places the utmost importance. Ordinarily at healthy vessel crossings there is no depression, but in arteriosclerosis the artery is more or less rigid, the walls being thickened, and upon crossing the vein compresses or indents the same, the distal end of the vein being as large as or usually larger than the proximal end; at times it is ampullated. This condition of the vessels is frequently referred to as Gunn's vessels. (3) A change in the vascular reflex, such as definite alteration in the vessel walls, showing a whitish strip of infiltration in the perivascular lymph sheaths; more marked brilliancy of the central light streak, due to intimal changes frequently described as "silver wire arteries"; last, a paleness and loss of vessel transparency. (4) Retinal changes, indicated by a grayish haze about the nerve head and along the course of the vessels. (5) Hemorrhages, usually manifested in the more advanced cases. There may be faint linear areas near and parallel to the vessels, or scattered round dots, or more extensive splotches. Often there are scattered yellowish white spots, many partially or wholly bordered by pigment.

9. The Education of Feebleminded Children.—A. W. Edson states that there should be established in every city a psychological clinic, possibly in connection with the city hospital, under the control and direction of the board of education, for the purpose of examining and classifying all children deemed by the teachers and school physicians as somewhat peculiar, below normal, exceptionally dull. Suitable classrooms in regular school buildings should be secured for these children, and suitable equipment should be provided. The classes should be small, with not more than twelve or fifteen children in a class, in order that these children may receive individual attention. Specially qualified teachers who have a natural aptitude for the work, should be selected—teachers who have infinite patience, tact, resourcefulness, intense human sympathy, an appreciation of effort, and unbounded faith in the young people intrusted to them. A suitable course of study should be provided—a course that gives emphasis to the essentials, that is flexible, and is adaptable to the needs of the individuals, a course that leads directly to some vocation. The instruction should be personal and individual, and should give emphasis to physical and manual training, to nature study, excursions, and illustrative material.

1. Sudden Obstruction of the Coronary Arteries.—J. B. Herrick calls attention to certain facts going to show that coronary obstruction is not always necessarily fatal; the coronaries are not so strictly end-arteries, as Cohnheim and others have thought. Careful dissections have shown anastomoses of considerable size in some cases. Besides the sudden fatal cases there may occur mild cases, though these have not been recognized clinically. In still another class the symptoms may be severe enough to be recognized as cardiac, but may not be immediately fatal, and the patient may recover. The author reports a case of this kind in which the patient survived fifty-two hours after the onset of the pain, and in which the condition was verified by autopsy. He has seen five other similar cases in which autopsy was lacking, but in which the symptoms were so characteristic as to convince him of the correctness of the diagnosis. When these cases are recognized the importance of absolute rest in bed for several days is clear. It would also be wiser to use cardiac tonics like digitalis or strophanthus, than to follow the routine practice of giving nitroglycerine or allied drugs. The hope for the damaged heart muscle is in securing its nutrition by a supply of blood through the remaining arteries. Clinical experience shows that digitalis is of great value in cardiac angina, especially in cases of low blood-pressure, and these obstructive cases come under this head.

5. Pleural Vomicæ.—By E. Smith. (See MEDICAL RECORD, Vol. 81, page 1119.)

7. Blenorrhagic Keratosis.—B. H. Roark reports a case of very marked and troublesome keratosis occurring after gonorrhea, confined to the soles of the feet at first and afterward appearing on the hands, and still later on other parts of the body, together with exfoliation and loss of toe and finger-nails. There was also an accompanying gonorrheal arthritis. The case was treated with gonorrheal mixed vaccine, under which the joint involvement improved. Later an autogenous vaccine made from the cultures obtained from nodules on the feet, which contained the ordinary pus staphylococci, was used with benefit.

8. Exophthalmos in Scurvy.—By L. R. De Buys. (See MEDICAL RECORD, Vol. 81, page 1163.)

9. Occupational Eye Diseases and Injuries.—M. D. Stevenson discusses first the common preventable accidents, such as from blows; the lodgment of small particles in the eye, especially in dry grinding, dressing rough edges of castings, etc.; and from burning sparks and flashes in forgings and castings. Fans made to carry the particles away from the eyes and various shield devices are on the market and are more or less used. Glass protectors and goggles are also employed, but they get dirty and marked by the flying particles and the workmen are likely to cast them aside. Where there is great heat glass protectors are inefficient, but good wire gauze protectors with asbestos around the mouth and neck are useful. Minute examination of the conjunctivæ of workmen engaged in these various dangerous occupations sometimes reveals hundreds of minute scars that may be so numerous as to affect vision. Other occupations involving the risk of eye injury are coal mining, masonry, quarrying, weaving, wire-drawing, and farming. Many accidents occur with the use of powerful explosives and from the bursting of bottles, water gauges, etc. Unslacked lime dust is especially dangerous and when it gets into the eye olive oil or even castor oil should be freely applied, or, when not available, large quantities of water should be used at once. Wurdemann advises the use of a from 3 to 10 per cent. solution of ammonium chloride to dissolve and carry away the lime. Ammonia

burns should be treated by profuse irrigation with water and in the case of workers in acids and alkalies neutralizing solutions should be at hand. Exposure to irritating gases and fumes occurs in textile factories, in bleaching and dyeing works and from the excessive light or heat are not uncommon among electrical workers, smelters, and glass annealers. Hyperasthesia of the retina may be relieved by proper lenses or colored glasses. In certain steel works frequent examinations of the white-hot metal have to be made with colored lenses, and cataracts are observed frequently among bottle-workers, puddlers, etc. Heat is claimed by the Germans to be the most important cause. Sudden strong light-flashes before the eyes must be avoided. The manufacture of explosives is dangerous on account of the poisonous fumes, and chronic lead-poisoning is attended sometimes with eye infections, and poisonous gases formed in certain lead processes are hurtful. Coal miner's nystagmus is due to a prolonged and peculiar use of the eye in working and in strained positions.

11. **Ureteral Obstruction in Women.**—H. D. Furniss from a study of the literature and his own personal observations concludes that stricture of the ureter is commoner in women than is generally supposed and is often diagnosed as some other organic trouble, especially when it occurs on the right side. It is slow, progressive and leads to serious renal trouble. It is generally of inflammatory origin and the infection may be either ascending or descending. There is usually a history of an antecedent pyelitis and, after the definite formation of a stricture, the symptoms become those of an intermittent hydronephrosis like that caused by obstruction with stone or from kinking. In most cases observed the symptoms have persisted for some time, the attacks being at first slight and far between, but becoming more common and severe. He does not consider exposure or excessive drinking of water as necessary causes, not having observed them in his own cases. The pain is generally in the renal region but may be referred to gall-stones or appendicitis. There may or may not be bladder disturbances. Oliguria during an attack with subsequent polyuria is often observed. The kidney function may be seriously affected even with moderate hydronephrosis. The diagnosis is best made with the aid of cystoscopy, ureteral catheterization, and radiography of the renal pelvis. With these methods and especially with pyelography one should be able in practically all cases to make a diagnosis before irreparable destructive kidney changes have occurred. With pyelography a graphic picture is obtained, not only of the location of the stricture, but of its extent, which makes it possible to form an opinion of the damage that has occurred above the stricture.

13. **The Natural and the Synthetic Salicylates.**—C. Eggleston points out that the evidence in favor of the "natural" salicylates rather than of the artificial ones is extremely slight, or what amounts to the same thing, the evidence against the artificial salicylates is even less. In nearly forty years of use by physicians all over the world, the artificial salicylates have been found quite as effective as the "natural" and no more liable to produce unfavorable actions under similar conditions than are the vastly more expensive "natural" products.

1. **The Relation of Pleurisy to Tuberculosis.**—Sir T. Clifford Allbutt states that it is not far from an axiom to say that a streak of pleurisy audible at the apex means pulmonary tuberculosis. So-called idiopathic pleurisies in persons over five years of age are tuberculous in 50 per cent. of the cases. As regards child life, the author's own impression from experience is that pleurisy in young children is rarely tuberculous; the incidence may not be more than 1 in 10; and even of these the pleurisy may be only incidentally associated with a tuberculous focus, or the tubercle may be a secondary consequence of a protracted empyema. Absorption seems to be slower in a tuberculous pleurisy than in any other form. The importance of a patch of dry pleurisy as a frequent precursor of frank manifestations of pulmonary tuberculosis is emphasized by the author. What is the prognosis of the acute serous form? In these cases there is a proclivity to later outbreaks of tuberculosis, especially pulmonary. The glueing together of the serous surface tends to the stifling and obliteration of the bacilli, and it may be that a direct origin thence of later manifestations is not the rule; that, generally speaking, any later events are not so much the effects of the pleurisy as kindred processes. A subsequent phthisis may not begin on the same side. Of more direct consequence are the stubborn retractions, with deformity of the chest and fibrous invasion of the lung and bronchiectasis, which belong rather to the tuberculous than to other kinds of pleurisy. Meningitis is a very rare sequence. More often one is disappointed to see these pleuritic cases drift into spinal or joint tubercle, or into tubercle of the urogenital parts. It seems that in most of these cases the bronchial glands are affected, and may form a link between the one and the other set of phenomena. Under the aseptic treatment now universal the tuberculous effusions show no great proneness to suppuration; if, unfortunately, this comes about, obstinate sinuses may be established with tendency to amyloid disease. The author has almost given up repeated exploratory, or plastic, surgical interference with these fistulous conditions, operations which are usually futile or worse; these cases do better under sanatorium treatment. It is a matter for serious consideration whether a patient on recovery from an acute serous pleurisy, which may have been tuberculous, should be submitted to vigilant sanatorium methods for some sufficient interval before entering again into his ordinary life.

2. **Drunkenness and the Physiological Effect of Alcohol.**—C. Mercier states that contrary to the views of prohibitionists, drunkenness is not as prevalent to-day as it was in former generations. The occupations by which men now earn their living require a skill, a nicety, a vigilance, an accuracy, an attention, which are incompatible with even occasional drunkenness. The majority of drinkers take alcohol for its euphoric effect; but this is not the motive with all of them. There is another physiological effect of alcohol which is upon occasion of the utmost value. Alcohol has the power to unlock the store of energy that exists in the brain, and to render available, for immediate expenditure, energy that without its use would remain in store, unavailable for one's immediate needs. If alcohol has this power of liberating latent energy, it will exercise the power, not only when the available energy is used up and exhausted, but at all times, so that even when energy is flowing freely out of store, the taking of alcohol will add to the freedom of the flow, and this augmentation of the supply of free energy will show itself in increased activity of body, or of mind, or of both. That alcohol does increase the activity of both body and mind there is abundant evidence to show. The increase is but temporary, and is apt to be followed by exhaustion, but increased activity there always is. What form the activity will take must depend upon the state of the different parts of the brain, as to repletion or exhaustion, when the alcohol is taken.

If the highest level of the brain contains plenty of energy, this energy will be set free by the alcohol, and the result will be increased activity of mind. If these higher levels are empty, more energy cannot be had from them, and what increase of activity results will be activity of body and will be crude and unintelligent; and between these two extremes there will be every grade.

5. The Colon Bacillus in the Blood.—P. N. Panton and H. L. Tidy call attention to the fact that while infections of the body tissues by the *Bacillus coli* are extremely common, and while there is every reason to believe that the spread of infection in no inconsiderable number of cases takes place by way of the blood stream, it is remarkable how rarely direct proof of blood infection can be obtained during life. Blood cultures made from persons suffering from undoubted coli infections are almost invariably sterile, but the authors have been able on three distinct occasions during the last nine months to obtain from the blood a pure growth of the colon bacillus. In two of the three cases the blood was withdrawn at the commencement of a true rigor, and while the patients were actually shivering. In the third case the blood was obtained three and a half hours after a rigor. In other and subsequent cases of similar infections blood taken a few hours after a rigor has been sterile.

November 30, 1912.

1. Report of the Committee on Treatment of Simple Fractures.
2. Further Experiment Concerning the Origin of Life. H. C. Bastian.

1. The Treatment of Simple Fractures.—The committee appointed by the Council of the British Medical Association presents an analysis of the material collected by the committee's investigators as to the results of the treatment of simple fractures. The following are the main conclusions: The statistics relative to the non-operative treatment of fractures of the shafts of the long bones in children (under the age of fifteen years), with the exception of fractures of both bones of the forearm, show as a rule a high percentage of good results. These are unlikely to be improved upon materially by any other method of treatment. In comparison with the non-operative results in children, the aggregate results of non-operative treatment in those past childhood (*i. e.* over the age of fifteen years) are not satisfactory. From the analysis of the age groups it is clear that there is a progressive depreciation of the functional result of non-operative treatment as age advances, that is to say, the older the patient the worse the result. In cases treated by immediate operation, the deleterious influence of age upon the functional result is less marked. In nearly all age groups, operative cases show a higher percentage of good results than non-operative cases. Although the functional result may be good with an indifferent anatomical result, the most certain way to obtain a good functional result is to secure a good anatomical result. No method, whether non-operative or operative, which does not definitely promise a good anatomical result, should be accepted as the method of choice. For this reason mobilization and massage by themselves have not been found to secure a high percentage of good results. They are, however, valuable supplementary methods of treatment. Similarly, of operative methods, those which secure reposition and absolute fixation of the fragments yield better results than methods which fall short of this; imperfect fixation of the fragments by wire or other suture has been found to be an unsatisfactory procedure in the treatment of fractures of the long bones, with the exception of the olecranon process of the ulna. Operative treatment should not be regarded as a method to be employed in consequence of the failure of non-operative measures, as the results of secondary operations compare very unfavorably with those of immediate operations. In order to secure the most satisfactory results from operative treatment it should be resorted to as soon after the accident as practicable. It is necessary to insist that the operative treatment of fractures requires special skill and experience, and such facilities and surroundings as will ensure asepsis. It is, therefore, not a method to be undertaken except by those who have constant practice and experience in such surgical procedures. A considerable proportion of the failures of operative treatment are due to infection of the wound, a possibility which may occur even with the best technique. The mortality directly due to the operative treatment of simple fractures of the long bones has been found to be so small that it cannot be urged as a sufficient reason against operative treatment. For surgeons and practitioners who are unable to avail themselves of the operative method, the non-operative procedures are likely to remain for some time yet the more safe and serviceable.

2. The Origin of Life.—H. C. Bastian believes that it is quite possible that in nature both Monera and blue-green algoid corpuscles may be constantly appearing *de novo*. But that is a mere supposition devoid of all positive evidence, as it must always remain till someone may be fortunate enough—whether chemist or biologist—to hit upon such combinations of materials as will, under necessarily restricted experimental conditions, suffice to engender either Monera or blue-green algae. For whatever the future researches of chemists may achieve in the way of synthetically building up the bases of protoplasm, when it comes to the demonstration of the production of actual living matter, they could never convince themselves or the world in general that they had succeeded in their quest till they were able to produce it under such restrictive conditions as the author has had to cope with in his experiments—that is within hermetically sealed vessels which, with their contents, had previously been sterilized. They, like the biologist, would have to eliminate all pre-existing life and securely guard against contaminations, and what the chemist may then produce no one can say, though he is certainly never likely to produce living matter in tangible lumps.

Berliner klinische Wochenschrift.

November 25, 1912.

Further Experience with Thyroid Therapy.—Heinrich Stern of New York states that most practitioners are still in the dark as to the possibilities of thyroid medication. One druggist reports but six prescriptions calling for thyroidin in a total of 2,000. The efficacy of this substance must to some extent depend upon a content of arsenic and the latter acts as a synergist when prescribed with thyroidin; and in such combination very small doses of each drug secure the desired action as well as much larger ones. The author combines thyroidin in the form of the dessicated gland substance with sodium cacodylate and further adds a minute quantity of epinephrin as an antagonist to any depressing action of thyroidin on the circulation. The author classes as forms of hypothyroidism a number of petty ailments—dry and rough skin, trophic disturbances of hair and nails, etc. The benefit is often striking, especially when the medicine is given in warm months. A similar influence is noted over bleeding gums and Rigg's disease, although these affections do not occur at all in many severe cases of hypothyroidism.

Etiology of Vasomotortrophic Disorders.—Zweig after analyzing a complicated case shows the coincidence of three different disease factors, viz., hyperthyroidism, circulatory disturbances, and abnormal psyche. Under the first factor he mentions exophthalmos and tremor. Should we regard the other two factors as of thyroid origin or as independent? The patient was subject to urticaria, volatile edema, and purpura accompanied by temperature

elevations. Articular swellings sometimes occurred. These so-called angioneurotic symptoms are believed to indicate some functional anomaly affecting the vasomotor and thermic centers. The coexistence of psychic excitation suggests that the cortex may be the primary seat of the mischief. The limited participation of the thyroid in cases of this type appears to show that this organ is involved secondarily. A possible primary factor is of course inherent instability of the sympathetic—an irritable weakness of the vegetative nervous system—which is naturally able to influence a number of organs—the thyroid among them—through changes in the blood supply. This instability might also affect the nerve centers themselves, disturbing the heat center. Another element must also be considered, to wit, the secretions of the ovary which are known to stand in some relation to the vasomotor system. The author is inclined to look upon psychic components as chiefly of independent nature, although probably aggravated by the sympathicoatonia and hyperthyroidism. When the latter affections improve there is no corresponding improvement in the psychoses.

Primary Sarcoma of the Muscles.—Landois refers to sarcomata which originate in the connective tissue of the voluntary muscles as different from the genuine muscle sarcoma which can be diagnosticated only by careful histological study. Naturally both forms are considered under one clinical head and a distinction has not seemed practicable. Thus in one surgical clinic of twenty such growths six were shown to have originated in the fascia, nine in the muscle proper, and in the others the precise origin could not be determined. In 1904 it was said that 109 proved cases of pure muscle sarcoma were upon record and quite recently the number was given as 130. The growths are chiefly the ordinary round cell and spindle cell sarcomata and myxosarcomata. There is known to exist, however, a primary or pure muscle sarcoma which bears no relation to the preceding in which the tumor elements are muscle elements. This form was termed by Grawitz myogenic sarcoma.

Münchener medizinische Wochenschrift.

November 26, 1912.

The Status Lymphaticothymicus.—Schridde enumerates the symptoms of this constitutional anomaly which has been recognized in life in recent years but which was formerly known chiefly in connection with a peculiar type of sudden death not alone in children. When death follows slight traumatisms or even psychical experiences we should find this rationale, and here belong without doubt certain deaths which follow salvarsan injections. Hence the great importance of being able to recognize in advance such a predispositon. This must first be studied on the dead. The cadavers are extremely pale and for the most part the victims are plump and have a good cushion of fat, which when incised is seen to be unusually whitish and moist. As a rule, the thymus shows a notable degree of enlargement. The anomaly, however, is not one of size but of histological alteration and of failure to undergo normal involution. Along with the thymic peculiarities we find many hypertrophies of lymphoid structures, not, however, of a sort to be readily recognized in life. The left ventricle of the heart invariably shows some degree of dilatation and hypertrophy. We know that the status thymicus may run in families and may prevail more in certain localities. We suspect its presence in pale, pasty, plump children. Naturally, the cardiac anomaly just mentioned should determine the diagnosis, but this is not often sufficiently marked to be readily recognized. When the thymus is very large it can be mapped out by percussion of the enlarged lymphoid structures recognizable in this connection; the most significant are nodes at the bends of the joints. The enlarged cervical nodes, tonsils, and pharyngeal tonsils may be due to some other causes. If there is no history of tonsilitis, enlarged tonsils are significant, and perhaps of all criteria the enlargement of the follicles at the base of the tongue is the most trustworthy evidence. The author employs this as a routine test. The blood shows some lymphocytosis.

Treatment of Dermatoses with Human Serum.—Heuck makes use of this resource with the view of correcting the abnormal blood state which apparently underlies certain dermatoses, having been influenced thereto by the remarkable results of pregnancy serum in pregnancy dermatoses. The author has thus far made 350 injections in 40 cases. He could see no benefit in psoriasis or moist eczema. On the other hand, he obtained prompt results in various cases of pruritus and in other cases in which there was present a marked nervous element. It was hoped that Dühring's disease might prove amenable to this treatment, but this result was in no wise obtained. The serum apparently has power over urticaria.

Rational Treatment of Asiatic Cholera.—Emmerich first mentions the old resource of saline infusion, the latter to be improvised from the various tablets made for the purpose. The infusion should be made into the veins as well as by other means, and the severe picture produced by the abstratction from the blood of its watery content may as a rule be promptly changed for the better. If collapse again appears, the infusion must be repeated. The great lowering of blood pressure which causes the collapse calls for special measures, for death actually occurs from uremia. The drugs to be used in connection with infusion comprise digitalis, strophanthus, adrenalin and pituitrin, always given by intravenous route. A resource of great promise when exhibited early is colloidal manganese, which is injected freely. The author also recommends for the same purpose amidosulphonic acid. Both of these substances attack and destroy the nitrogenous substance which forms the cholera toxin and which is now believed to be deadly by reason of its nitrous acid or nitrite content, which kills by causing extreme lowering of blood pressure.

Pneumococcus Phlebitis.—J. Chalier and R. Crémieu state that this is a relatively rare complication of pneumonia, occurring most frequently at the time of the defervescence and during the period of convalescence. The veins usually affected are the femoral.—*Le Bulletin Médical.*

Growth of Displaced Normal Tissue.—C. V. Craster concludes that the repeated transplantation of a piece of skin from one animal to another confers no exceptional power of growth upon that skin. The repeated implantation of skin into one animal decreases, if anything, its receptivity for such grafts. The burial of skin in the interior of the body causes, after a time, a change in the skin of such a nature that it cannot resume its normal function as an external covering tissue, even when its circulation is well maintained and it is buried in the body of the same animal. The author's experiments do not determine how long the cells of the skin actually remain alive, and indeed it is conceivable that the mere maceration of the protective horny layer puts the skin, when re-exposed, into the position of a moist tissue, such as the intestinal mucosa, so that it readily dries up and succumbs. Nor do the experiments throw any light upon the possible existence of cytolytic substances in the circulating fluids, although, naturally, the idea of such an action has always been present in the author's mind in observing the gradual loss of vitality in the transplanted tissues.—*Journal of Experimental Medicine.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

HISTORICAL SKETCH OF LIFE INSURANCE.*

LIFE insurance was practically originated in England in the sixteenth century by individual underwriters whose contracts were more or less in the form of wagers, based on crude guesses at the chances of life and death. On account of the nature of the transactions, the rates were high and the term of insurance short. The few records show that the most favored method was a form of agreement between two or more parties upon the life of some individual. In other words, a policy was written on the life of a certain person (A), by some other person (B), at the request and expense of a third party (C). If the insured (A) died before a given date, the payer of the premium (C) would be the winner; if, however, the insured (A) survived the stated period, the insurer (B) would win. A distinctive feature in these ventures was the absence of legal insurable interest, the beneficiary possessing merely a monetary interest in the insured's death. "St. Catherine's Guild" came into existence about the same time for the purpose of extending aid to its members in the event of fire, flood, robbery, or other calamity, and to give support in sickness or old age.

These methods were entirely inadequate for a reliable conservation of the home, for the protection of widows and orphans or to actually provide against want in old age. Insurance could not become effective until issued by permanent and properly managed corporations instead of individuals whose business transactions came to an end at death, and the lack of experience, absence of data, and proper business supervision delayed the formation of serviceable corporations until a comparatively recent date, although superficial observations on the chances of life and death and attempts at the construction of tables based upon the law of mortality are recorded as having taken place towards the end of the seventeenth and the beginning of the eighteenth centuries. A royal charter was granted for "The Amicable Society for a Perpetual Life Assurance Office" in 1706. The "Royal Exchange" and the "London Assurance," which had been started exclusively for writing fire and marine insurance, had their charters amended so as to permit them to issue policies for life insurance in 1721. Later on in 1756 "The Equitable Society for the Assurance of Lives and Survivorships" was incorporated by a number of men as a purely mutual affair and as an intended improvement over the older societies. The careers of these companies were uncertain and characterized by illiberal action and exorbitantly high premiums. Nevertheless, the business of life insurance was encouraged in England at this time by governmental and popular support, whereas it was practically forbidden on the Continent by edicts and ordinances, especially in France and the Netherlands, and this accounts to a great degree for the sluggish advancement of life insurance in those countries up to within comparatively recent years.

By the beginning of the nineteenth century the theory of life contingencies had been worked out to a considerable extent through the studies of Price and Morgan and the consequent construction of the Northampton, Chester and Swedish National tables, and not less than eight insurance companies were doing business in Great Britain. By 1844, over 140 companies and societies had become established in Great Britain and the subject received some consideration that year from the British Parliament. Among these companies, the "Equitable Society for the Assurance of Life and Survivorships," with its methods brought up to the prevailing standard, occupied a prominent place and still flourishes, and to it must therefore be accorded the honor of being the oldest representative of modern life insurance.

Life insurance had received some recognition in America by the founding of the "Presbyterian Ministers Life Fund of Philadelphia," an institution of such limited and restricted importance that it is generally accepted that life underwriting, in the true sense of the word, began in America in 1843 when "The Mutual Life Insurance Company of New York" issued its first policies to 250 original subscribers. This company, it may be noticed, started its career one year before the value of life insurance to society was first definitely recognized in England as a subject worthy of parliamentary debate. It was followed by "The New England Mutual" in 1844, "The Mutual Benefit," "The New York Life," and "The State Mutual" in 1845, and "The Connecticut Mutual" in 1846. Since 1843, life insurance in the United States has far outgrown its operations in England; this progress may be attributed to a greater adaptation to the needs of the people, to the support it had received as a business, and to the energy and impulse of its managers and agents.

Life insurance has passed from the humble beginnings of 150 years ago to the status of a great financial factor in the business world, from a condition of more or less speculative and sentimental possibilities to that of a rational, professional, and commercial necessity. This improvement is largely due to the important work done in the United States during the past fifty years by its most eminent actuaries, and through combined efforts in Great Britain and the United States the business of life insurance is now conducted as a science with deductions based upon the enormous experience which investigators have at their command.

*It is proposed, beginning in this number, to devote a few articles to the consideration of the general construction of the principles and business of life insurance. Information on this subject will be found useful by examiners when, as often happens, they are consulted by their patients or when they are communicating with the home office.

The Significance of Children's Diseases in Insurance.—Grohmann says that no special space is usually allotted to questions about children's diseases in application blanks, yet a history of these diseases is of great importance in judging an applicant. It is necessary to find out the specific affections from which he has suffered, for suspicious findings in the urine gain much in significance if a history of scarlet fever, for instance, has been obtained. On the other hand, partial deafness explained by inflammation of the middle ear in the course of scarlet fever, or scars in the neck following abscesses of lymphnodes during a similar illness in childhood, have much less significance than in case no history of children's diseases has been obtained.—*Blätter für Vertrauensärzte der Lebensversicherung.* Vol. III, No. 4, 1912.

Book Reviews.

PUBLIC HEALTH CHEMISTRY AND BACTERIOLOGY. A Handbook for D. P. H. Students. By DAVID MCKAIL, M.D. (Glasg.), D. P. H. (Camb.), F. R. F. P. S. G. Lecturer on Public Health and Forensic Medicine, St. Mungo's College, Glasgow; Lecturer on Hygiene to Nurses, Glasgow Royal Infirmary, etc. Price $2.50. New York: William Wood & Company, 1912.

THIS is a book of unusual excellence and usefulness. The subjects considered are of the highest importance to all medical men no matter what their special activities may be, and it would be very desirable if such a course as is here outlined were made part of the curriculum of every medical college. The average student of medicine learns far too little concerning such vital subjects as the determination of the wholesomeness of water supplies, foods and beverages, etc., as well as the practical application of bacteriology, which he ordinarily acquires purely as a theoretical subject. About one-third of the present volume is devoted to chemical matters and the remainder to the study of microorganisms. In both cases the author displays complete mastery of the subjects and gives admirable working directions for all of the most approved methods concerned. The introductory chapters in the bacteriological portion of the book include discussions of the general principles of bacteriology and of immunity and anaphylaxis that are remarkable in their completeness and clearness of expression. Indeed this portion of the book if bound separately would form a much more satisfactory textbook of bacteriology than many works devoted to this subject alone and enjoying high favor. The few instances in which local conditions in the British Isles are taken into consideration do not in any way detract from the suitability of the volume for use in this country and its excellence deserves to be made known widely.

THE ANATOMY OF THE HUMAN EYE AS ILLUSTRATED BY ENLARGED STEREOSCOPIC PHOTOGRAPHS. By ARTHUR THOMPSON, M.A., M.B., F.R.C.S. Professor of Human Anatomy in the University of Oxford. Oxford: At the Clarendon Press, 1912.

MR. THOMPSON'S work includes 61 pages of text, 67 pages explanatory of the plates, an index and a cabinet containing 67 stereoscopic views arranged so that they can be satisfactorily viewed by means of the ordinary stereoscope. The text is devoted to a detailed description of the gross and minute anatomy of the tissues of the eyeball as studied from anteroposterior sections and equatorial sections, the latter regarded from the anterior and also from the posterior aspect. Dissections of special parts are also described. The photographs are in the main true to the condition of the tissues during life. Where artefacts appear the proper explanation is found in the text.

A careful study of Thompson's work cannot fail to result in the acquirement of a comprehensive knowledge of the anatomy of the tissues of the eyeball. The work is conscientiously written, is of a high character, and deserves commendation.

A MANUAL OF AUSCULTATION AND PERCUSSION. Embracing the Physical Diagnosis of Diseases of the Lungs and Heart and of Thoracic Aneurysm and of Other Parts. By AUSTIN FLINT, M.D., LL.D. Late Professor of the Principles and Practice of Medicine and of Clinical Medicine in the University and Bellevue Hospital Medical College, etc. Sixth Edition Revised and Enlarged by HAVEN EMERSON, A.M., M.D. Associate in Physiology and Associate in Medicine, College of Physicians and Surgeons, Columbia University; Assistant Visiting Physician, Bellevue Hospital. Illustrated. Price $2.00. Philadelphia and New York: Lea & Febiger, 1912.

WHILE it would in any case be a source of much gratification to have a new edition of this celebrated work appear, it is doubly so to have it issued in its present form. To attempt at this time to rehearse the excellencies of the original work would appear presumptuous for it stands as an acknowledged masterpiece, but it is pleasant to pay tribute to the thoughtful care with which Dr. Emerson has carried out the difficult task of bringing the book into thorough accord with present teachings. Although the alterations are numerous and in some instances have necessarily been extensive the original plan of the work has been faithfully preserved and it still remains a model of precise and elegant diction. While at first thought it might seem that the additions on such subjects as the use of the *x*-rays, the electrocardiograph, the sphygmomanometer, the interpretation of polygraph tracings, etc., might advantageously have been made at somewhat greater length, a little reflection convinces the reader that the editor's judgment in this respect deserves only commendation. It is far better for the student to place in his hands a book like the present which informs him how much may be ascertained by highly trained senses and powers of observation, and stimulates him to develop these faculties, than to allow him too early to rely on the assistance of complicated apparatus, representing refinements which the beginner is unfitted to appreciate. A section deserving especial notice is the new one on the irregularities of the pulse which is a true *multum in parvo* and presents all the essentials of the subject with remarkable clarity and conciseness. It is hard to conceive of a better book than this for the purpose of the student, or of one which can be read with greater profit by more advanced diagnosticians.

STATE BOARD EXAMINATION QUESTIONS AND ANSWERS OF THE UNITED STATES AND CANADA. Practical Work Giving Authentic Questions and Authoritative Answers in full that will prove helpful in passing State Board Examinations. Reprinted from the MEDICAL RECORD. Fourth Edition. Thoroughly Revised. Every Question Answered in Full. Price $3.00. New York: William Wood and Company, 1912.

THIS volume will prove invaluable to students who are preparing to pass their State Board Examinations. The contents of the book are sufficiently indicated on the title-page, and the present work differs from all others of a similar character in that it answers all questions and does not merely make a selection.

INTERNAL MEDICINE. By DAGID BOVAIRD, JR., A.M., M.D., Assistant Professor of Clinical Medicine in the College of Physicians and Surgeons of Columbia University; Associate Visiting Physician of the Presbyterian Hospital, and Visiting Physician of the Seaside Hospital in the City of New York. With 100 illustrations in the text and 7 colored plates. Price $5.00. Philadelphia and London: J. B. Lippincott and Company, 1912.

IT goes without saying that there are many good and few superlatively good text books of medicine, but as Dr. Bovaird aptly points out in his preface there has rarely been a teacher of medicine who has been satisfied with the books which his students have had to use, which is to say that all earnest and able teachers of medicine have their own ways of teaching which do not always fit in with the views of other authorities. The book before us is intended to give in compact form the more important facts of the subjects included in the domain of internal medicine. It is, as the author claims, only a framework of internal medicine. The descriptions given are admirably lucid and concise and follow the latest views. The arrangement of the subjects has been dictated by the wish to put the simpler first and to present something of a logical order of study, but the classification followed will not be found in consonance with the views of some of the highest authorities; but as the author remarks, "we must act upon our present knowledge with full consciousness that much of it may to-morrow require revision." The plates and illustrations are remarkably good and the book will undoubtedly find much favor as a peculiarly clearly written text book for students.

A MANUAL OF PHARMACY FOR PHYSICIANS. By M. F. DELORME, M.D., Ph.G., Assistant Professor of Materia Medica and Pharmacology, Long Island College Hospital, New York. Third Edition, with nineteen illustrations. Price $1.25 net. Philadelphia: P. Blakiston's Son & Co., 1912.

THIS edition is a great improvement on the former one in that the section on Prescription Latin has been rewritten and now looks more like Latin. It is a pity that a similar drastic revision was not accorded the whole book; to take only one example, and that at random, in the index on pages 219 and 220, under the heading Tincturæ, we find: Tincturæ benzoini compositi, Tincturæ cannabis indica, Tincturæ cinchonæ composita, Tincturæ Dover's powder, Tincturæ ferri pomata, Tincturæ gambir composita, Tincturæ guaiac ammoniata, Tincturæ krameria, Tincturæ lobelia, Tincture ipecacuanha et opii, Tincture valerianæ ammoniata, Tincturæ veratrum. Immediately following these gems we find Trochisci mentha piperita. Zanthoxylum appears to be the author's way of spelling Xanthoxylum. After looking through this book we are more than ever convinced that students, physicians and authors who do not know Latin should write their prescriptions in English.

REPORTS FROM THE MONDAY CONFERENCE OF THE NEUROLOGICAL INSTITUTE OF NEW YORK.

First Division—Dr. Joseph Collins.

Astasia-Abasia.—Dr. Collins, in presenting a case of astasia-abasia developing immediately after trauma in a woman who on examination is found to have tabes, said it is no uncommon experience of the neurologist to encounter patients who claim to be paralyzed as the result of accident and injury, especially where there is liability for damages. Such cases resolve themselves into instances of malingering, hysteria, or organic disease of the central nervous system. Rarely is the paralysis found to be dependent upon a disease whose pathogenesis has no real relationship to trauma such as tabes. In the present case such dependency was not obvious. In fact there was a coincidence of pathological conditions that is very interesting.

The patient was a married woman 46 years old, by occupation a dressmaker. Three weeks ago, being then so far as she knew in good health, she was in the act of alighting from a trolley car when she noticed a taxicab coming a short distance away. The next thing she remembers was that she was in a shop and a surgeon was sewing a wound in her scalp. She was taken home and remained there until four days ago, when she was brought here. During these three weeks she was wholly unable to stand or to move her legs. Her only complaint in addition to this was that it made her tired and exhausted to talk, to think, or to attempt to do anything.

Her complaint when she entered this hospital was of inability to stand or walk; pain in the left knee, sensation of weakness and fatigue in the back and legs, and a feeling of syncope when made to sit up in bed. Examination showed a scalp wound in the left side of the parietal region and another wound practically healed on the left leg below the knee. Aside from these there were no indications of traumatism. Further examination revealed a complete inability to put her lower extremities in motion. When the most vigorous attempts to stand were made, she did not accomplish anything in this direction. A fortnight ago, when an endeavor was made to get her on her feet by having some one lift her from the arm pits, she went into a heap quite like a cadaver that has lost its rigidity. She had some capacity to move her feet and her legs when she was lying down, that is she could lift the right leg off the bed, but the left leg she could not move. The Hoover sign was negative. The upper extremities and head she could move, but the strength in the upper extremities was extremely slight. The knee jerks and ankle jerks were absent both on direct stimulation and reinforcement. In striking contrast to this was the preservation of the direct myotatic irritability of the quadriceps extensor muscles. The tendon jerks of the lower extremities were not elicitable. The plantar reflex was flexor in type, the abdominal and epigastric reflexes were present.

Examination of her sensibility showed that there was an anesthesia for thermal and thermal sensibility of the left side of the body from the neck downward. The cornea and the pharynx showed no insensibility and there was no disorder of the senses of sight, smell, or hearing. The pupils were normal and reacted promptly to light. There was no disorder of her vascular system that could be made out.

Examination of the cerebrospinal fluid revealed an excess of globulin, 22 lymphocytes in each cubic millimeter. The Wassermann reaction of the cerebrospinal fluid and of the blood was positive.

On the day after her arrival here it was noted that when she was lifted out of bed her legs collapsed so that she fell to the floor face forward. When lifted into a chair she let the body relax and the head loll from side to side. She complained of no weakness in the legs or arms, but refused to use them for her support. She was put under treatment by cold packs, massage, and suggestion. A week later it was noted whereas she lay in bed apparently paralyzed from waist down, unable to use arm and neck muscles, she has made daily improvement.

At first when she attempted to sit up she strained all the muscles of the neck and arms; later while holding the assistant's hand she pulled herself into a sitting posture, meanwhile being apparently on the point of falling out of bed, exerting herself more than was necessary. At the end of a fortnight she could sit up without assistance, and holding an assistant's hand, she rose to a standing posture, the legs being held very rigid while standing. Three weeks after her entrance here she was walking unaided about the hospital.

She is now able to walk and to stand in a way that seems to be quite normal. Physical examination, however, reveals the signs that permit the diagnosis of tabes to be made unhesitatingly. These signs are: absence of the tendon jerks of the lower extremities, disorder of postural sensibility in the legs, segmental hypesthesia in the trunk and thighs, a positive Wassermann reaction of the serum and cerebrospinal fluid, and a decided increase of lymphocytes in this fluid.

She maintained that she was quite well until she was injured. The only symptom that she will admit is slow urination. She denies having had diplopia, girdle sensation, pedal paresthesia, leg weariness, pains, or other common early symptoms of tabes.

This case is described as one of astasia-abasia, which is the designation that has been given to a disorganization or suppression of the coordinated movements concerned in walking or in standing upright. It has been written of extensively by French and German writers, and for a while it seemed as if we were in danger of having another disease added to our already unwieldy list of nervous disorders, but it is now universally recognized that astasia-abasia is but a symptom or manifestation of the medical sphinx, hysteria. The chief reason for so labeling this case is to call attention to the fact that it differs in certain points from the classical cases of astasia-abasia, and briefly to discuss its relation to injury. In typical cases of astasia-abasia the affected individual who is entirely unable to stand or to walk and who when he attempts to do so pitches forward on his face and falls quite like an inanimate object, is when lying in bed able to make any movement of the extremities quite as a normal individual does. For a week or so after the patient came into the hospital she could move her extremities but feebly. Thus the case may more aptly be called hysterical paralysis, but in reality that is what astasia-abasia is.

Its relation to the tabes is purely coincident. The accident chanced to afflict one who was already afflicted with a syphilitic disease of the spinal cord and meninges, but which had not yet begun to cause active symptoms. It has no real relationship to the tabes. There have been those who have contended that tabes is in some instances dependent upon trauma, and one hears in the courts not infrequently such claim made by physicians. It will be made less frequently, or less successfully in the future now that the diagnosis of tabes may be corroborated by serological investigation, for few will be so partisan or interested in the litigation as to contend that change in the cerebrospinal fluid which is now recognized to be pathognomonic of syphilis (plus Wassermann, excess of globulin, reduction of Fehling, and lymphocytes) may be induced by trauma.

The outcome of this patient's hysterical manifestations

is gratifying enough, but for her the greater compensation is that the tabes has been discovered in a stage when, in all likelihood, its progress may be arrested, and we propose to urge her to submit herself to vigorous salvarsan and mercurial medication.

SECOND DIVISION—DR. FREDERICK PATERSON.

Temporosphenoidal Epilepsy.—Dr. KENNEDY presented a case of temporosphenoidal epilepsy. P. L., Frenchman, age 58, admitted Oct. 17, 1912. On admission he complained of headache and a "funny feeling" over the whole right side of the body. He had syphilis six years before which had been treated at the time with mercurial injections and, in March, 1912, by six full doses of salvarsan, otherwise his health had been good. A nasal polypus had entirely destroyed the sense of smell. The history of his condition was as follows:

On the third of August, 1912, he experienced a violent headache which in a few hours was followed by marked dizziness and then sudden unconsciousness. He was taken to the Presbyterian Hospital, where he remained in an allegedly delirious condition for a week, at the end of which time he was able to recognize his relatives. He remained in the hospital for about two weeks and was discharged, according to his own account, physically well, but with a "cloudiness in the head and a memory that was poor." Subsequently he went to his business for about an hour or so every day but his "head" was never clear, and he began to have attacks which can best be described in his own words: "I have flashes in my head and a queer funny feeling; scenes present themselves to me but I can't place them. They seem like something I have been through but I cannot remember where and I feel that I am always going to remember and just miss it." At the time of these scenes and curious sensations he is always conscious of a very foul odor. He knows that this odor must be subjective as for twelve months he has been utterly unable to smell anything whatsoever.

In September he began to have occasional vomiting, frequent nausea and disagreeable epigastric sensations, synchronous for the most part with the attacks as above described. Of late he has had a sensation of haziness in his right visual field and particularly has he had numbness and tingling from time to time in the right trunk and in the right arm and leg. One of the scenes described by the patient as of particularly frequent occurrence and of a less complex nature than others is as follows: "I see before me small white balls, one or two at first, but these get larger and larger and multiply again and again, the increase in their size being accompanied by a feeling of intense fear on my part, and when they are about me in their greatest numbers they suddenly disappear." The phenomenon of multiplication and increase in size is characteristic of whatever visionary objects he sees. A feeling of detachment and dreaminess accompanied by fear is also present and the evil odor is constant.

On examination he is a small, rather undersized man apparently of the age stated. He may be described as intelligent, keenly alert, interested in himself, striving to make every word describe exactly his condition for the doctor's benefit. He is perfectly well oriented in long distant and recent and contemporaneous events. His ocular fundi show a certain tortuosity in the arteries; the disks are slightly congested but not edematous. Both pupils are slightly irregular but can scarcely be described as sluggish to light or on convergence. He has no tremor in his lips and has no speech defect whatsoever. His gait is normal; no tremor in his hands; sensation everywhere good. The right knee jerk is slightly less active than the left; the right plantar reflex is rather less active than the left, though neither is changed in type. The right abdominal reflex is less than that on the left side. No sphincter trouble. A serological examination of his blood showed a positive Wassermann reaction; an examination of the spinal fluid showed a lymphocytosis of 27 cells per cubic millimeter, an excess of globulin, and a strongly positive Wasseremann reaction. According to most authorities this serological formula is demonstrable proof of this man being a general paretic, but his clinical examination would tend to show him rather as suffering from a localized lesion in the tip of one or the other temporosphenoidal lobes, in all probability of a pachymeningitic character.

The case is shown as one of cerebral lues of a pachymeningitic type which if left untreated will probably subsequently develop into paresis. Incidentally the case is interesting as affording an opportunity for the observation of a peculiar variety of temporosphenoidal epilepsy; the result of irritation of the uncus and contiguous areas. The mechanics of dreamy mental states have never been satisfactorily given, but in lower vertebrates the hippocampal lobes are enormously developed, owing to the preponderance of the sense of smell in them, so that these brain areas may fill in such lower animals the functions located in man in the frontal lobes.

As each individual goes through, in his development from embryonic to adult life, stages analogous to those through which the race has passed in its evolutionary periods, we may suggest that the hippocampal lobes may fulfill intellectual functions in the infant and in early life, functions which are later more fully sustained by the frontal lobes. Memories contained therein never die, but are, when apparently lost, only more difficult to facilitate to the threshold of consciousness; so irritation of the hippocampal lobes may bring almost to consciousness memories incoordinate and but half resuscitated, which have been thought long ago to be dead.

THIRD DIVISION—DR. PEARCE BAILEY.

Bárány Tests in Cerebellar Disease.—Dr. LOUIS CASAMAJOR presented a case of cerebellar disease, illustrating the use of the Bárány tests in cerebellar localization. Optic nystagmus may readily be divided into two groups: (1) Undulating nystagmus in which the eyes move in each direction with equal rapidity. This is the type ordinarily seen in multiple sclerosis: (2) Rhythmic nystagmus in which there is a marked difference between the rapidity of the movements in the two directions. This is the type seen in labyrinthine disease and cerebellar lesions.

This rhythmic so-called vestibular nystagmus is spoken of as nystagmus to right or to left according to the direction of the rapid movement of the eyes. Thus when the rapid movements is toward the right and the slow to the left, it is said to be nystagmus to right. The nystagmus is always increased when the patient looks in the direction of the rapid movement and lessened when he looks in the direction of the slow one.

While in cerebellar disease the resulting nystagmus is usually in the direction of the side on which the lesion is located, nevertheless this is not invariably the rule, for in these cases daily fluctuation in the intensity and direction of the nystagmus occur. Hence we must find a more certain method of approach in these cases and this method is afforded by the Bárány tests by which we determine the activity of the vestibular apparatus governing rythmic nystagmus, *i.e.* the semicircular canals.

Bárány, in 1907, elaborated tests by which the functional activity of the auricular vestibula could be determined.

A brief outline of the technique is in order:

1. *Rotary Nystagmus.*—The patient with eyes closed is rotated in a revolving chair 10 times in about 20 seconds. After being stopped, he shows nystagmus in the direction opposite to that in which he was turned. That is, if he

had been turned to the right, expressed by the military order—"right about face"—the resulting nystagmus is toward the left. In normal individuals the direction of the nystagmus after such turning is about 40 seconds according to Bárány.

2. *Caloric Nystagmus.*—With the aid of an irrigating apparatus the ear to be examined is irrigated with water at a temperature of about 86 deg. Fahrenheit. The eyes are watched and the onset of nystagmus, which in this case is always in the direction away from the ear irrigated, is noted. A convenient, though a not very accurate estimation of the irritability of the vestibula is obtained by recording the length of time required by the irrigation to produce nystagmus on the two sides.

The practical utilization of these tests is shown in the following cases:

M. S.—21 years of age, single, German, waitress, was referred to the third division by Dr. Conyers Herring on October 11, 1912, complaining of dizziness, diplopia and headache. Family history and early life negative. She denies luetic infection. Does not indulge in alcohol.

Present Illness.—In February, 1912, the patient finding herself 2 months pregnant took quinine to produce an abortion, 3-5 gr. pills q d for one week. At this time she suffered a great deal from dizziness, which passed away when she discontinued the quinine. The abortion was later performed by operation. Hereafter the patient was well until the early part of August, 1912, when she began to complain of continual dizziness and headache. She also noticed at this time that she would see double when she looked at distant objects, while for near vision there was no diplopia. The headache is frontal and almost constant at times varying in intensity. There never has been any nausea or vomiting. About a month before the onset of this headache, the patient noticed that her eyes were unequal in size. She does not know whether they were always this way, whether one has grown larger or the other smaller.

Physical examination on admission showed a well developed young German woman, who in walking and standing has a tendency to fall to the right. There is no paralysis, tremor or incoordination. On showing her teeth there is a slight right facial weakness. There is some adiadochokinesis on the right. Marked asynergia. Her deep reflexes are very active and equal. No Babinski or clonus. The right epigastric and abdominal reflxes are less active than those of the left. No sensory disturbances.

Laboratory reports: Urine negative, blood Wassermann positive. In the past 3 weeks the patient has received two injections of salarsan 0.6 grams and six inunctions of mercury ointment gr. xl q d between the two salvarsan injections. Has made practically no improvement.

Physical examination now shows practically the same findings as on admission. Nystagmus unchanged, right facial weakness a little more marked. Slight cerebellar ataxia in right arm and leg. Adiadochokinesis marked in right arm. All reflexes active and equal.

Dr. Holden's report on the eyes.—Corneal sensibility normal. Pupils unequal; right greater than left. Reaction normal. Mobility normal. In constant diplopia with red glass. Left palpebral aperture narrow. Vision right 20/20, left 20/40. Fields slightly contracted. Fundi normal.

Interpretation: Inhibition of left cervical sympathetic. The most prominent feature is the nystagmus which is spontaneous, rotary, and caloric.

Spontaneous Nystagmus.—Eyes in mid line—no nystagmus; coarse horizontal and rotary nystagmus to right; fine rapid horizontal and rotary nystagmus to left; coarse irregular vertical nystagmus upward. The results of the Bárány tests are of interest.

Rotary Nystagmus.—Turning to right 10 X; head upright; coarse horizontal and rotary nystagmus to left for 45 seconds. Turning to left 10 X; head upright; coarse horizontal and rotary nystagmus to right for 55 seconds. (Interpretation: Right labyrinth less irritable than left.)

Caloric Nystagmus.—Water at 86° F. Head upright. Irrigating right ear: Horizontal and rotary nystagmus (slight) to left 1 minute 30 seconds. Irrigating left ear: Horizontal and rotary nystagmus (active) to right after 45 seconds. (Interpretation: Right labyrinth less irritable than left.)

Hearing: right ear watch at 2 feet; left ear watch heard at the same distance. The following is an analysis of the present case:

(*a*) Local signs: 1—right facial weakness; 2—diplopia on looking at a distance, possibly very slight degree of external rectus palsy (rt. N. VI. ?)

(*b*) Vestibular mechanism signs: 1—horizontal and rotary nystagmus in all directions, most marked toward right; 2—decreased irritability of right labyrinth to turning and caloric tests. That is irritation of right vestibular mechanism with decreased conducton from periphery.

(*c*) General cerebellar signs: 1—dizziness; 2—tendency to fall to the right; 3—slight cerebellar ataxia on right; 4—adiadochokinesis on right.

(*d*) Pyramidal tract signs lacking: 1—muscular power not disturbed; 2—no change in reflexes.

This case is then offered as one of right cerebellar hemisphere lesion, probably new growth on account of the history of gradual progression. It is possibly a gumma. In favor of this is the positive Wassermann. Against it is the failure of improvement on active antiluetic treatment. Possibly it is a cerebellar neoplasm which has no relation to the syphilitic infection.

A final point of interest is the remarkable susceptibility this patient showed to the action of quinine in that she showed dizziness after administration of very small doses of the drug. It is possible that in this case the cerebellar growth at the time of the ingestion of the quinine was not of sufficient size to cause symptoms, but its presence intensified the action of quinine in causing irritation of the vestibular apparatus.

In this connection I wish to mention Bárány test results of another young woman who was on the service of the Third Division the past summer.

S. P.—Age 31, was admitted Aug. 3, 1912 suffering from undoubted signs of a tumor of the left cerebellopontine angle. Choked disk with beginning atrophy, 6th, 7th and 8th nerve paralysis on left. Adiadochokinesis on left, together with some very slight cerebellar ataxia. No change in the deep or superficial reflexes. In this case also the nystagmus was a prominent feature.

Spontaneous Nystagmus.—Eyes in medium line; slight horizontal and rotary nystagmus to right; looking to right marked rapid horizontal and rotary nystagmus to right; looking to left, irregular course and rotary nystagmus to left.

Rotary Nystagmus.—Turning to right, horizontal and rotary nystagmus to left 11 seconds; turning to left horizontal and rotary nystagmus to right, 7 seconds.

Caloric Nystagmus.—Water at 84° F. Head upright: left ear no nystagmus after two minutes; right ear slight horizontal and rotary; nystagmus to left after 1 minute 15 seconds.

Interpretation: Vestibular nystagmus caused by the irritation of the intercranial vestibular mechanism of both sides, right greater than left. Loss of irritability of right labyrinth and marked diminution of the left.

Dr. Taylor did a two-stage operaton on August 23, removed a soft tumor about one inch in diameter from the left cerebellar hemisphere where it overhung the cerebellopontine angle. Patient died a few days later of pneumonia. Autopsy refused.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Sixty-fifth Anniversary Meeting, Held November 21, 1912.

DR. WILLIAM K. POLK IN THE CHAIR.

The Doctor's Future.—Dr. CHARLES L. DANA made this address in which he considered the subject in its relation to the advances in public hygiene. He said that the position of a prophet was one of much delicacy and he did not pretend to have the qualifications of a sound and competent soothsayer, so he could not look very far ahead. There were, however, certain conditions and tendencies which were very much in evidence. These were not guesses but facts, and by recognizing and interpreting them one could make some inferences as to the immediate future. The number of physicians had increased much faster than the population and the number of medical colleges had increased until there were one hundred and fifty-one in 1900. Since that time they had been decreasing in number and improving in quality. There were now about five thousand fewer medical students than seven years ago. Germany had one physician to every two thousand population, while we had one to every five hundred population. There was going to be a further decrease in the number of students, for the community was awaking to the fact that it must have really well educated and well trained medical men and that this was expensive. The disease and mortality rates were steadily decreasing and there would be less need of so many physicians. The decrease in the number of medical men would, however, probably stop before it reached the German ratio. Perhaps the American doctor was an important and useful citizen for he seemed to be more esteemed and ranked higher socially than in other countries. As the number decreased it was reasonable to expect that those left would have more to do and would be in a better economic position. There were, however, disturbing factors. Charlatanism throve and the patent medicine fungus clung to every phase of civilization. They had the drug counter practice and the various obsessive and commercial cults with which to contend. These might not be so much a hindrance to the doctor for "fooling with disease always brought disaster." The death rate had fallen until it was now from one-third to one-half what it was thirty years ago. Many agencies had contributed to this result. There was in consequence a more enlightened community in respect to health laws and prevention of disease, and, as a result, a steadily diminishing mortality and morbidity rate. There was also developing a change in the methods of treatment. In the future drugs would be given more, but more wisely, and they would be not exactly drugs, but chemical and mental foods, glandular extracts, and the protective sera. More cures would be made and the periods of illness would be shorter. There was a tendency to institutional and colonization treatment of certain classes of the chronically sick. In the future state, insurance of the working classes would be a modifying agency which the doctor would have to take into consideration. The doctor had always helped on movements which had lessened his work and had thus committed honorable harakiri so far as his own personal fortunes were concerned, and he would help along this movement still more. Thus he became a more important man in the community and in the management of public affairs. In managing the health of the Nation he had a greater function than in prescribing for the individual. Medicine would become a part of statecraft and doctors would direct affairs of State more and lawyers less than in the past. Meanwhile the progress of prophylaxis was going to be slow and all doctors need not leave their clinics and plunge into the crusade. They could show active sympathy and render assistance by daily personal teaching and by evincing genuine public spirit. The doctor's cue was to oppose institutionalism in so far as was wise. All did not wish to become lodge doctors, government doctors, or institutional doctors. There must be an opportunity for high individual effort, for talent to rise, and for genius to reach its proper level. In regard to the teaching of medicine, the day would come when the institutions for graduate study would be under control of the regents or its equivalent. The day of casual teaching would pass. All really great hospitals would be allied with universities. The hospitals would be under the medical control of fewer doctors and these would give a definite part of their time and it was to be hoped that they would be paid for it. There would still be room for private work. The old fashioned doctor and general practitioner was a splendid figure and a useful person in his day, but he was badly trained, often ignorant, and made many mistakes; force of character and a genial personality could not make a diagnosis of appendicitis or recognize streptococcus infection. The old general practitioner was going and it was a good riddance. There was developing a general practitioner of higher type, soundly educated, and knowing the human body, knowing enough both of medicine and surgery to recognize rare as well as common diseases, and also knowing his own limitations. He could be human and benignant, too, and always should be honest. This new type of family doctor was not going to be swept aside by a group of specialists. These could only adorn and enrich his progress. The specialist would till his little field, the internist would gather. The surgeon of the large centers would become more and more specialized. All over the country would be small hospitals where the general practitioner and the surgeon would do traumatic and emergency work. It was to be hoped that the surgeon would learn to take a keener range of view and become a little less appropriative, objective, and technical, less amazed at his own resources, more thoughtful, sympathetic, and touched by awakening social conscientiousness, becoming beloved for what he would not do as well as for what he would do. Women physicians had been decreasing in number faster than men. They had done good work, but not brilliant or constructive work. There was a distinct field for them in laboratories and institutions. They were quick to see the need of social reforms and a great help in preventive medicine. The doctor of the future would be a schoolhouse doctor. There would be a bureau of child hygiene in every town; the doctor would make teaching easier and better; he would be very useful but very expensive and very much beloved. Now he was none of these things. He would see that workers were protected from long hours, bad sanitary conditions, dangerous trades, and accidents incurred in work. He would see that the poor as well as those not poor had better opportunities for amusement. The people could do without faster transportation and without bigger business, but they could not do without these reforms. "Take to your hearts a saner view and warm your souls with more useful fires; guard the child, bring it up to be healthy and morally sound; guard the home and the individual so that he will not be fed on poisons or live in foul conditions; keep the community free from disease, from insanity, from weakmindedness, depravity and infections; make them breed healthy children and live long, sane, healthy lives—greed and dishonesty will spoil every one of my visions."

The Doctor's Future.—Dr. ALGERNON T. BRISTOW read this paper in which he considered the doctor's future in relation to national medical insurance. He said that the medical profession had for years been trying to accomplish the impossible experiment of getting blood out of a stone. It had blamed the superabundance of hospitals, dispensaries and the numerous undoubted abuses of these public charities for the sterility of its experiment. It had never seemed to occur to them that they had been trying to accomplish the impossible. The science of medicine differed from the other learned professions in that it was a necessity to the public. It might become a luxury to the rich, but to the poor man medicine was a necessity. A man could die without the intervention of the clergy, and if he had little property the lawyer had no interest in him, but he could not die without the doctor except by the kind assistance of the coroner. Dr. Bristow cited from the investigations of Scott Nearing, showing that 90 per cent. of the adult males in the United States had an annual income of less than $800, 75 per cent. less than $600, and fully 50 per cent. less than $500 per annum. More recently John A. Kingsbury, general agent of the New York Association for Improving the Condition of the Poor, had said that at present $1200 was essential for the maintenance of a normal standard of living for a family of five, man, wife, and three children. An income of $900 would provide only the minimum of nourishment and comfort and would not meet any extra demands that might be made on the family. Such families had to economize in every way and in times of sickness must depend on the free dispensaries. The fact was that the vast majority of city dwellers had the narrowest possible margin between their fixed charges and their total income and the same was true of the dwellers on the land, with the difference that for the latter it was possible to live off the soil, at least in favorable years. They were not quite so badly off in case of sickness as the dweller in the large city, whose income was cut off when he took to bed and who had no farm products stored in his cellar to feed hungry mouths. As a result of these economic conditions the people had flocked to the dispensaries, had filled the hospital wards and had

become pauperized not from choice but from necessity. The result of all this to the medical men had been that a few with wealthy and fashionable clients had grown rich, while the larger proportion with clients of the middle class or of those with moderate but adequate incomes made a comfortable living, but the vast majority of medical men were as poor as their patients. To sum up the condition which then presented itself, they had, on the one hand, the greatest number of citizens with fixed charges almost equal to their incomes who were unable to bear the financial strain of illness and disability combined and were compelled to seek charity. On the other hand they had a body of men whose education was the most costly of any of the learned professions who were compelled to contemplate with such calmness as might be the curtailment of their incomes by the advances of prophylactic medicine, while not only were their living expenses steadily increasing but also the cost of their education in both time and money. The people needed medical attention for which they were unable to pay and the medical profession needed some relief from the inroads which science and the State were making on the incomes of its members. For a number of years in this country and for a much longer period in Europe the people had been combining in associations of sick-benefit lodges in order to get medical attention which was within their means. Thus the resort to lodge and contract practice had been the answer to the problem of obtaining medical attendance in their homes when they needed it. Dr. Bristow quoted statistics showing the extent of lodge practice in New York, there being over 275 mutual benefit societies in Greater New York. This was exclusive of the Figli d'Italia, of which there were over 45 in the city. In New York there were about 500 Jewish physicians engaged in lodge practice, getting from one to two dollars a year to attend to five or six hundred members, and in many instances looking after the families of the members for one dollar additional per family. That the practice itself was poor and that the services rendered were second rate was obvious from the amount of work at low pay which this lodge practice entailed. Lodge practice in this country was not confined to the two nationalities referred to above. There were many native Americans in the rural districts who belonged to the Foresters and countless other organizations with fanciful names. Various county societies had at times issued pronunciamentos against these societies, and had threatened with expulsion many of their members who were under contract to lodge or benefit societies. One such physician, on threat to bring him before the Kings County Society, replied: "If it is a question between my wife and children and the County Society I shall choose my family every time." The reply seemed convincing. Lodge practice was with us and it was here to stay. Nothing that this body, or the County Society, or the State Society could do would change the situation one hair's breadth so far as the continued existence of these societies was concerned. From the standpoint of the people lodge practice was nothing more than a system of medical insurance. No one thought it wrong to take out an accident policy, a liability policy, a sick benefit policy, or a life insurance policy in an old line company. Why should it be proper for the members of this academy to hold sick benefit policies and wrong the poor man for doing the same thing according to his needs and means? What was the difference between the two cases? Briefly, it was a difference of method. The old company paid its beneficiaries a weekly indemnity for a specified time and the insured employed his own physician and paid him. There is no question but that this was the better way both for patient and physician. Was it possible to apply the same principle to the poor man? The cost of the old-line policies was entirely beyond the means of the poor man. If they could bring themselves with fairmindedness to admit the necessity of medical insurance for the large mass of the people, a long step would have been taken in the direction of the solution of the problems which had been vexing them. Dr. Bristow said that it was his opinion that the future of the doctor was going to be largely influenced by the view which they as medical men took of medical insurance. They could either recognize the facts and meet them with advantage to themselves as well as to the people whom they served, or they could blindly shut their eyes to the facts and cry that it was unethical to attend the poor man for a price within his means. When the English government incorporated the principle into a law and created a system of national insurance against sickness they might be certain that ultimately the same principle would gain recognition in this country. Dr. Bristow begged those interested in this subject to read the supplements to the *British Medical Journal* entitled "National Insurance," where they might see the magnificent example that the British Medical Association was setting their own organization of what it was possible to accomplish by loyalty and unanimity of purpose when the interests of the medical profession were involved. The various sections of the British Medical Association had passed resolutions on the subject in which the most important points were the income limit, the choice of a doctor, and the passing of the control of the insurance from the hands of the friendly society to the doctors. This was in accord with sound economic principles. No insurance company could exist for a year if its rates were determined by the insured. These were subject to the calculation of the actuaries, and somewhat similar methods would have to be adopted in any scheme of State or national insurance. Of one thing they might be sure: the medical profession would never shirk its responsibilities and would ever consent to suffer wrong rather than withhold a helping hand.

Dr. Abraham Jacobi said that both speakers had referred to the medical men of the future, but it should be remembered that it was not only the medical profession, but the State and society that would be responsible in building up this future. The State must help them a great deal. If they would look over the lists of men active in sanitation they would find that most of them had not been specialists, but that this work had devolved on the general practitioner. The general practitioner had many opportunities presented to him that others had not and he had gained a great deal that the specialist did not have the opportunity of getting. He was giving better service not only to his own patients but to the community at large. Dr. Jacobi referred to the passing of the old-fashioned American home and with the old-fashioned doctor, but he was confident that saner consideration would yet restore the home to its former importance and with the return of the home would come the return of the family doctor, modified in a sense but still a general practitioner and the friend and confident of his patient.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Annual Meeting, Held November 25, 1912.

The President, Dr. Charles Gilmore Kerley, in the Chair.

Executive Session.—Dr. John Van Doren Young read the minutes of the previous Stated Meeting, which was followed by the reports of the various committees, among which were the following:

Report of the Committee on Legislation.—Dr. E. Eliot Harris submitted this report. He said that there were introduced into the Legislature during 1912 bills to the number of 2,859, which were amended so as to raise the printed number to 3,527 bills in both houses. Of that number 553, or about 19 per cent., were enacted into laws. These bills were received by the Chairman of the Committee on Legislation, divided among the members of the committee for review, and were reported promptly at the meeting of the full commmittee. The committee then acted on these bills and submitted its report to the next meeting of the Society. The committee had also to consider many communications received from other societies on matters of medical legislation, such as prison reforms and bills affecting marriage licenses. The report then reviewed the bills that they had been interested in promoting which embraced bills affecting the Tenement House Law, Domestic Relations Law, Deportation Law, the Pure Food Law, the Labor Law and the Agricultural Law as well as those bills affecting more directly the questions of public health and the practice of medicine. The committee had not only been active in constructive legislation but had done a good work in defeating the antivivisection bills that were introduced. This class of bills demanded the greatest activity on the part of the medical profession. They would no doubt be introduced into the next Legislature and would require active work on the part of all the committees on legislation and animal experimentation in order to secure their defeat. The report recommended that the Legislative Index be continued for the coming year.

Report of Committee on Hospital and Dispensary Abuse.—Dr. William S. Thomas submitted this report. He said that this committee, which was instructed to investigate and report upon the subject of lodge and contract practice as well as upon hospital and dispensary abuse, had completed its work and laid its report before the Comitia Minora. They had decided that, in view of

the importance of the report and the time needed for its consideration and discussion, a summary should be made and read before the Society. The committee found that as it was to exist for one year only, and if it was to be limited to its stated appropriation, it would have to confine its activities largely to the investigation of the dispensary abuse. The investigation of lodge and contract practice had been referred to a sub-committee. The dispensary abuse had been investigated in two separate and distinct directions. First, individual members had visited representative institutions during their working hours and reported to the committee in writing upon the details of their management in reference to the existence of abuse of charity. Second, the committee engaged the services of an expert social worker to investigate the subject from the standpoint of the patient. In 1911 over 665,000 new patients were treated in the dispensaries of this county. In order to get a true idea of the proportion of those who applied this year unworthily it was decided to investigate in their homes 1,000 applicants without discrimination, as their names appeared on the books of 13 representative dispensaries. The results of these investigations had been thoroughly digested and would be laid before the Society at its February meeting. Of the 1,000 applicants investigated, 255 of them, or 25.5 per cent., could not be found at the addresses given. Of the remaining 745 applicants whose homes were visited about 10 per cent. seemed to be able to pay for medical treatment. A surprisingly large proportion of the applicants resided out of town. The investigation of dispensaries by individual members of the Committee proceeded on the lines suggested by the regulations of the State Board of Charities governing dispensary administration and the following points were especially considered: 1. Posting of the law in dispensaries. 2. Registrars and their capability for their work. 3 Admission of applicants, the admission and the representation card. 4. Enforcement of the laws against false representation. 5. Regarding the payment of fees in dispensaries. 6. Location of patient's homes in relation to the dispensary. The results of the investigation in these particular points, together with the committee's recommendations, would be laid in full before the Society at the February meeting.

Annual Report of the Counsel.—Dr. ALMUTH C. VANDIVEER submitted this report.—He stated that the general character of the work done was best shown by referring to the individual prosecutions. The work done had covered every form of violation of the Medical Law. The counsel felt that the active and vigorous prosecuting of medical quacks had won the respect of the entire community of the City of New York. During the past year the counsel of the Society had been consulted by the Board of Health, the Police Department, the Tenement House Department, the State Board of Charities, the Committee for the Prevention of Blindness, the Charity Organization Society, the State Education Department, the United States Post Office Department, the United States District Attorney's Office and the District Attorney's Office of the County of New York. The work of the Society in protecting the public health had met with the approval of the Courts and the public officials. The counsel felt that the Board of City Magistrates of the City of New York and the Justices of the Courts of Special Sessions now gave their careful consideration to all medical offences prosecuted before them. The counsel had prosecuted violators of the medical law, had investigated complaints concerning violations of the law by unlicensed persons when submitted to him, had inquired into the character and practice of physicians, whether members of the Society or not, had defended in the civil courts actions brought against the Society by members of the Society, and had rendered to the Comitia Minora and to the Board of Censors legal advice upon all questions presented to him. Persons practising medicine under the cloak of religion had been arrested, tried, and convicted upon the complaint of this Society. Institutions attempting to grant degrees to practise various branches of the healing art had been investigated and prosecuted. Fraudulent medical concerns carrying on their business in such a way as to avoid coming within the law of the State of New York had had their activities called to the attention of the United States Post Office inspectors. Arrests and prosecutions had followed upon the complaints submitted by the counsel to the Post Office authorities. During the past year at least three hundred persons had called at the office of the counsel to have their queries concerning medical questions answered. The counsel then reviewed a number of cases that had come before him, among them those of Schmidt, Kunizer, and Ewald. He called special attention to the conviction and subsequent pardon of Edward E. Conrad and George J. Gladman, each of whom was convicted in the counties of New York and Onondaga, respectively, of an attempt to commit the crime of abortion. The pardon of these men had demonstrated to the counsel the absence of any express provision in the law in the State of New York to meet such a situation. The statutes provided that when a convicted lawyer had been pardoned he might apply to the Appellate Division of the Supreme Court for reinstatement to practice. There was no such provision in the Medical Statute. There was, however, a provision to the effect that no person who had been found guilty of a felony might thereafter practise. It had been contended by the counsel for Dr. Conrad, the Honorable Asa Bird Gardiner, that his pardon completely wiped out his guilt and restored him to all his rights and privileges which he possessed before his conviction. The following paragraph was suggested for insertion in the Medical Statute: "Where a duly licensed physician is convicted of a crime and thereafter pardoned, such pardon does not restore his right to practise medicine, but such practitioner may within three months after the receipt by him of a pardon make application to the Board of Regents for restoration to practice." There was in the Medical Statute setting out the causes for the revocation of licenses of practitioners of medicine no statement to the effect that unprofessional or dishonorable conduct, aside from fraud and deceit in practice, was a sufficient ground to revoke a practitioner's license. There was such a provision in the Dental Law, and in the opinion of the counsel there should be such a provision in the Medical Law. It was also the opinion of the counsel that the Board of Regents should be given the authority to suspend a practitioner of medicine from practice for such a time as in their discretion the charges of which he had been found guilty merited. The Appellate Division had such authority as regarded lawyers and the State Board of Regents had such authority as regarded dentists. In the opinion of the counsel, incurable insanity should also be a ground for the revocation of a license of a practitioner of medicine. There was no such provision at the present time. A statute had been recently passed prohibiting corporations from practising law as corporations or through the medium of hired lawyers. The Court of Appeals, in the Woodbury case, held that a corporation might not practise medicine by employing registered physicians. This decision should be crystallized into a legislative enactment following the same lines as the drastic statute in regard to the practice of law by corporations. Mr. Vandiveer then reviewed the case of Vernon Cole, who was prosecuted for practising medicine under the cloak of Christian Science and of several other individuals practising under other religious tenets. A great number of complaints concerning druggists who were practising medicine illegally had been investigated and when sufficient evidence had been obtained a vigorous prosecution of the offender had been presented in court. Mr. Vandiveer also told of the work done in investigating the practices of midwives and certain clairvoyants. He stated that he regarded as one of the greatest compliments to his work the fact that the investigators employed by him, Mrs. Frances Benzecry and Mr. Stephen Fontana, were believed by all the judges before whom they appeared. In many cases the unsupported word of these witnesses had obtained convictions. The strict supervision by means of investigations had caused a wonderful change in the fraudulent practices of medical concerns in this city. Complaints as to the taking of great sums of money from poor persons were less frequent than they were three or four years ago. Business concerns now interviewed the counsel of this Society concerning the reputation and standing of persons whenever they were connected with medical practice in any way whatsoever. During the period from November 25, 1911, to November 22, 1912, $4,100 in fines had been awarded to the treasurer of this Society, but it might readily be seen that the expenses of prosecuting violations of the Medical Law were about equal to the fines imposed.

Annual Report of the Comitia Minora.—Dr. JOHN VAN DOREN YOUNG made this report. He stated that the Comitia Minora had held eight Stated Meetings and three Special ones, and that there had been a quorum at each and every meeting. At the eight Stated Meetings the average attendance had been 220 and the total attendance 1765. There had been added to the membership of the Society during the year 129 new members and 21 candidates for election at the present meeting. Last year the membership had been increased by 184 members. There had been 20 deaths during the year and 21 resignations. At the present time the membership numbered 2,469. This report then reviewed the amendments to the Constitution and By-Laws that had been adopted by the So-

ciety at the Annual Meeting of November 27, 1911. The report reviewed the executive work and the scientific programs of the past year and showed that 170 members of the Society had taken part in the executive work, that 17 had read papers, and 41 had discussed the same, making a total of 228 who had served the Society during the year.

Spasm of the Pylorus in Infants and Congenital Stenosis of the Pylorus.—Dr. Henry Koplik read this paper. He said that in his first paper on pyloric spasm and pyloric stenosis he made an analysis of those cases in which the spasm with only a relative amount of stenosis played a leading rôle and those in which a distinct growth of congenital origin existed at the pylorus with symptoms of spasm of the pylorus as an accompaniment. Strange as it might seem they could not as yet say that all were agreed that such a condition as pure spasm without any anatomical change in the structure of the pylorus existed as a distinct uncomplicated entity. Pfaundler maintained that all the cases with which Dr. Koplik's paper dealt were those of pure spasm. He had since modified his views, dividing the cases of pure spasm of the pylorus from the true congenital hypertrophy of the tissues of the pylorus. Only this should be borne in mind that Ibrahim reiterated his doubt as to the existence of a true pyloric spasm in infancy without any anatomical changes at the pylorus. Cantley had published post-mortem cases of pure spasm of the pylorus and Dr. Koplik had recently seen a case occurring in the surgical service of the Mount Sinai Hospital which, in every way, seemed to have been a case of spasm of the pylorus with pyloric tumor as met in congenital hypertrophy. They had thus cases of spasm of the pylorus which during life might or might not give a palpable tumor and which at operation gave a palpable tumor and at post mortem the tumor persisted. It was even conceivable that microscopical examination of such a pylorus would show the tissues thickened. Whether this thickening was to be interpreted as a hypertrophy or the result of contraction of muscular fiber, future investigations would show. Pylorus spasm with relative stenosis of the lumen of the pylorus was therefore a distinct entity. All knew that the infant stomach was exceedingly sensitive to changes in the composition and reaction of the food. It was rather far fetched to try to compare the conditions in infancy with those met in the adult. His classification of all of the cases of this affection was as follows: (1) Pure spasm of the pylorus and the pyloric end of the stomach without any palpable pylorus, with peristalsis and explosive vomiting, loss of weight, and consequent inanition. The constipation present might be only a relative constipation, *i.e.* some fecal matter passed, or there might be several movements, green and fluid, in twenty-four hours, or of a brownish color; again the constipation might be absolute and on forced movement of the bowels, little or no fecal matter passing. (2) Pyloric spasm with relative and actual stenosis, with slight or marked thickening or hypertrophy of the tissues of the pylorus. Such cases gave rise to vomiting of the explosive type, coming soon on after birth and continuing for some time with a palpable pylorus at first or subsequent to the onset of the symptoms. The pylorus could be felt to harden under the finger at the time of greatest peristalsis of the stomach and soften after vomiting had occurred. There was constipation, complete at first, which after some duration of the disease mitigated and fecal particles might appear in the stools. There was marked progressive atrophy and inanition. (3) Congenital hypertrophy of the pylorus so-called with stenosis. These cases, which were only relatively more marked in their symptomatology to the previous class, gave exactly the same symptoms; there was the same spasm of the pylorus as an accompanying symptom; the pylorus could be felt just as in the previous class, the peristalsis was just the same, and the constipation was the same, only more marked. In fact, clinically it was the same condition that was present, only it might manifest itself in more aggravated forms than in the cases in which the hypertrophy and stenosis were not so marked. He thought, therefore, they were practically the same set of cases and might show considerable enlargement and hardening of the pylorus than was evident before the operation. Recovery depended on the resistance of the patient, the skill with which the case was managed, and the power of the sufferers to overcome the baneful effects of inanition. The question of prognosis was also bound up not only in the course of treatment but with the amount of spasm and stenosis present. Vomiting which might be violent, peristalsis, and loss of stationary weight were no indications for surgical interference, however alarming the symptoms might appear at times. Such cases should never be submitted to the surgeon. From a careful study of all his cases, numbering twenty-five, he believed that cases of congenital pyloric stenosis with spasm and hypertrophy of the tissues of the pylorus could in the vast majority of instances be brought through without surgical interference. He thought that the cases which must come under the knife must be exceedingly rare. Reports of the fatal cases were not always published. The mortality of these cases with some operators was fully fifty per cent. Dr. Koplik thought that inasmuch as ninety per cent. of his apparently hopeless cases had come through without operation he would submit that the risk involved in the operative interference was so great at present as not to encourage them to place any of these cases in the hands of the surgeon. Einhorn had proposed to pass through the stenotic pylorus a bucket and on the leading string of this bucket a dilator. This treatment of dilating the stenosis was quite attractive if it could be accomplished in the extreme cases. This was absolutely impossible in some cases; often a filiform probe could not be passed, much less a small bucket or guide. Any pylorus which would admit the passage of a bucket guide and dilator would recover without this procedure. Another procedure proposed had been the passage of a duodenal catheter, and leaving it in the lumen of the pylorus for a length of time, or feeding the patient through such a catheter in the duodenum according to the methods advocated by Einhorn and Hess. This procedure he believed to be of limited value also. In marked hypertrophy and spasm he has found that the catheter failed to pass. They were therefore reduced to the former methods which included exceedingly patient study of the feeding, lavage at times, opium, and what was of the greatest moment, persistent attention to details. Dr. Koplik closed his paper with a reference to the direction in which the feeding might take in the future. In a very suggestive series of studies by Cowie and Lyon on the acid control of the pylorus in infants, the mechanism of the opening and closure of the pylorus, as explained by Pawlow in the adult, had been carefully worked out in infants. It appeared to Dr. Koplik that in the feeding of infants suffering with pyloric spasm and hypertrophy more attention should be given to the relative acidity of the stomach content than had been done in the past. In this way a relief of symptoms might be more readily attained.

Dr. Henry Dwight Chapin said that he would like to go on record as having expressed the opinion that many of these cases of pyloric spasm got well under careful dieting and the giving of alkalies which reduced the spasm.

Dr. Albert Ashton Berg believed that the diagnosis of these cases of pyloric stenosis in infancy rested upon the internist, especially those cases of pure spasm with a relative hypertrophy. It was a very important fact that the surgeon should ask for greater diagnostic acumen. It was an accepted law among pediatrists that when an infant lost one-third of its body weight it went on to death; when this amount in weight was lost there was no doubt about a fatal ending. From a surgical standpoint there was no doubt but that in these cases the burden was on the shoulders of the physician who first saw them. More should be done toward differentiating the cases that were or were not relieved by medical treatment. The cases that should be referred to the surgeon should be those that could not be relieved by medical means.

Dr. Howard Lilienthal said that he had had three cases of pyloric stenosis occurring in infants; one got well without operative interference, another got well, making an operative recovery, but the third died because of leakage. Dr. Lilienthal thought that the time to operate was as soon as it was proven that there was a complete obstruction at the pylorus. The first effort in these cases should be the attempt to relieve by medical means; next, they should attempt the passage of some instrument if this was possible; if unsuccessful and the instrument could not be passed through the pylorus, they should try the fluoroscope with the bismuth meal. If nothing went through and the patient was losing weight he should be at once sent to the surgeon. With regard to technique, he believed in a quick operation without the use of clamps; without the employment of clamps there was little danger of leakage and no hemorrhage would result.

The discussion was continued by Dr. Max Einhorn and Dr. Godfrey R. Pisek.

Bone Transplantation for Pott's Disease of the Spine.—Dr. Fred H. Albee read this paper. He said that too great emphasis could not be placed upon the mechanical element of crushing of the vertebral bodies in the prolongation of the convalescence of Pott's disease. He also believed with Ely and others that bony fixation of tuberculous joints was an absolute panacea. The following summary was offered: (1) The bone splint insert gave firm

fixation the moment it was sutured in place and afforded even before bony union far more efficient immobilization than any external brace or plaster-of-Paris jacket could possibly supply. (2) No normal anatomical structure or support of the spine was severed or destroyed. The full leverage of the spinous processes, which was the only physiological means of holding the spine in hyperextension, was preserved and taken advantage of, thus preventing kyphotic deformity. It should be noted in this connection that the nearer the bone transplant was to the tips of the spinous processes (or the more superficial) the greater mechanical advantage was derived. (3) The operative procedure was superficial and confined to bone and ligamentous structures; therefore, it was of short duration, usually taking from fifteen to thirty minutes, and was associated with a minimum amount of shock and hemorrhage. (4) The bed, into which the bone was placed, was of an ideal nature for a bone graft; it was composed of freshly severed ligamentous and bone structure. It was claimed that one bony contact, of recipient bone to graft, was sufficient for the establishment of a proper blood supply for the latter. In the case of their graft there were two bony contacts for each spinous process involved, and they were only the distance of the interspinous space apart. (5) On account of the fixation being applied internally and directly the vertebræ involved, and those only, the function of the rest of the spine and respiration was not interfered with. Long confinement on a frame, or in a plaster-of-Paris jacket, or spinal brace was no longer necessary. (6) The post-operative treatment was simple in character and of short duration. It consisted of dorsal recumbency on a gas-pipe frame or a firm mattress with a board under it and in the region where the kyphosis came (fracture bed) for a period of five to twelve weeks. At the end of this time bony union had taken place between the bone splint and vertebræ and no further supportive or immobilization treatment by plaster, jacket, braces, etc., was necessary. (7) The field of operation was superficial and distal from the neural arches; therefore, there was no danger of encroachment upon the spinal canal by overgrowth of bone or infection which might arise from operative trauma. (8) If bone union of graft to spinous processes should not by chance occur, the same mechanical effect of the splint action of the bone transplant and the leverage of the spinous processes would still obtain in a large degree. (9) Diseased tissues were not entered. The field of operation was entirely in healthy tissues; therefore, primary union could be expected. (10) A continuous bridge of bone with periosteum and endosteum was furnished, spanning the entire number of vertebræ, which were desired to be immobilized and therefore, should be under the influence of Wolf's anatomic law and become greater in diameter and length as the parts developed. In other words it was an imitation of nature's success. In dogs this bone transplant lost its identity in four or five months and became continuous and homogeneous with the spinous process into which it was placed and as apparently innervated by the same trophic nerves. (11) Perfect immobilization and support of the involved vertebræ in the respiratory area of the spine was secured. (12) The procedure was not a formidable one. The technique was very simple. In three cases the operating time was not over fifteen minutes. (13) When possible a recession of the kyphosis by recumbency on a convex gas-pipe frame should be secured. The bone graft offered great promise of holding permanently the correction obtained; without the artificial support there was a great tendency to a relapse of the deformity when ambulatory treatment was later resumed on account of the inhibition of the tuberculous bacillus to the rapid new bone formation between the diseased vertebræ. (14) Metal splints placed into or on bone would not hold for any length of time because of bone atrophy and absorption; this took place very easily wherever contact was between metal and bone. Therefore the advantage of a bone graft over metal was apparent. (15) One of the most gratifying features of this mode of treatment had been the large amount of kyphotic recession obtained at this time of operation and the first days after in early cases of angular deformities from the straightening effect of the bone transplant sutured under later tension into the dense inter- and super-spinous ligaments. Dr. Albee said his report of bone transplantation was based upon 112 human cases and 18 extensive animal experimentations. The human cases had been 84 cases of Pott's disease, 9 cases of clubfoot, 7 cases of ununited fracture, 6 of paralytic deformities of the feet, 1 osteomyelitis cavity, 1 astragalus transplanted into hip, and 1 paralysis of the wrist. In many of these cases enough time had not elapsed to be safe to draw trustworthy conclusions. But as the bone graft with its periosteum and marrow substance was properly in contact with the recipient bone, he felt that he was safe in expecting permanent results. Attention should also be called, Dr. Albee said, to the fact that the bone graft stimulated an active osteogenesis on the part of the recipient bone itself and thus increased the assurance of permanency of result.

Dr. Robert E. Soule said that such an innovation as Dr. Albee had presented must necessarily meet with the most severe criticism, not alone because of its being another method of treatment but because it was claimed that this was *the* method of treatment above all others to be applied to this condition. The treatment of tubercular joint disease was immobilization. The joints of the spine were the most difficult to immobilize, particularly in the dorsal region, and, owing to this fact, the various methods at present in use were open to much criticism. Under these methods it was necessary to continue treatment for a long period of time and in a great many instances, though the disease was arrested or cured, there would still remain a marked kyphotic deformity; this deformity was the rule and not the exception. Again they found the disease recurring after years of quiescence. Patients were often incapacitated for work not by the disease *per se* but by the weak spine and increasing deformity after the disease had been arrested. Another criticism of these methods was that they were not properly carried out by the average surgeon; it took more skill and experience in making a well applied plaster-of-Paris packet, or in designing, fitting, and applying a properly adjusted brace, or in dealing with the recumbent methods of treatment than the average surgeon possessed. Taking all the objections to present methods into consideration, it seemed to him that the method presented by Dr. Albee offered the best solution of this vexed problem that they had considered up to the present time. It had been his privilege to assist Dr. Albee in his experimental work on the spines of a number of dogs. He had seen these engrafted segments of the spine after varying periods of time removed, gross and microscopical sections made, and felt that this method, so simple in technique, so free from danger to the patient, and so sure of accomplishing absolute immobilization of the diseased vertebrae was the most rational and feasible method yet devised for the treatment of tubercular disease of the vertebral bodies. Cases of Pott's disease from early childhood to adult life with marked paraplegia cleared up after this operation in a much shorter time than could have been expected under the hitherto accepted methods of treatment. The pain disappeared in a very short time, the abscess absorbed, or the sinus closed, and a general improvement manifested itself. One adult was up and about the ward five weeks after the operation, not because it was advisable but because she was feeling so well that she persisted in getting up. She had no other support than that furnished by the engrafted bone splint. In regard to the theory that Wolf's law would apply to this bone graft, time would settle that question. The point that presented itself was when to resort to this bone splinting. The immobilization of three or four vertebrae did not materially hamper the general mobility of the back, yet one did not wish to lock up any joint of the body when its mobility could be of any service to the individual. It seemed to him that these cases presenting bony changes from the activity of the tubercular process as shown by the *x*-ray and clinical findings, those older cases of Pott's disease where acute exacerbations manifested themselves, and cases where the disease had been arrested or cured but deformity still progressed, as was often found in the upper dorsal region, would be cases well selected. As to other cases of questionable type clinical experience and close observation would determine. Dr. Soule asked whether in those cases where ligamentous and muscular attachments were not interfered with and which were engrafted at an early stage of the disease and cured without deformity or evidence of destructive bony changes in the bodies of the vertebrae there could be any objection to the removal at a later period of a sufficient part of the bone graft bridging the spinous processes to restore flexibility. Dr. Albee had made a strong step forward and placed them in a much firmer footing in dealing with bone tuberculosis.

Officers Elected.—*President*, Dr. Brooks H. Wells; *First Vice-President*, Dr. T. Passmore Berens; *Second Vice-President*, Dr. Howard Lilienthal; *Secretary*, Dr. John Van Doren Young; *Assistant Secretary*, Dr. J. Milton Mabbott; *Treasurer*, Dr. Charles H. Richardson. The following were elected as *Censors:* Dr. David Bovaird, Jr.; Dr. Joseph B. Bissell; Dr. John J. McPhee. Seventeen delegates to the Medical Society of the State of New York, to serve two years, were also elected.

Pathological Society of Philadelphia.

At a stated meeting held October 24 Dr. A. Weber, Geheimer Regierungsrat, of Berlin, Germany, delivered an address entitled "Organization of the Health Department and of General Sanitary Conditions in the German Empire," illustrated by lantern slides. He spoke especially of the measures taken to prevent the development and spread of smallpox, cholera, and plague. Smallpox occurs only in isolated instances in Germany since the institution of compulsory vaccination and revaccination. All children must be vaccinated within the first year of life and again at the twelfth year, and in the case of those eligible for the army a third vaccination is practised at the time of enlistment. As a result of these measures the number of cases since the extensive epidemics following the Franco-Prussian war has been a progressively diminishing one. Human lymph was for a time employed, but of recent years only calf lymph is used. Numerous laboratories are provided in various parts of the Empire for the manufacture of smallpox vaccine. Cholera has been practically eradicated from Germany since the great epidemic at Hamburg in 1892. In that instance the disease was spread through contaminated Elbe water used unfiltered. Careful bacteriological examination of the stools is made in all suspicious cases, and in a number of instances cholera carriers have been discovered. The spread of plague is prevented by special attention to rats. It has been shown that the prevalence of plague in rats and in man pursues a parallel line. For the destruction of rats, both on ships and on land, fumigation is practised either with sulphur dioxid or a mixture of carbon monoxid and carbon dioxid. All three of the diseases named are common in Russia and this country constitutes a source of constant danger, particularly by reason of the large volume of emigration from that country. At convenient places throughout Germany bacteriological laboratories have been established to provide means for the early recognition of the infectious disease and it is owing to this circumstance that their spread and prevalence have been greatly diminished. Marked progress has taken place also in the control of other infectious diseases, such as typhoid fever, tuberculosis and others, whose etiological factors are clearly understood, and the mortality from which has fallen greatly within recent years. Especially striking have been the results in the case of diphtheria since the introduction of the antitoxin. On the other hand, there has been an increase in the morbidity and mortality of diseases, like carcinoma and sarcoma, whose etiological factors have not been determined.

Dr. Arthur H. Hopkins presented a communication entitled "Hemolysins in the Fecal Filtrate," relating observations tending to show, contrary to results recorded by others, that filtered extracts of intestinal discharges from patients suffering from various disorders failed with any degree of constancy to exert hemolytic effects, and disposing of the view that pernicious anemia is due to the action of hemolysins of gastrointestinal origin.

Drs. Randle C. Rosenberger and Truman C. Terrell presented a communication entitled "Amebiasis in the Insane Department of the Philadelphia Hospital, with a Study of Tests for Occult Blood." Examinations of the stools of two hundred patients disclosed the presence of *Amœba coli* and also of occult blood in nearly 50 per cent., although the two conditions did not invariably coincide.

Drs. O. M. Perry Pepper and J. H. Austin presented a communication entitled "Some Unusual Results with the Phenolsulphonephthalein Test." They reported three cases in which the results following subcutaneous injection of the drug differed from those ordinarily encountered in tests for the functional capacity of the kidneys. One of these was a case of parenchymatous nephritis in which, while the elimination of the drug through the urine conformed to the normal, there was deficient elimination of chlorids. In another case, one of polycystic kidneys, there was no measurable elimination of the drug, although in other respects the renal function appeared to be well performed until within a short period before death, when uremia developed in conjunction with an intercurrent cholangitis secondary to gallstones. In a third case in which both kidneys had been decapsulated for the relief of threatening uremia the secretory function of the kidneys appeared to be maintained. These observations show that while the phenolsulphonephthalein test is useful for the determination of the functional ability of the kidneys, like other signs, symptoms, and tests it is not infallible.

Drs. James E. Talley and C. W. Laders presented a communication entitled "Relation of the Ventricular Pulse to Tricuspid Regurgitation," illustrated by a profusion of diagrams showing tracings of arterial, venous, and cardiac pulsation.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

Arizona State Board of Medical Examiners.

July, 1912.

(*Concluded from page* 1061.)

BACTERIOLOGY.

1. Describe the technique of staining for tubercle bacilli.
2. Define immunity and classify same.
3. Define (*a*) phagocytosis, (*b*) antitoxins, (*c*) vaccine.
4. Describe the gonococcus and give method of staining.
5. Give Koch's rules or dicta in regard to the bacterial cause of diseases.

PRACTICE OF MEDICINE.

1. Differentiate between cerebral vomiting and gastric vomiting.
2. In what diseases does leucocytosis occur?
3. What is the significance of prolonged expiration?
4. Describe the mitral regurgitant murmur; give the topography of the chest, showing where this sound is best heard.
5. Mention the causes and describe the treatment of primary lobar pneumonia.
6. Define angina pectoris. What pathological condition may cause it?
7. On what symptoms would you base a diagnosis of typhoid fever?
8. Give the period of incubation and of the eruption of the exanthemata.
9. What is the cause of syphilis?
10. Give the symptoms and blood picture of chlorosis.

OBSTETRICS.

1. Give the diameters of the fetal head in inches.
2. Give the diameters of the pelvis in inches.
3. Differentiate between normal pregnancy, tumors within the abdominal cavity, and ectopic gestation.
4. What maternal condition would warrant destruction of fetal life?
5. When the action of the uterus is insufficient what measures and remedies may be used to bring about normal contraction?
6. Should you find albumin and tube casts in the urine of a pregnant woman what morbid condition would be indicated, and what would be your treatment?
7. Diagnose placenta prævia and give treatment.
8. What is the principal cause of ophthalmia neonatorum, and what means should be used to prevent it? How would you treat a case?
9. Give position of fundus at three, five, and seven months.
10. Name some of the causes and dangers incident to protracted labor.
11. Make a diagnosis of syphilis in the new-born State something concerning the prognosis.
12. Describe how you would conduct normal labor.

GYNECOLOGY.

1. (*a*) Define endocervicitis, (*b*) symptoms, (*c*) treatment.
2. What are the indications for curettage?
3. Define (*a*) dysmenorrhea, (*b*) amenorrhea, (*c*) menorrhagia, (*d*) metrorrhagia.
4. Mention the varieties of uterine displacements.
5. Define (*a*) urethral caruncle, (*b*) its history, (*c*) symptoms, (*d*) treatment.
6. (*a*) Make a diagnosis from the following history: Woman 26 years of age, mother of three children. Menstruation stopped two months ago. Patient seized with abdominal pain, cramp-like in character, appearance of uterine hemorrhage; rapid pulse, anemic, increased leucocyte count, temperature first subnormal then elevated. Physical examination shows breast enlarged, uterus enlarged, os soft, and mass in lateral fornix. (*b*) Describe in detail the treatment.
7. Discuss the etiology of cancer of the uterus.
8. Describe the clinical history of a large ovarian cyst.
9. Make a differential diagnosis between interstitial fibroids of the uterus and an ovarian cyst.
10. Describe an operation for amputation of the cervix.

SURGERY.

1. What is inflammation? How does inflammation extend and how may it terminate?
2. Give the symptoms, diagnosis, and treatment of phlebitis.

3. Name the inflammatory diseases of bone.
4. How would you arrest epistaxis?
5. What symptoms follow division of the radial nerve?
6. Name the varieties of shoulder-joint dislocations.
7. Name the causes of delayed bone union and give treatment.
8. Differentiate dislocation of the head of the femur from fracture of its neck and give essentials of treatment of each.
9. Describe a method of amputation of the last phalanx.
10. Describe dermoid cysts. In what situations are they most commonly found?

ANSWERS.

BACTERIOLOGY.

1. To demonstrate the existence of *tubercle bacilli* in the sputum: The sputum must be recent, free from particles of food or other foreign matter; select a cheesy-looking nodule and smear it on a slide making the smear as thin as possible. Then cover it with some carbolfuchsin, and let it steam over a small flame for about two minutes, care being taken that it does not boil. Wash it thoroughly in water and then decolorize by immersing it in a solution of any dilute mineral acid for about a minute. Then make a contrast stain with solution of Loeffler's methylene blue for about a minute; wash it again and examine with oil immersion lens. The tubercle bacilli will appear as thin red rods while all other bacteria will appear blue. The tubercle bacillus is rod shaped, is from 1½ to 3½ mikrons in length and about one-third to one-half a mikron in breadth, is a strict parasite, is not motile, and has no flagella. It is slightly curved, does not form spores, is not liquefying, and nonchromogenic; is aërobic; it resists acids; it grows well on blood serum; stains well by Ehrlich's, Ziehl-Neilsen's, or Gabbett's method; it is Gram-positive.

2. *Immunity* is the power of resistance of cells and tissues to the action of pathogenic bacteria. Immunity may be either natural or acquired.

Natural immunity is this power of resistance, natural and inherited, and peculiar to certain groups of animals, but common to every individual of these groups.

Acquired immunity is this resistance acquired: (1) By a previous attack of the disease caused by the bacteria, or (2) by the person being made artificially insusceptible. The conditions which give immunity from the pathogenic action of bacteria are: (1) A previous attack of the disease; (2) inoculation, with small quantities of bacteria, so as to produce a mild attack of the disease; (3) vaccination; (4) the introduction of antitoxins; (5) the introduction of the toxins of the bacteria.

Active immunity follows an attack of a certain disease and secures immunity for that alone; or it follows inoculation of a virus weaker than necessary to cause the typical disease; or it follows inoculation by bacterial products apart from the organisms themselves.

Passive immunity is the term applied to the effect of a serum derived from an immunized animal and injected into one not immune.

3. *Phagocytosis* is the faculty of certain cells (notably the mononuclear and polynuclear leucocytes) to take up and destroy bacteria.

Antitoxins are substances formed in the body of a protective character and capable of rendering inert the poisonous products of bacteria.

Vaccine is a modified and attenuated virus of a disease, not capable of producing a severe infection but able to afford protection against the action of unmodified virus.

4. The *Gonococcus* is a diplococcus with a special predilection for the mucous membrane of the urethra and vagina. It is sometimes found on the conjunctiva. The appearance is that of two coffee beans; the gonococcus is found in the pus cells, stains with ordinary anilin dyes, but not by Gram's method. It is aërobic, and can be cultivated on human blood serum; it will not grow on gelatin, agar, bouillon, or potato. It was discovered by Neisser. To demonstrate *gonococci:* On a cover-glass make a smear with the discharge as thin as possible, and let it dry in the air; cover it with a freshly made solution of anilin-oil-gentian-violet for one or two minutes; wash it in distilled water, leave it in Gram's solution for two minutes; wash it in 95 per cent. alcohol until decolorized; wash it in distilled water; counterstain with a dilute carbolfuchsin without heat, or with a saturated aqueous solution of Bismarck brown; wash in distilled water, dry with filter paper, mount, and examine with an oil-immersion lens. The gonococci will appear as *diplococci within the leucocytes,* which have been *decolorized by Gram's stain,* and have taken the counterstain.

5. To *prove that bacteria cause disease* it is essential: (1) That the microorganism be found in the tissues, blood, or secretions of a person or animal sick or dead of the disease; (2) the microorganism must be isolated and cultivated from these same sources; it must also be grown for several generations in artificial culture media; (3) the pure cultures, when thus obtained, must, on inoculation into a healthy and susceptible animal, produce the diseases in question, and (4) the same microorganisms must again be found in the tissues, blood, or secretions of the inoculated animal.

PRACTICE OF MEDICINE.

1.

CEREBRAL VOMITING.	GASTRIC VOMITING.
Little or no nausea, vomiting continuous.	Nausea relieved by vomiting, returns when food is taken.
No tenderness on pressure over liver or stomach.	Liver and stomach are tender, pressure produces inclination to vomit.
Pulse infrequent and hard.	Pulse frequent and weak.
Tongue clean, breath sweet, conjunctivæ normal or injected, headache primary.	Tongue furred, breath offensive, conjunctivæ often yellowish, headache secondary as to time.
Constipation generally obstinate.	Griping abdominal pain, diarrhea and clay-colored stools.
No salivation.	Increased salivation.

(From Potter's *Therapeutics.*)

2. *Leucocytosis occurs* in: Inflammatory conditions; certain toxic conditions; many infectious diseases (such as pneumonia, diphtheria, erysipelas, smallpox, septicemia and pyemia, rheumatism, meningitis); tonsilitis, appendicitis, osteomyelitis, salpingitis, pleurisy, percarditis, peritonitis, leukemia, diseases of the lymphatic glands, gout, uremia, and after hemorrhages.

3. *Prolonged expiration* is found in asthma, emphysema, and at the commencement of pulmonary tuberculosis.

4. The *mitral regurgitant murmur* is systolic, blowing, heard best in the mitral area at the apex, and may be transmitted to the left axilla or under the left scapula. It may occur with or take the place of the first sound of the heart.

5. LOBAR PNEUMONIA. *Causes: Diplococcus pneumoniæ* of Frankel. Lowered vitality, bad hygiene, infectious disease, nephritis, exposure to cold and wet all predispose.

Treatment: "Consists in rest in bed, milk diet, and the administration of fractional doses of calomel followed by a saline in the early stage. The nervous symptoms and temperature may be controlled by applying ice-bags or compresses wrung out of cold water (60°-70° F.) to the chest or by the use of the warm or cold wet-pack. The heart and pulse should be sustained by the administration of alcohol, strychnine (gr. 1/60-1/20), atropine, caffeine, strophanthus, and nitroglycerin. Digitalis may also be employed. Inhalations of oxygen afford temporary relief when the dyspnea and cyanosis are extreme. In young, vigorous, and plethoric adults, with hyperpyrexia and a high-tension pulse, bleeding may be beneficial in the first 48 hours. Convalescence should be guarded, and tonics, stimulants, etc., will be found very useful in this period of the disease." (*Pocket Cyclopedia.*)

6. *Angina pectoris* is a condition in which there occur sharp paroxysmal, cardiac pains, usually extending into the left shoulder and down the left arm, accompanied by a feeling of constriction of the thorax and a strong fear of impending death. It may be caused by disease or obstruction of the coronary arteries, or inflammation of the aorta.

7. A *diagnosis of typhoid fever* may be based on: The peculiar temperature curve, the rose eruption, the enlarged spleen, a positive diazo-reaction and a positive Widal test.

8.

EXANTHEM.	PERIOD OF INCUBATION.	TIME OF APPEARANCE OF ERUPTION.	DURATION OF ERUPTION.
Erysipelas.	Few hours to 3 or 4 days.	Within 24 hours.	4 to 8 days.

EXANTHEM.	PERIOD OF INCUBATION.	TIME OF APPEARANCE OF ERUPTION.	DURATION OF ERUPTION.
Measles.	10 to 12 days.	4th day.	4 to 5 days.
Rötheln.	8 to 17 days.	Within 48 hours.	3 days.
Scarlatina.	1 to 21 days.	Within 24 hours.	7 to 10 days.
Typhoid Fever	5 to 35 days.	7th day.	Each crop 3 to 5 days. Last 10 to 20 days or throughout the whole course of the fever.
Typhus Fever.	4 to 12 days.	Usually 5th day; may be on 3d or not until 7th day.	Few days, or may last throughout the course of the disease.
Varicella.	4 to 14 days.	Within 12 to 24 hours.	5 to 8 days.
Variola.	8 to 14 days	4th day.	21 to 25 days.

9. The *cause of syphilis* is the *Treponema pallidum.*

10. The *symptoms of chlorosis* are: Malaise, languor, anorexia, cardiac palpitation, hemic murmur, cold extremities, fainting, dyspnea, constipation, yellowish-green or pale skin, bright eyes, slight edema. The *blood-picture* shows a great diminution in the amount of hemoglobin; the red cells are slightly diminished in number, and may be misshapen; normoblasts may be present, also a slight leucocytosis.

OBSTETRICS.

1. The fetal head has the following diameters: Occipito-frontal, occipito-mental, bitemporal, biparietal, suboccipito-bregmatic, trachelo-bregmatic, and mento-bregmatic. Of these the occipito-frontal is 4½ inches, the occipito-mental is 5½ inches, and all the others are approximately 3¾ inches.

2. *Measurements of diameters of pelvis (approximately):*

	ANTERO-POSTERIOR.	OBLIQUE.	TRANSVERSE.
Brim.....	4 inches	4½ inches	5 inches
Mid-plane.....	4½ "	4½ "	4½ "
Outlet.....	5 "	4½ "	4 "

3. In *normal pregnancy:* The tumor is hard and does not fluctuate, is situated in the median line, and may give fetal heart sounds and movements; the cervix is soft, and the other signs of pregnancy are present. The rate of growth of the tumor, and the general condition of the patient's health may also help in arriving at a diagnosis. In *abdominal tumors:* menstruation is irregular and sometimes very profuse; absence of the signs of pregnancy; the tumor is nodular, firm, irregular in outline, and while sometimes placed somewhat centrally is not generally in the median line, and is not symmetrical; the rate of growth is irregular, being, as a rule, slow, and sometimes extending over years. In *ectopic gestation:* menstruation is irregular; pelvic pain may be present; the tumor has a progressive growth, but the uterus does not enlarge with it; the uterus is displaced and empty.

4. *Maternal conditions which warrant destruction of fetal life:* Some exceptional cases of hemorrhage, sepsis, or shock, in which the mother's condition is such that destruction of the child is the only means of preserving her own life.

5. When the action of the uterus is insufficient, normal contraction may often be brought about by: Rest, strychnine, ergot, chloral, bromides or opium, quinine, and massage.

6. Probably eclampsia or toxemia would be indicated. *Preventive treatment:* (1) The amount of nitrogenous food should be diminished to a minimum; (2) the production and absorption of poisonous materials in the intestines and body tissues should be limited and their elimination should be aided by improving the action of the bowels the kidneys, the liver, the skin, and the lungs: (3) the source of the fetal metabolic products and the peripheral irritation in the uterus should, if necessary, be removed by evacuating that organ. *Curative treatment:* (1) Control the convulsions (by chloroform, veratrum, or chloral); (2) eliminate the poison or poisons which are presumed to cause the convulsions; (3) empty the uterus under deep anesthesia by some method that is rapid and that will cause as little injury to the woman as possible.

7. *Placenta prævia* is the condition in which the placenta is attached in the lower uterine segment, and may be near or over (partially or completely) the internal os. *Symptoms:* Sudden hemorrhage, accompanied by syncope, vertigo, restlessness, and feeble pulse. *Treatment:* Stop the hemorrhage by a vaginal tampon; this must be tight and thorough. *Accouchement forcé* is indicated; this consists of dilatation of cervix, version, and immediate extraction of the child.

8. OPHTHALMIA NEONATORUM. *Causes:* The gonococcus or some other pyogenic microorganism; the secretions of the mother contain the infecting agent, and transmission may occur directly during parturition, or indirectly by the fingers of physician or nurse, cloths, instruments, etc. *Symptoms:* Swollen eyelids, with copious purulent discharge; ulceration of the cornea may ensue. *Prophylaxis:* Whenever there is the possibility of infection, or in every case, wash the eyelids of the newborn child with clean warm water, and drop on the cornea of each eye one drop of a 1 per cent. solution of nitrate of silver, immediately after birth. *Treatment:* Wash the eyes carefully every half hour with a saturated solution of boric acid; pus must not be allowed to accumulate. Two drops of a 2 per cent. solution of nitrate of silver must also be dropped on to the cornea every night and morning. The eyes must be covered with a light, cold, wet compress. The patient must be isolated, and all cloths and compresses used must be burnt.

9. At three months, the fundus is rising over the symphysis pubis; at five months, it is midway between the symphysis and the umbilicus; and at seven months, it is midway between the umbilicus and the ensiform.

10. PROTRACTED LABOR. *Causes:* Obstruction, uterine inertia, uterine exhaustion. *Dangers:* Asphyxiation of fetus, post-partum hemorrhage, sepsis, pressure-necrosis and fistulæ, exhaustion or death of the mother.

11. *Hereditary syphilis:* Supposing the child to have been born alive, it usually shows no evidence of disease for a period ranging between two and six weeks, sometimes longer, after birth. It then, as a rule, gradually loses its healthy appearance, begins to snuffle, becomes fretful, and wastes more or less rapidly. The child's skin assumes a dull dirty color, and, though loose and wrinkled, is very brittle and easily breaks round the mouth and nose into chaps and fissures, the scars of which often form a characteristic sign in after life, if the child survive. *Prognosis.* "This is good in cases of moderate severity. Children born with the rash upon them nearly always succumb. Much depends on the mother, whether she is able to nurse the infant or not, for a syphilitic child which has to be reared artificially has a very poor chance of life. The earlier the symptoms appear after birth the more severe the type of the disease. About 10 per cent. of those suffering from congenital syphilis develop some nervous trouble, such as idiocy, progressive mental deterioration, hydrocephalus, etc. Any considerable degree of marasmus is rarely recovered from." (Aids to *Diseases of Children.*)

12. "*Management of normal labor. During the first stage* a rectal enema of soapsuds with turpentine (5i) should be given, and when the os is dilated to the size of a silver dollar the patient should be placed in bed, lying upon the side toward which the fetal back looks. If the pain is severe, chloral hydrate (gr. 15) may be given every half-hour for 3 doses.

During the second stage, examinations should be made when necessary. In multiparæ the membranes may be ruptured with the finger or with some aseptic instrument. Care should be taken not to injure the child's scalp or the lower uterine segment. The pain may require the administration of chloroform or ether, but not to the extent of complete anesthesia. The expulsive force of the abdominal walls may be increased by directing the patient to pull upon a sheet firmly secured to the foot of the bed. Attempts may be made to prevent laceration of the perineum by making firm backward and upward pressure against the occiput during the pains; by restraining voluntary expulsive efforts during the pains; and by securing expulsion of the head between the pains. The head should be supported when born; the eyes should be cleansed with sterile water; and if the cord is coiled about the neck, it should be loosened or slipped over the head. Delay in delivery of the shoulders may be overcome by stimulating the uterus by friction through the abdominal wall or traction. The cord is ligated and cut when pulsation has ceased, and the child is placed by the mother's side with its face turned away from the maternal discharges.

During the third stage, 3i of fluidextract of ergot is administered and irritation of the uterus by friction through the abdominal wall is practised for 10 or 15 minutes. If the placenta is not expelled by this time, the uterus is firmly grasped between the thumb and four fingers and compressed. Firm pressure is then made from above downward and backward in the direction of the pelvic canal. This usually causes delivery of the placenta. A vulvar pad of salicylated cotton and carbolized gauze and an abdominal pad and binder are then applied." (*Pocket Cyclopedia.*)

GYNECOLOGY.

1. *Endocervicitis* is an inflammation of the mucous membrane of the cervix of the uterus; it is "usually secondary to some impairment of the general health or to displacements of the uterus, laceration of the cervix, and gonorrhea. The symptoms are headache, backache, pain in pelvis, and the presence of characteristic, whitish, opaque, thick, and tenacious discharge. A possible cause should be sought for and corrected. The general health will be improved by the administration of preparations containing iron, such as Blaud's pill, Basham's mixture, and the four chlorides. Exercise, diet, and the condition of the bowels should receive attention. The local treatment consists in the administration of hot vaginal douches two or thre times daily; the use of glycerin tampons for 12 hours, twice a week; the application of tincture of iodine to the cervix, once a week; and the application of silver nitrate, zinc chloride, pure carbolic acid, or Churchill's tincture of iodine directly to the cervical mucous membrane." (*Pocket Cyclopedia.*)

2. The *indications for curettage* are: For diagnosis, to remove pieces of retained placenta or decidua; for endometritis, mucous polypi, uterine hemorrhage, dysmenorrhea, and endocervicitis.

3. *Dysmenorrhea* is unduly painful menstruation.
Amenorrhea is absence of menstruation.
Menorrhagia is excessive menstruation.
Metrorrhagia is uterine hemorrhage at other than the menstrual period.

4. *Varieties of uterine displacements:* Retroversion, retroflexion, anteversion, anteflexion, prolapse, ascent, and displacement to one side.

5. *Urethral caruncle* is a small red fleshy growth generally situated on the posterior part of the meatus of the urethra. There are local pain and tenderness, which may be excessive; a burning sensation is experienced on urination; it may bleed. The proper treatment is to excise it or destroy it with the thermocautery.

6. The *diagnosis* is—Ectopic gestation. The *treatment* is—Laparotomy. "After thorough cleansing and sterilization of the abdomen and pubes, as well as of the instruments and hands of the operator and assistants, the bladder is emptied and the patient anesthetized. An incision 3 inches long is then made in the median line above the pubes down to the peritoneum, any bleeding vessels being twisted before opening the peritoneal cavity. The peritoneum is then incised; the intestine kept back by pads of cotton or gauze wrung out of sterilized water; the operator's fingers bring out the distended tube and ovary at the incision after having freed them from any existing adhesions; the pedicle is then transfixed by a double ligature of sterilized silk, and each half of it tied securely according to surgical rule. The pedicle is cut, and the entire mass—the Fallopian tube, with the cyst, fetus, ovary, and effused blood, removed, extra care being taken, in the ruptured cases, to quickly secure the bleeding vessels of the ruptured tube from further hemorrhage. The pads are then withdrawn and the abdominal incision closed and dressed in the usual manner. In case of threatened collapse from hemorrhage during the operation, the peritoneal cavity may be flooded with a 1 per cent. sterilized solution of common salt at a temperature of 100° F., a quart of this solution having been previously prepared. It is rapidly absorbed by the peritoneum, and acts as a restorative—like transfusion."—(King's *Obstetrics.*)

7. *Etiology of cancer of the uterus:* "The causes of cancer are unknown; the predisposing or favoring conditions are as follows: (1) *Age*—the disease occurs most frequently between forty and fifty. The extreme limitations are between eight and seventy-six. (2) *Heredity*—an apparent predisposing cause. (3) *Social state*—more frequent among the poor and ignorant. (4) *Race*—relatively rare among negroes. (5) *Trauma of labor*—laceration of the cervix a possible predisposing cause. (6) *Endometritis and endocervicitis* are said to be favoring conditions."—(Dudley's *Gynecology.*)

8. A *large ovarian cyst* causes the following symptoms (apart from complications): "From pressure on the bladder and rectum there may be frequent micturition and constipation; from pressure on the vessels, edema of the lower limbs and genitals; from pressure on the sacral and lumbar plexus, pains in the back, pudenda, and legs; from pressure on the stomach, nausea and vomiting; on the intestines, diarrhea or colicky pains; on the portal vein, ascites and hemorrhoids; on the kidneys and ureters, albuminous and highly concentrated urine, rich in urates. Later, as the tumor extends upward, there will be embarrassed breathing and dyspnea from pressure on the heart and lungs while finally emaciation sets in, and the patient dies of exhaustion, if not carried off by an intercurrent attack of peritonitis from rupture of the cyst."—(Spencer and Gask's *Surgery.*)

9.

FIBROID TUMOR.	OVARIAN CYST.
1. Slow growth.	1. Usually more rapid growth.
2. Facial expression unchanged. Face may be full and flushed; later pale from hemorrhage.	2. Facies ovariana.
3. General health usually unimpaired except from loss of blood, if submucous or mural; may be painful.	3. General health early impaired from emaciation. Not painful.
4. Abdomen usually very asymmetrical from irregular shape of tumor.	4. Abdomen more symmetrical, especially when tumor is large.
5. Abdominal veins not usually enlarged.	5. Usually enlarged, especially in large polycysts.
6. Action of kidneys normal.	6. Kidneys less active.
7. Usual menorrhagia.	7. Menstruation unchanged or diminished.
8. Elasticity, not fluctuation. No percussion wave.	8. Fluctuation marked. Percussion wave marked.
9. Surface firm and usually lobulated.	9. Surface yielding; in monocysts, regular; in polycysts, irregular.
10. Vaginal touch and conjoined examination show tumor dense and firm, and continuous with uterus. Uterus large and heavy.	10. Uterus normal, except displacement from pressure. Tumor compressible, fluctuating, detached from uterus.
11. Uterine cavity much elongated.	11. Not materially elongated. (This is a most important diagnostic point.)
12. Uterus moves with tumor.	12. Does not move with tumor.

—(From Dudley's *Gynecology.*)

10. *Operation for amputation of the cervix:* "The cervix is thoroughly exposed by the introduction of the bill of a large speculum; with the sound the operator determines the position of the cervical canal and estimates the mobility of the uterus; by means of the vesical sound the precise relation of the bladder to the cervix is ascertained. The cervix is firmly grasped with a stout volsella and drawn down; with a scalpel the surgeon transversely divides the mucous membrane on the anterior wall of the cervix as high up as the bladder permits; the assistant keeps him informed of the position of the bladder by retaining the sound in the lowest part of the vesical cavity. Having divided the mucous membrane, the bladder is easily detached from the cervix by the handle of the scalpel. The knife is then carried through the mucous membrane on the sides and posterior aspect of the cervix. The next step is to secure the uterine arteries as they run to the sides of the cervix near the spot where the vaginal mucous membrane is reflected on to it. When the bladder is detached and held apart from the cervix by a retractor, while the cervix is drawn down by the volsella, the artery may be seen, and is easily secured. It is well to secure it as close to the center as possible in order to avoid the ureter. Having secured the artery on each side, the cervix may be amputated with a scapel or with scissors. When the uterine arteries are deliberately exposed and secured there is no bleeding from the stump, but a small artery here and there in the cut edge of the vaginal mucous membrane may require to be seized or ligatured. The vagina is then douched and the patient returned to bed."—(Sutton and Giles' *Diseases of Women.*)

SURGERY.

1. *Inflammation* is the succession of changes which take place in a living tissue as the result of some kind

of injury, provided that this injury be insufficient immediately to destroy its vitality. Inflammation *extends* by the blood-vessels, by the lymphatics, and by continuity of tissue. Inflammation may *terminate* in return of the tissues to health (by resolution, by organization, or new growth) and in death of tissue (by suppuration, by ulceration, or by gangrene).

2. PHLEBITIS. *Symptoms:* A hard, painful, cord-like swelling forms over the vein. Skin over this is dusky, congested, and edematous. If the vein is superficial there are no other signs. If it is the main deep vein of the limb, massive solid edema occurs, with considerable lymphatic engorgement (white leg). Superficial veins enlarge in order to carry on the collateral circulation. Fever, with rigors, occurs, and is proportioned to the infectivity of the process. Abscesses develop round an infective phlebitis. *Treatment:* Rest and elevation in bed for six weeks. Belladonna applications for pain. Excision of the veins in recurrent superficial phlebitis. Incision, removal of clot with proximal ligature in infective phlebitis, *e.g.* in the jugular vein following acute mastoiditis.—(*Synopsis of Surgery.*)

3. The *inflammatory diseases of bone* are: *Periostitis*, ostitis, and osteomyelitis

4. *To arrest epistaxis:* (1) Try to cauterize the bleeding point; (2) plug the nasal cavity with gauze soaked in adrenalin; (3) inject into the nares a solution of peroxide of hydrogen; (4) plugging the nares, anteriorly and posteriorly; (5) an inflating plug may be used.

5. *After division of the radial nerve*, there will be loss of sensation in the skin over the metacarpal bones and the first phalanges of the thumb and index finger. There will be no paralysis, for no muscles are supplied by this nerve.

6. The *varieties of shoulder-joint dislocation* are: (1) Subcoracoid—forward, inward, and downward; (2) Subglenoid—downward, forward, and inward; (3) Subspinous—backward, inward, and downward, and (4) Subclavicular—forward, inward, and upward.

7. *Delayed union in fracture is caused by:* Ill health, want of approximation of the end of the bone, want of blood supply in the bone, defective innervation of the bone, disease of the bone, lack of rest, and immobility.

Treatment is given by DaCosta as follows:

"When delayed union exists, seek for a cause and remove it, treating constitutionally if required, and thoroughly immobilizing the parts by plaster. Orthopedic splints may be of value. Use of the limb while splinted, percussion over the fracture, and rubbing the fragments together, thus in each case producing irritation, have all been recommended. Blistering the skin with iodine or firing it has been employed. If the case be very long delayed, forcibly separate the fragments and put up in plaster as a fresh break. If these means fail, irritate by subcutaneous drilling or scraping, or, better, by laying open the parts and then drilling and scraping at many places."

8. In fracture of the neck of the femur, the head of the femur will be found in the acetabulum; in dislocation, the acetabulum will be empty, and the head of the femur will be found elsewhere, *e.g.* on the dorsum of the ilium. In the fracture, crepitus *may* be elicited; in the dislocation, never. In the dislocation, there is inversion and a fixed position of the limb, both of which are absent in fracture. In fracture there is shortening and outward rotation.

The *treatment* in *intracapsular fracture* is: "Rest in bed with the leg between sandbags. Weight extension. If any signs of congestion of the lungs appear, the patient must get up and walk on crutches. Never disimpact, and always examine such cases very gently for fear of disimpaction." In *extracapsular fracture:* "Always disimpact in young healthy patients when there is much displacement. Long Liston's splint from the axilla to below the ankle, maintained from rotating by transverse bar. Limb is pulled on by weight attached by strapping and bandages well above the knee. Hodgen's splint is often more effectual than Liston's in reducing the deformity. Maintain splint and extension for six weeks." In *backward dislocations:* "Flex the knee and thigh in position of adduction. Abduct the thigh and evert simultaneously. Bring the leg down straight. Lift up, bend out, roll out. Direct traction of the thigh forward in a line at right angles to the body." In *forward dislocations:* "Thigh is flexed in a position of abduction. Abduct the thigh and then invert it. Bring the thigh down straight. Lift up, bend in, roll in."—(*Synopsis of Surgery.*)

9. *Amputation of last phalanx* (of finger): "The space is so limited that the saw-line can only be placed between the matrix of nail and proximal end of second phalanx. (1) Palmar incision—from saw-line downward along lateral aspect of phalanx, midway between dorsal and palmar surfaces, around the center of the pulp, and back to the saw-line on the opposite side. (2) Dorsal incision—connects upper ends of palmar incision, passing transversely over the dorsum with slight downward convexity. Having outlined these incisions, carry the palmar incision to the bone, dissect up all palmar tissues down to the bone, deepen the dorsal incision to the bone, retract the soft parts, in the entire circumference, and saw the phalanx with a light saw, while holding the tip of the phalanx with bone-holding forceps (as there is generally too little room for the fingers of the operator to grasp). Ligate the palmar digital artery on each side. Suture the deep flexor tendon to the periosteum or flap. Suture the palmar flap to the transverse dorsal line."—(Bickham's *Operative Surgery.*)

10. "*Dermoid cysts* of the simpler kind have a wall composed of the structures forming the skin and its appendages, viz., stratified squamous epithelium, dermis, hair-follicles with hair, sebaceous glands actively secreting their contents; also subcutaneous fat and sweat-glands. They are commonly met with: (*a*) in the skin of the scalp, or (*b*) attached to the periosteum and quite separate from the skin, above the outer angle of the orbit, (*c*) in the middle line of the floor of the mouth, below the tongue, (*d*) in the lines of the embryonic fissures in the neck, (*e*) in connection with the thymus, (*f*) in connection with the ovary in the female, and (*g*) between the bladder and rectum in the male. The more complicated dermoid cysts which merge into the teratomata are especially those connected with the ovary, with the base of the skull around the hypophysis protruding into the nasopharynx as hairy polypi, and with the spinal column."—(Spencer and Gask's *Surgery.*)

BULLETIN OF APPROACHING EXAMINATIONS

STATE	NAME AND ADDRESS OF SECRETARY	PLACE AND DATE OF NEXT EXAMINATION†	
Alabama*	W. H. Sanders, Montgomery	Montgomery	Jan. 14
Arizona*	J. W. Thomas, Phoenix	Phoenix	Jan 6
Arkansas	F. T. Murphy, Brinkley	Little Rock	May 13
California*	Chas. L. Tisdale, 929 Butler Building, San Francisco	San Francisco	April 1

*No reciprocity recognized by these States.

†Applicants should in every case write to the secretary for all the details regarding the examination in any particular State.

Pennsylvania.—Reciprocity exists at present with Nevada, Illinois, Ohio, New Jersey, and Vermont.

Miscellany.

The "Rabbet" Woman of Godlyman.—Early in the eighteenth century a certain woman of Godalming, "Godlamin," or "Godlyman," in Surrey, having been affrighted by a rabbit running from a hedge, at a time when she professed herself pregnant, was afterwards brought to bed of "rabbets." She seems to have successfully enlisted the sympathy of the local practitioner; and, perhaps finding the mystification profitable, continued to be delivered of portions of "rabbets," so that she became something more than a nine days' wonder. She was brought to town, was attended by various physicians of eminence, and, until finally discredited, even excited the interest of the royal family. Stories of animal births have cropped up for centuries, and are still believed in by not a few. It is not fifteen years since a peasant, aged fifty-six or so, living in a Northamptonshire village, declared that she had been brought to bed of puppies. A medical man was sent for. He assisted at the "confinement"; declared that he had himself seen the products of conception; maintained that they were expelled from the vagina, and stoutly adhered to his narration at a meeting of a local medical society. In this case some story of a fright by a dog was forthcoming; and there were village hints of a darker explanation. But the general professional belief was that the doctor called in had been himself deceived, and that what had been taken for puppies was nothing but blood-clot. This is not, however, the true explanation; and since it is possible that even yet there may occur in some remote village episodes reminiscent of the Woman of Godlyman, and this later peasant in Northamptonshire, a few moments' consideration may not be amiss.

That occasional bestialities do occur among women, as among men, is not unknown to every experienced practitioner; and the birth of a monstrosity, or the occurrence of a multiple abortion, has often, by the vulgar, been connected with some scandalous rumor, so that the popular notion of animal births has become fixed. In other cases, too, evidence which cannot be disputed has shown that there is some basis for a belief in maternal impressions. But, it would appear that in such apparent cases of gross deception as those of the women of Godalming and Northampton, one has to deal with those who either have imagined themselves pregnant, have had good reasons for wishing themselves to be thought pregnant, or have feared pregnancy. And it is not to be overlooked that psychoanalysis has shown how, very often, women have the oddest notions of the way in which pregnancy occurs; and that many girls and women have spent years of misery and apprehension on account of some real or fancied sexual transgression which they have feared might have resulted in pregnancy. Hysterical autosuggestion, then, accounts for the subjective signs of the fancied pregnancy; and also for the unconsciously or subconsciously simulated objective signs, by way of pseudocyesis. The unconscious workings of the hysterical brain suggest, as a defense against detection if there has been any perverted practice, reliance on the popular belief in frights and impressions, to explain away the dreaded exposure; or, in other cases, to account for the non-production of an advertised child in due course. A mythoplastic atmosphere is created, and is reinforced by the sympathetic interest displayed by others; then, as a desperate resource, products of animal conception are placed in the vagina and "expelled," so that in the end a monstrous system of imposture becomes elaborated from an original self-deception, that in some cases, at any rate, is the result of a true anxiety or repression psychosis.—*The Universal Medical Record*, November, 1912.

Alcohol and Civilization.—G. E. Partridge applies the principle "give the devil his due" in a highly interesting chapter concerned with the history of drinking. He reminds one that it is unfair to regard alcohol merely as man's subtle and relentless enemy. He has a good word to say for it: "Alcohol and its kindred have been of great importance in fostering those social traits upon which our present civilization rests. It is difficult to conceive, in fact, what the social life of uncivilized man might have been without the use of alcoholic drinks. The greatest obstacles to social amalgamation, to treaties, to intercourse among tribes were overcome by the intoxication festivals and drink customs. It is possible, indeed, that alcohol may have been the deciding factor at a certain stage of civilization, when man's future as a social being hung in the balance." —"Studies in the Psychology of Intemperance."

The Avaricious House-Surgeon.—F. W. Langridge quotes the following anecdote related by Harrison Cripps: A patient swallowed a halfpenny one afternoon and next morning the house-surgeon on examining him extracted this halfpenny from the rectum. It had passed down without much trouble, but had been unable to pass the rectum. This was the case in which the house surgeon got into trouble with the lay governing body of the hospital. He was charged with having extracted a fee from an out-patient. But as the amount in dispute was small he thought he had better hand it over to the hospital authorities to avoid prosecution.—*The Clinical Journal*, October 2, 1912.

The Functions of the Pigtail.—Budberg of Charbin attributes to this symbol of Chinese nationality certain hygienic virtues. It increases the circulation of blood in the brain. When rolled up on the top of the head it acts as a substitute for a cap, and protects the head from the glare of the summer sun and the cold of winter. It also serves as a neckcloth and a pillow. As a cord it is ever at hand to check hemorrhage.—*British Medical Journal*, December 7, 1912.

The Self-Styled "Consultant."—J. G. Mumford draws a picture of the "young internist, five or ten years established, immersed in hospital and academic work: his best energies so occupied; supported, perhaps, by his modest patrimony, or having taken to himself a wife with money. From such material, general practitioners—able, experienced, resourceful—are not made. These hospital men do not stand ready, day and night, for small fees or for no fees, to rush to the aid of the afflicted. Soon they learn to call themselves 'consultants,' and to keep hours and appointments so irregularly that practice cannot find them. Then patients float off—to the virtuous and patient rank and file, to irregular practitioners, to osteopathists, to Christian Scientists, and the like. When the chief shepherds have, for a generation, so neglected their flocks, what can you expect? Many of these self-satisfied seekers after causes have become so inexpert in the treatment of disease that the successes of psychotherapy are a cause for bitterness and intolerant outcries."—*"A Doctor's Table Talk."*

OSTEITIS DEFORMANS (PAGET'S DISEASE).

REPORT OF ONE CASE WITH RADIOGRAPHS.

By S. FOSDICK JONES, M.D.,

DENVER, COLO.

CHRONIC inflammatory lesions of bones have been the subject of much study and have claimed the attention of the medical profession since the earliest history of medicine, but it was Sir James Paget who first applied the term "osteitis deformans" to that form of bone disease which is characterized by softening, hypertrophy, and roughening, and later by distortions of the long bones of the skeleton, and thickening and enlargement of the cranium, with pathological changes noted in the spine.

During the past winter the writer has had the opportunity of observing a typical case of Paget's disease, and in view of the rarity of this condition, would report the case and present a careful résumé of this most interesting subject.

Review of the Literature.—In 1876 Sir James Paget[1] reported before the Royal Medical and Chirurgical Society of London a rare bone affection, which he termed osteitis deformans. Although Paget was not the first to observe this affection, he is, undoubtedly, entitled to the credit, as he was the first observer to point out clearly its typical characteristics and to differentiate it from other chronic deforming bone lesions. Among the earlier cases was one published by Wrany[2] in 1867, cases by Wilks[3] in 1869, and a case by Rullier[4] in 1812, all of these being noted by Paget.

Sir James Paget's case concerned a man of forty-six years, who at that age first complained of "aching pains" in the thighs and legs, particularly noted after active exercise. These pains were followed one year later by distortion of the tibiæ, which became broadened, thickened, and nodular. Similar changes were noted in the femur, but there was no tenderness on pressure. After a lapse of three years, during which time the patient's general health was excellent, there was noted a progressive distortion and thickening of the left femur and tibia. There was distinct widening of the left side of the pelvis and the left limb was about one-quarter of an inch shorter than the right. Seventeen years later he was again seen by Paget, who then describes his condition as follows:

"The left femur and tibia are larger, heavier and more curved; the right femur being also distorted, and both thighs are nearly the same size and shape. The skull has become gradually larger, and his hat and the helmet which he wore needed to be enlarged. The spine very slowly became curved and almost rigid. The whole of the cervical vertebræ and the upper dorsal spine formed a strong posterior curve, not angular, and an anterior curve of similar shape was formed by the lower dorsal and lumbar vertebræ. The length of the spine seemed lessened, and from a height of six feet one inch he sank to about five feet nine inches. The chest became flattened, contracted, and narrow, and the movements of the ribs and spine were lessened. The shape and habitual posture of the patient were thus made strange and peculiar. His head was advanced and lowered, so that the neck was very short and the chin, when he held his head at ease, was more than one inch lower than the sternum." All the changes of shape and attitude are well shown in the sketches from photographs taken six months before the patient's death, which the writer has reproduced from Sir James Paget's original article. (Fig. 1.)

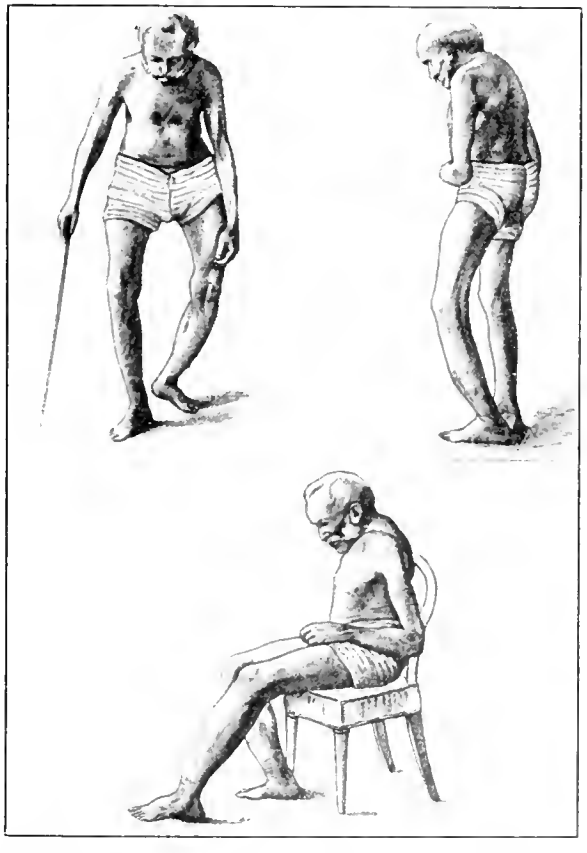

FIG. 1.—Osteitis deformans; reproduction of photographs of the case of Sir James Paget. (From the original paper in the Medico-chirurgical Transactions, Vol. LX, 1877.)

Paget, in further describing this case, states "that the patient's general health was good. The mind was clear, and his only pain experienced was in the left arm, which was of a neuralgic character. A short time before his illness the patient began to lose flesh and strength and became greatly emaciated, and, finally, after an illness of two days,

he died of a right-sided pleural effusion." A post-mortem examination was held, and very full and complete pathological findings are given in Paget's original report.

Seven similar cases were reported by Sir James Paget[5] in 1882, and again in 1884-85 the same

FIG. 2.—Skiagram of the left tibia and fibula. Showing the marked bowing of the shafts and greatly thickened cortical edge, with marked nodosities on the posterior surface of the tibia.

author[6] demonstrated before the Pathological Society of London the post-mortem specimen of the long bones taken from two cases of osteitis deformans.

Following Paget's original and classic description of this disease, which bears his name, numerous contributions were made by later observers. One typical case of this affection was reported in the Guy's Hospital records by Symmonds[7] in 1881, which was followed two years later by reports of cases by Barlow[8] and Pick,[9] two English observers. Later observations were made by Stilling,[10] and also Thibierge,[11] in his report of 1890, tabulates forty-four cases collected from the literature; twenty-one of these cases occurring in men and twenty-three in women. V. P. Gibney,[12] on March 7, 1890, reported before the Practitioner's Society of New York a typical case of osteitis deformans, occurring in a man of fifty years of age. The lower extremities were markedly bowed, but of equal length. There was thickening and enlargement of the bones of the arms, and the cranium had also increased in size. The patient's disease was not preceded by any "acute illness." A monograph by Jourcheray[13] in 1893 upon this subject tabulates but sixty authentic cases, and in the same year Thibierge[14] adds two personal observations to his own contribution. In 1893 H. L. Taylor[15] adds two typical cases to those previously reported, and again in 1894 Watson[16] and Guthrie[17] each report one case. Westerman[18] in 1895 adds one case, occurring in a man of fifty-three years, and in 1895 Clutton[19] demonstrated before the Pathological Society of London a specimen obtained from a case of osteitis deformans which showed a lengthening of the affected long bones. De Hall's[20] case was reported the following year. Levi[21] adds one case to those previously reported. In 1901 a most interesting and lucid article upon this subject, with the report of a typical case, was published in the *American Journal of the Medical Sciences* by Packard, Steele, and Kirkbride,[22] and in 1902 Wilson,[23] another American observer, reports one case. Two cases are reported in 1903 by Menetrier and Gauckler,[24] and one case by Schmieden.[25] Sonnenberg[26] contributes one case in 1904, and in the same year Roberts[27] reported before the Philadelphia Academy of Surgery one typical case occurring in a man of forty-seven. In the following year Daser,[28] Hochheimer,[29] and Auffret[30] each add one case to the bibliography. Saunders,[31] Medea and De Fano,[32] Bardenheur,[33] Tedeschi,[34] Mackey,[35] and Von Kutscha[36] each added one case to the literature in 1906. Two cases were reported by Apert and Bornait-Legeule[37] in 1907, and in the same year one case by Schlesinger,[38] and also Stanley,[39] Waterhouse,[40] T. Cohn,[41] and Wetterer.[42] Chartier and Descomps[43] also report one case in 1907. In 1908 Bramwell,[44] White,[45] Glaessner,[46] and Parkes-Weber[47] each add one case. In 1909 one case is reported by M. Klippel and Pierre Weil,[48] and one by M. Pascarolo and M. Bertolloti.[49] Klippel and Weil's case concerned a woman of fifty-six years in whom the disease had made its appearance eleven years previously and had progressed slowly. There was a marked scoliosis of the vertebral column and thickening and hypertrophy of the bones, and marked distortions of the long bones which was confined almost entirely to

FIG. 3.—Anteroposterior view of the right femur, showing the greatly enlarged and thickened cortex and a characteristic irregular outline. The medullary canal is absent and there are areas of rarefaction.

the right side of the body. A singular manifestation of this case was noted in the fact that there was an increase of surface temperature on the affected side. R. Manwaring White[50] contributes two cases in 1909. Maier,[51] in the same year, contributes one case occurring in a woman of sixty-

four years, and Matsuoka[52] also reports a case concerning a man of sixty-seven years of age. In 1910 R. G. Hann[53] reports one case occurring in a patient of sixty, terminating with cerebral symptoms. Vasek's[54] case was reported in 1911, occurring in a man of sixty-eight, who for twenty years past had noticed a gradual increase in the circumference of his right leg and knee, which was later accompanied by pain in both extremities and back.

One of the most complete and interesting reports upon this subject is by Higbee and Ellis,[55] published in the *Journal of Medical Research* for 1911. Post-mortem findings of this case being carefully recorded.

B. Franklin Stahl,[56] another American observer, in 1912 reports one case with radiographic and necropsy findings.

In the *Am. Jour. of the Medical Sciences* for November, 1901, Packard, Steele, and Kirkbride tabulate sixty-seven cases occurring in the literature; of these 61 per cent. occurred in males and 35 per cent. in females. Wilson in 1903 collected seventeen cases occurring in North America, and Shirmer[57] in 1908 collected eighty-six cases up to that year; of these, forty-six were men and forty in women. So far as the writer is able to ascertain there are but twenty-six cases reported in this country since Packard, Steele and Kirkbride's communication, which number includes the writer's report of one case.

Clinical Manifestations.—According to Paget's original description, the disease usually occurs during middle or advanced years, and is slowly progressive or may remain quiescent for a long period. However, Elsner[58] reports one case occurring in a girl of seventeen years, and Sonnenberg's case concerned a girl of sixteen years of age. The oldest case was that of Stilling's, occurring in a woman of ninety-two years.

The general health is seldom impaired. The mind is clear and the brain never becomes involved as a result of the disease, even when the cranium is greatly thickened. The long bones are usually primarily affected, particularly those of the lower extremities, and later the skull and upper extremities are involved. In some of the recorded cases the earliest sign complained of by the patient was the increase in the circumference of the skull, which necessitated the wearing of a larger hat. In addition to the changes in the bones of the extremities, resulting in softening, thickening and distortion, pathological changes occur in the spine. There results a marked forward flexion of the spine and the length of the vertebral column becomes shorter. Owing to the increased thickening of the cranial bones the neck is flexed and the head bent forward. With the onset of the disease the tibiæ and fibulæ are usually first affected, later the femora becomes hypertrophied, roughened and bowed outward, and finally, in order of frequency, the ribs, the bones of the hands and feet, and the cranium and spinal column become involved. In some of the cases, however, the first sign of the disease was a thickening and enlargement noted in the cranial bones. The joints are rarely involved. The pelvis is thickened and broadened and resembles the osteomalacic type. As a rule, the lower extremities are much more distorted and thickened than the upper limbs, so that walking is often difficult. This was particularly noted in the writer's case. The vertebral column often presents a marked rounded kyphosis in the dorsocervical region, and the entire vertebral column is bent forward. The thickening of the ribs and the sternum often leads to respiratory disturbances, and pneumonia and pleurisies are not uncommon complications. Ankylosis of the vertebral column often occurs and may be partial or complete. Pain is often complained of in the affected bones, varying in severity, and frequently characterized as rheumatic or neuralgic. Constitutional disturbances are not present and there is no febrile reaction accompanying the disease. The blood picture is not altered and there are no urinary changes.

Numerous theories have been advanced as to the cause of Paget's disease, but up to the present time the etiology is still unknown. Czerney[59] was inclined to believe that syphilis was the etiological factor, while other observers considered cancer, rheumatism, arteriosclerosis, and trauma as the cause of osteitis deformans. The duration of the disease varies from five to thirty years. Death occurring from some intercurrent affection. In three of Paget's cases carcinoma was present.

Fig. 4.—Anteroposterior view of the left femur showing marked thickening, enlargement and bowing of the entire shaft. There is a great thickening of the cortex and an entire absence of the medullary canal. At the greatest convexity of the shaft is the site of an old fracture.

Complications.—Arteriosclerosis and atheromatous changes are not uncommon, and trophic skin eruptions and leg ulcers are often observed. Pulmonary emphysema and pleural effusions and hypostatic pneumonia complicate the disease, due to a compression of the thorax and fixation of the ribs, sternum and clavicles.

In one of Paget's cases Bright's disease with valvular changes in the heart and general anasarca was noted in a patient of sixty-five years. Pathological changes of the nervous system secondary to osteitis deformans were observed at autopsy in the case of Stilling, and Levi observed a marked sclerosis of the spinal cord in his case of a woman of sixty-two years.

Pathological Findings.—A complete necropsy was performed by Goodhart in 1869 upon Wilks' case,

which findings agreed with those demonstrated by Butlin,[60] who autopsied the first case reported by Sir James Paget. The Haversian canals are greatly dilated and enlarged, and there is a resorption of bone substance and a marked production of new-formed bone. This is termed "fibro-osteoid" tissue by Higbee and Ellis. The periosteum is roughened and greatly thickened. The new bone which is formed has its origin from periosteum. This new bone being devoid of calcium salts, softening and distorition results, particularly noted in the long bones. Rarefaction takes place in the interior of the bones, with the formation of compact tissue beneath the periosteum. The bones are, therefore, roughened, heavier, thicker, and greatly curved.

Packard, Steele, and Kirkbride summarize the pathological changes as follows: "First, there is absorption of the compact bone substance with subsequent enlargement of the Haversian canals. Second, there is a formation of new bone, this new bone later undergoing absorption, and does not become calcified. Third, there is a transformation of the marrow into a vascular connective tissue, containing giant cells, fat, and leucocytes. Fourth, owing to the deficient calcification of this newly developed bone substance, softening results which leads to marked curving and bowing of the shafts of the long bones."

The first radiographic examination in this disease was made by Gallois in 1901, in the Beclere Institute, upon a case reported by Gaillard. The skiagram showed marked thickening of the radius and ulna, particularly of the cortical substance of these bones. Both femora were involved, and the tibiæ, especially, showed enormous thickening. The tibial artery was plainly visible and presented well-marked sclerosis. In the radiogram taken of Sonnenberg's case there was not only a thickening and roughening of the long bones, but also an actual increase in the length of the affected bones. This writer was the first to obtain a skiagram of the pelvis in a case of osteitis deformans, which was found to resemble the osteomalacic type.

As to the treatment of this progressive disease little or nothing has been accomplished. Up to the present time it can be said to be only palliative. Massage, electricity, dietetic and internal medication seems to have no effect whatsoever upon the disease. De Hall claims that the severe pain in some instances has been relieved by the administration of potassium iodide combined with quinine. Cauterization and cantharides plasters applied to the spine have been of value in affording relief from pain in some instances. In some cases orthopedic apparatus in affording support and fixation of the spine has proven of great value. Osteotomies of the tibiæ have been undertaken but are not to be advised. In Sonnenberg's case an osteotomy was performed for the correction of the deformity; the wound healed by primary union, but a pseudoarthrosis resulted.

Most authorities are, therefore, agreed that surgical intervention is not warranted.

The case which came under the writer's notice concerned a woman of twenty-five years. She is unmarried. Born in Kansas and has resided in Colorado for the past year. Occupation, housewife.

Previous History.—The patient was a healthy, normal child at birth. She had an attack of measles during early childhood. There was no history of rickets, tuberculosis or rheumatism. When five years of age she fell, fracturing her left femur. From this injury she made a complete recovery. Up to the time of her present illness she always enjoyed excellent health. The father died at the age of fifty, of locomotor ataxia. The mother is living, but is in delicate health. The grandmother died of pulmonary tuberculosis. The patient's menstrual history is negative.

Present History.—When ten years of age she first began to have pain in both thighs, which was increased by exercise. At the age of sixteen years she fell, striking upon her back and left hip, not, however, sustaining a fracture of any bone. She was confined to her bed for three weeks, owing to severe "bruises" sustained to the left thigh as the result of the accident. One year following this accident she began to have pain of a rheumatic character in her left thigh and leg. This pain was not severe, and at times was entirely absent. Salicylites were administered but without beneficial effect. Three years later pain in the lower spine developed, sometimes radiating down the back of the thigh to the knee. Stiffness of the spine was also noticed. This pain was always more severe at the time of her menstrual periods. Coincident with this lumbar pain the patient complained that after even mild exercise she tired easily, and that both thighs were becoming "bowed." There was no decrease in height noticed. Her general health remained good. Her appetite was excellent and she slept well.

One year previous to her coming to Colorado the pains in the thighs and back increased and the curvature of the thighs became so marked it was with difficulty that she was able to walk. Her gait became waddling and she "stumbled" easily.

Examination.—A well-nourished young woman, not anemic, and of keen intellect, walking with a marked waddling gait, with her shoulders stooped and back in slight forward flexion. Weight of eighty-seven and one-half pounds, and height of four feet, eight inches. Temperature was normal and a pulse of sixty-eight.

The heart and lungs were normal and the abdomen was negative. There was no evidence of rickets, tuberculosis or arteriosclerosis. The head was carried erect and was of normal size and shape. There is no change of contour of the facial bones. There is no discoloration of the skin.

The Spine.—There was no kyphosis, but there was a mild degree of rigidity in the entire spinal column: the vertebral column being bent forward; the most marked flexion being in the lumbar vertebræ. Motion, although restricted, was not attended with pain. The width of the pelvis was increased and the crest of the ilia thickened.

The upper extremities were normal.

The lower extremities were greatly curved, the femora being most markedly bowed outward. All the long bones of the lower extremities were enlarged and thickened, and this could be easily detected in the tibiæ, particularly that of the right side. There is an anterior as well as outward bowing of both tibiæ.

Extension of the thighs was normal, but rotation outward was restricted. Both the right and left trochanter measured two inches above Nélaton's line. There was no ankle clonus, and Babinski's sign was absent. The knee jerks were not increased. Pressure on the thighs and legs was not painful, and there were no skin lesions on any part

of the body. The measurements: From the right anterior superior spine to the internal malleolus was 27½ inches (R. A.). From the left anterior spine to the internal malleolus was 27¼ inches (L. A.). From the umbilicus to right internal malleolus was 30½ inches (R. U.), and from the same point to the left internal malleolus was 30½ inches (L. U.). Circumference of the left thigh measured 4½ inches down from the anterior superior spinous process of the ilium was 18½ inches, and 10 inches down from the same point was 12 inches. Circumference of the right thigh measured 4½ inches, down from the anterior superior spinous process of ilium was 16¾ inches, and 10 inches down from the same bony point was 11⅞ inches. Circumference of the left calf was 11 inches, and of the right calf was 10¾ inches. Owing to the bowing outward of the femora, the spacing between the thighs measured 7½ inches. The width of the pelvis was 16½ inches. The knee and ankle joints were normal. The tibiæ are of the same length. The urine examination was negative.

The excellent radiographs, which confirmed the writer's diagnosis of this case, were very kindly taken for me by Dr. S. B. Childs of Denver, and show the characteristic bony changes observed in this disease.

The radiographic examination taken of the lateral view of the left tibia and fibula (Fig. 2) shows the marked bowing of the shafts of each bone with a greatly thickened cortical edge, associated with marked nodosities on the posterior surface of the tibia, and anterior and posterior surfaces of the fibula. The lighter areas indicate zones of rarefaction. There is an entire absence of the medullary canal. The cortex is greatly thickened and irregular, and the dark linear shadow overlying the posterior surface of the tibia is caused by the overlying dark shadow of the fibula.

Skiagram of the anteroposterior view of the right femur (Fig. 3) shows a greatly enlarged and thickened cortex, the entire bone with the exception of the head and part of the neck being greatly enlarged. The great trochanter is situated three inches above the head of the femur and connected thereto by a long, distorted neck. The thickened cortical edge, with its characteristic irregular outline, is well shown in this skiagram, as well as the areas of rarefaction and the entire absence of the medullary canal and bony striæ.

The anteroposterior view of the left femur (Fig. 4) shows marked thickening and enlargement of the entire shaft of the bone, particularly of the upper third. There is a great elevation of the greater tuberosity and close approximation to the ilium, with a marked upward obliquity of the femoral neck. At the greatest convexity of the shaft is the site of an old fracture. There is marked thickening of the bone throughout its entire length, especially of the cortex, and an absence of the medullary canal.

The case which the writer has had the pleasure of reporting is, he believes, typical of this rare bone affection, but differs from the majority of similar cases recorded in the literature in the fact that the first manifestation of the disease occurred at the age of sixteen years, affecting primarily the lower extremities, and later the vertebral column.

I wish to express my thanks to Dr. F. Robbins of New York City, and to Miss M. Malins of Denver, who aided me in reviewing the literature upon this subject.

KNIGHTS OF COLUMBUS BUILDING.

REPORT OF A CASE OF LUPUS ERYTHEMATOSUS DISSEMINATUS.

BY ANDREW J. GILMOUR, PH.B., M.D.,

NEW YORK.

CONSULTING DERMATOLOGIST, MANHATTAN STATE HOSPITAL; ASSISTANT ATTENDING DERMATOLOGIST, NEW YORK CITY CHILDREN'S HOSPITAL AND SCHOOLS.

J. F., male; white, age nineteen years; nativity, Austria; occupation, bartender.

Father died of heart disease at the age of forty-five. Mother is living and well. One brother, twenty-two years old, two sisters aged twelve and eight years, respectively, are living and well.

The patient, when he was a child, suffered from

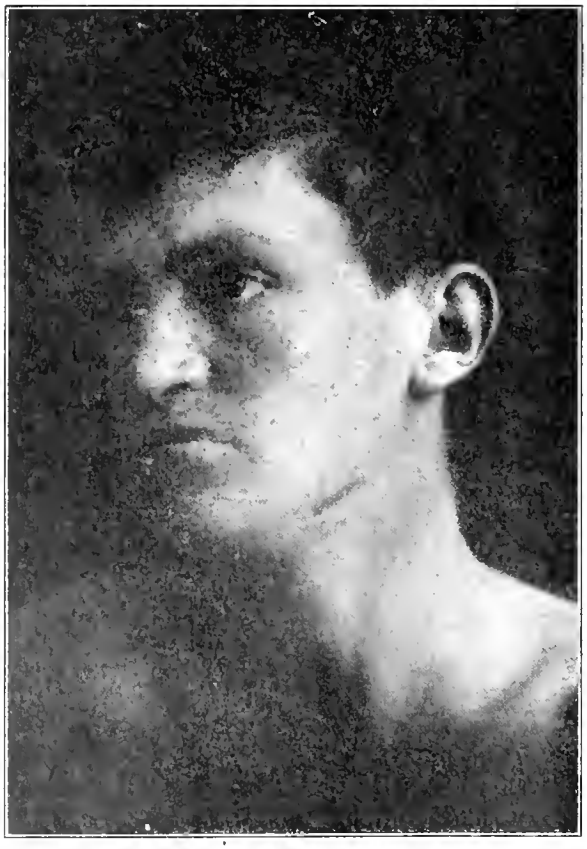

FIG. 1.

an abscess on the left side of the jaw. The scar from this is still plainly visible.

For eighteen months previous to November, 1908, the patient was employed as a lineman for the Western Union Telegraph Company. About December 1, 1908, the patient had the left ear frozen. Shortly after this the patient noticed, as he expressed it, "the skin behind this ear got crumbling." He employed cold cream without effect. The following April, 1909, the disease appeared on the right side of the nose. He then had treatment at one of the New York clinics without an improvement of his condition. Six months later, October, 1909, numerous spots appeared simultaneously on the abdomen. Eighteen months ago, April, 1910, lesions began to appear on the palm of the left hand. These lesions on the hand were not large ones, all smaller than a one-cent piece. They were active about ten months, then healed. After eight months slight scarring is still present.

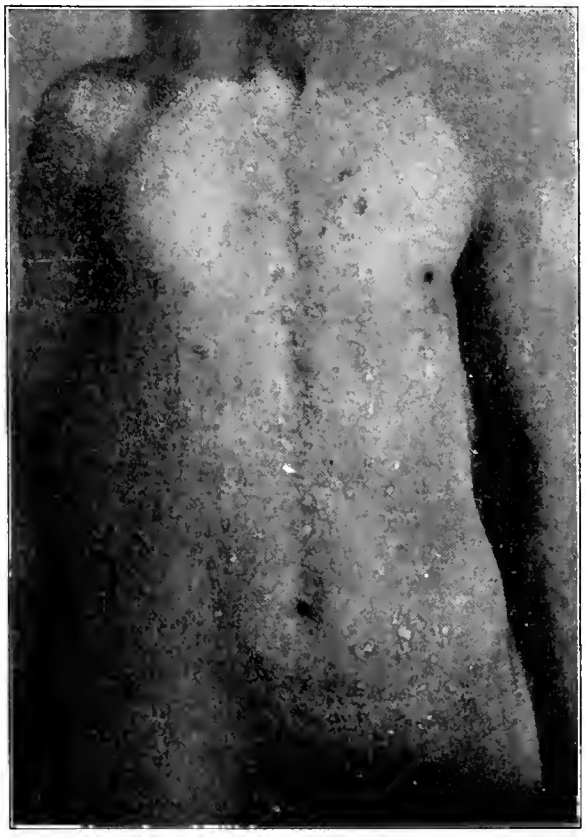

FIG. 2.

One year ago lesions began on the tips of the ring fingers. These lesions have grown under and gradually raised the nail in a ridge parallel to the long diameter of the nail. This process has caused a splitting of the free edge of the nails at the crest of the ridge. White, closely packed scales, which have the appearance of mortar, are seen under these nails.

Physical examination shows that the entire nose is involved in an atrophic process and is covered with fine, white scales. At its upper half the lesion runs just a little beyond the nose on either cheek. There is a round spot the size of a twenty-five cent piece in the middle of the left cheek.

Eight small areas, in diameter about one-half inch each, are between this spot and the left ear. The entire left ear and an area extending one-half inch behind it is involved.

A lesion, with the diameter of half an inch, lies two inches behind the tip of this ear. The entire right ear is affected, but not as severely as the left ear. There is the same extension behind this ear as in the case of the other ear. The same small spot is present two inches behind the tip. Three-

quarters of an inch in front of the middle of each ear there are two spots each three-quarters of an inch in diameter and situated one above the other. These are more or less fused. We see that the involvement of the ears and the surrounding area are symmetrical in extent, but not in degree.

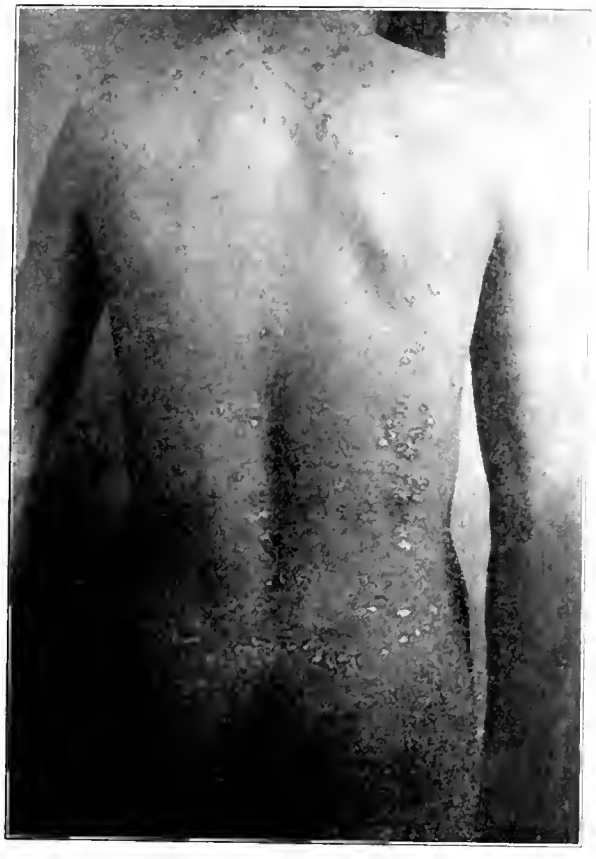

Fig. 3.

The top of the head shows a dozen small spots of atrophy. Two of these spots are larger than the others, having a diameter of one inch. These two large ones show well-marked atrophy, scaling and loss of hair. Both arms show a few lesions on their outer aspect.

The forearms on their flexor surface are free. The right forearm has four spots on its extensor aspect. The right hand has five spots on its dorsal aspect. The ulnar side of the hypothenar eminence of this hand is slightly affected. The right thumb shows four spots on its inner side. The right little finger is involved on the inner side of the back of the terminal phalanx. The right ring finger shows lesions of the back of the terminal phalanx of the tip of this finger, and an involvement beneath and of the nail.

The left forearm has four lesions on its extensor surface. The back of the left hand has a small lesion one inch above the junction of the little finger with the hand. The left thumb is affected on the dorsal and ulnar side of the last phalanx. The left index and middle finger has the dorsal surface of the terminal phalanges involved. The left ring finger is affected on the back and ulnar side of its terminal phalanx. The tip of this finger and nail are involved in the same extensive manner as the right ring finger. The left little finger has the dorsal surface and tip of the terminal phalanx slightly involved.

The entire front of the chest and the abdomen, except for a rectangular area extending one inch below, two inches above and to either side of the umbilicus is thickly studded with lesions one-quarter to one inch in diameter.

The form of these spots is in general oval or round. In places several of these spots have fused, forming more or less kidney-shaped areas about two inches in length. The back at its upper part is involved in a crucial manner. An area three inches broad runs for about six inches down the spine from the neck; another area of small lesions crosses this following the spines of the scapulæ. The middle transverse area of the back is quite free from lesions.

The lower third of the back has an area of lesions running down the spine. Numerous lesions are scattered on either side of this area. A thickly involved area runs across the back above the gluteal fold. A few spots are present on the upper inner part of the left gluteal region. The sides below the floating ribs are free from lesions, except for one spot one-quarter of an inch in diameter situated on the left side. Except for two small spots on the thighs the lower limbs are free.

The individual lesions range in size up to one inch in diameter. They have a pinkish border with a grayish white, scaly base, which in most lesions is below the level of the surrounding skin.

The more atrophic lesions are pigmented and have lost considerable of the grayish color. Von Pirquet and Wassermann tests were both negative. The patient is in fair physical condition and considers himself well except for the eruption.

Fig. 4.

Treatment has been applications of carbon dioxide snow to the nose with a good result. The patient came to the clinic when out of work, but since obtaining a position he has not returned.

133 East 57th Street.

ADENOMATOUS HYPERPLASIA OF THE PROSTATE GLAND.*

OPERATION AND POSSIBLY CONSEQUENT CHRONIC SUPPURATIVE NEPHRITIS WITH CALCULI IN KIDNEY, URETER, AND BLADDER.

By VICTOR COX PEDERSEN, A.M., M.D.,

NEW YORK.

The following case is unmistakably difficult and complicated in its course and illustrates very well the saying attributed to Virchow, "If we would know more thoroughly, we must examine more carefully."

J. A. D. (Case 12,590), U. S., white, fifty years, single, retired policeman. February 26, 1912. Referred by Dr. Lester Laurens Roos.

Family history states that father died by accident; mother of nephritis; three brothers of scarlatina, drowning, and alcoholism, respectively; one sister in childbirth. Personal history, childless and divorced; wife without venereal disease. His own general health has always been good up to the present affliction which began two years ago. Denies all infectious disease, excepting malaria twenty years ago. No renal injury or disease remembered. Denies all causes of nephritis, except scarlet fever and an alcoholic habit, seemingly too moderate to be a factor. Denies causes of albuminuria (other than nephritis) except prostatic disease as later stated.

Former venereal history: denies syphilis and chancroid, but admits urethritis thirty-three years ago, persisting for five or six years with frequent relapses, but no complications, without definite treatment, except in drug stores. Bilateral epididymitis began twelve years ago without previous exposure to cold, injury, instrumentation, or reinfection. Persisted for twelve days under private treatment with poultices but without operation. He next remained in good health up to February, 1910, when he was admitted to one of the large hospitals of this city, with the following condition:

I am indebted very deeply to the attending surgeon for permission to publish the record of the case at the hospital.

J. A. D., admitted February 24, 1910, diagnosis, hypertrophy of the prostate. History, patient returns for permanent relief following a visit to the hospital for retention of urine. Discharged February 17, 1910, after relief by passage of a filiform and tunneled sound and eventually plain 22 F sound. Gives a history at that time of inability to urinate for three days previous, except for overflow dribble and of several ineffective attempts outside the hospital to catheterize him. Never any blood. Previous to this time, gives history of slight diminution of size and force of urinary stream for about a year, but no previous attacks of retention. At present, no pain or interference with urination, except increased frequency, two or three times by day and two times by night. Appetite good; bowels regular. Gonorrhea thirty years ago; denies syphilis. Four years ago had abscess of the rectum.

Physical examination: Very well nourished; good color; tongue clean; lungs slight emphysema; heart-sound muffled; second aortic accentuated; pulse regular; good force; walls slightly thickened.

Surgical condition; A meatus small, but admits 24 F sound, with considerable pain; about 2 ounces of clear, pale residual urine drawn by catheter after urinating. By rectal examination, prostate enlarged and firm, especially over middle lobe; no tenderness; pressure causes desire to urinate; external sphincter tight and somewhat tender.

Operation: February 26, 1910, perineal prostatectomy, gas and oxygen anesthesia. Lithotomy position; tunneled sound introduced; midperineal incision made; urethra opened; bladder entered; prostate gland enucleated with the finger; perineal tube inserted with iodoform gauze packing.

Ward records show uneventful but rather long convalescence, with the usual standard medical and surgical management.

Second operation: March 21, 1910, dilatation of urethral stricture; chloroform anesthesia; dorsal position; meatus incised; plain gauze introduced; sounds introduced; stricture found at the membranous urethra; dilated to 30 F. Patient discharged from the hospital May 16, 1910.

Pathological report: Diagnosis, adenomatous hyperplasia of the prostate gland (may prove malignant). February 26, 1910.

Macroscopical, fragments of prostate gland, hard, fibrous-like, on section.

Microscopical, increased glandular elements with some increase of fibrous connective tissue.

It should here be added that the ward notes show nothing significant in the uranalyses. Patient recalls no symptoms at all in the urine itself.

It is not our function to criticise the foregoing data for the briefest moment or in the mildest degree. Incidentally, however, and in the light of that which followed in this case, it is to be regretted that no cystoscopy, radiography, or ureteral catheterization seems to have been carried out on this patient at this time. There certainly was no direct indication for any of these procedures, but it will be at once obvious to the reader as he proceeds that a comprehension of the later history and pathology and termination of the case would have been rendered more positive than at present had these procedures been followed and their results recorded.

The patient seems to have developed incontinence of urine after the operation from which he never recovered fully, although he was able to start and stop the stream of urine more or less successfully at command, provided the bladder was not very full. He was obliged to wear a rubber urinal day and night, which soon led to his resignation from the Police Department and to partial invalidism. Syphilis was denied, and examination for the signs of locomotor ataxia was negative.

For the incontinence he sought the advice of the operating surgeon, who referred him to a urologist for cystoscopy, with the resulting report that the muscle at the neck of the bladder appeared to be in trouble. No more detailed diagnosis than this, however, seems to have been possible, or really could be expected.

He was first seen by me in company with his physician about Christmas time, 1911. His great need of hospital treatment led me to refer him to one of the large hospitals. Radiography was negative as to stones in the urinary tract. Cystoscopy at this time showed a generalized cystitis, a greatly deformed bladder floor, a nearly normal left ureteral mouth, and a right ureteral mouth inflamed and so situated in the midst of the inflammatory zone

*Read before the Medical Progress Club, October 9, and before the West Side Clinical Society, October 12, 1912.

as to be difficult to make out and impossible to enter. The urine showed all the symptoms of cystitis. The man was examined carefully and it was decided that his seminal vesicles were inflamed and that a double drainage operation might relieve the symptoms. It was distinctly stated in my presence that one could not promise the patient anything definite, but that the indications and hope of the case lay in the direction of this operation. The procedure was carried out on the patient on January 7, 1912, with immediate and promising relief, and a convalescence without incident. Soon after leaving the hospital, however, the fever, pain in the right kidney region, and cystitis all increased. The renal region showed no definite physical signs. The most marked of the three was the cystitis, which had taken on the form of calculous irritability.

This distinct and sudden increase in symptoms looked to me like a relapse, which led me to cross-question the man again carefully as to whether he had ever had similar though milder attacks. Even with careful afterthought he assured me that he had nothing the matter with his genitourinary tract, including the urine, prior to February, 1910, when he applied for relief. Be it remembered that the urine was at this time normal, so far as recorded examinations show.

I consequently decided to make another attempt to cystoscope the patient and if possible catheterize the ureters, which was done February 26, 1912. A stone the size of the little finger tip was located, apparently phosphatic. The patient recalled no renal colic in explanation of the stone, and I know that the cystoscopies done just prior to the vesiculotomies would have found it had it then been in the bladder. These two facts forced the conclusion that the stone must have been delivered from the ureter of the right side during the operation of seminal vesiculotomy, and the local improvement under the examining finger after the operation was probably due to the absence of this stone.

J. A. D. URANAYLSIS OF URETERAL CATHETERISM February 26,1912

	Left	Right
Kidney		
Appearance	Clear, small sediment	Clear, decided sediment
Volume	Estimated drachms 6	Estimated ounces 1½
Specific gravity		1021
Reaction		Acid Normal
Color (Vogel's scale)	No. 2 light yellow	Red
Chlorides		Normal
Albuminuria (Purdy's method)	0.1%	0.5%
Sugar	None	None
Urea (Carbonid)	0.3%	1.9%
Pus cells	One-fifth as many as right	Innumerable, distorted
Epithelial cells	Few, flat	Few, flat and round
Renal casts	None	None
False casts	None	None

Remarks: The divergence in quantity between the two kidneys seems to have been due to leakage around the catheter in the left ureter. The very small urea output from the left side, combined with the slightly decreasing excretion seems to indicate susceptibility of this kidney to instrumental invasion. Much of the pus from the right side was undoubtedly vesical in origin.

Ureteral catheterization, February 26, 1912. Water taken, four ounces at 10.30, 10.53, 11.25, 11.50 A.M., and 12.08, 10.50 A.M. 6 F. catheter into left ureter. Catheter into bladder to catch urine from right kidney after thorough washing of bladder.

Left kidney. Catheter in ureter, 10.50 A.M., first urine, 10.50 A.M.; phenolsulphonephthalein 1 c.c. 11.30 intravenously; color appeared, 12.15. Discharge of urine very slow, decreasing to drops about 12. Total urine, about six drachms (not measured).

Right kidney. Soft rubber catheter in bladder, 10.50 A.M., first urine, 11 A.M., color appeared 11.42 A.M. Total urine, about one and a half ounces.

J.A.D. CATHETERIZATION OF URETERS March 1, 1912

	Medication	Left Ureter	Right Ureter
11:00 A.M.	Water oz. VI.		
11:06 A.M.		Catheter in 15 cm.	
11:13 A.M.			Catheter in ureter obstructed at 3 cm
11:15 A.M.	Water oz. VI.	Urine appearing.	
11:30 A.M.	Water oz. VIII.	Urine No. 1 oz. I.	
11:43 A.M.	0.7 c.c. phenolsulphonephthalein intravenously	Urine No. 2 oz. I.	No urine at all.
11:55 A.M.	Water oz. IV.		
12:05 M...	Water oz. IV.	Urine No. 3 oz III.	
12:15 M..		Urine No. 4 oz. IV.	Oz. III. urine thru cystoscope from floor of bladder, similar in appearance to that from left kidney (leakage?).
12:20 M...	Water oz. IV.		
12:40 M...		Urine No. 5 oz. IV.+	
1:00 P.M.		Urine No. 6 oz. III. paling out.	
1:05 P.M.			Catheter out. Bladder washings saved for pus from right kidney.
1:07 P.M.		Catheter out.	
1:15 P.M.	Evacuated mixed urine oz. I.		

It will be noticed that this catheterization was far from satisfactory. There must have been a good deal of leak around the ureteral catheter, and seemingly an anuria of the left kidney. No local anesthetic had been used in the bladder, which may have been the basis of these conditions. Great gentleness and deliberation in the work rendered such anesthetic not necessary.

On March 1, 1912, the catheterization was repeated. The bladder was washed very thoroughly with 2 per cent. boric acid water, until the return was clear and shredless. Then a 2 per cent. solution of alypin was instilled into the bladder and urethra, retained fifteen minutes, evacuated, and replaced with 150 c.c. of warm 2 per cent. boric acid water. The patient was now ready to cooperate fully. The Brown-Buerger cystoscope was introduced readily and a view very much better was obtained. The stone was located again on the left side in a normal depression, just beyond the plica ureterica, pyramidal, about the size of the little finger-tip; bladder as a whole in good condition, except for signs of universal cystitis. Right ureter has no mucus sticking from it, but is enlarged, reddened, granular, patulous. Left ureter nearly normal. Left ureter easily entered with a 6 F instrument for 15 cm. without blood or pain in about six minutes. Right ureter entered with great difficulty after seven minutes. Slipped out, was reintroduced for only 3 cm., when an obstruction was encountered. Great pain, virtually ureteral colic, was caused by entering and moving the catheter in the right ureter. When withdrawn it brought with it several strings of mucopus, blood-stained, and very tenacious. The left ureteral catheter, on removal, brought with it no blood, mucus or pus. In taking the separated urine at this catheterization the separate specimens were taken about every fifteen minutes, hoping to show the conditions progressively. The chart indicates, however, that this was not a success.

On March 13, 1912, in consultation with Dr. James Pedersen and Dr. Roos, we attempted to

prove the presence of stone in the right ureter near the bladder by passing the probe catheter. On this occasion we found another small stone in the bladder, either broken from the first one or subsequently discharged from the ureter. The combined urines showed 28 per cent. of phenosulphoneph-

Fig. 1—Radiograph showing large calculus in the right ureter which, through its oblique position, cast a shadow larger than itself; also showing the small calculi in the bladder just above the symphysis pubis of the same apparent size as seen through the cystoscope.

thalein during the first, and 16 per cent. during the second hour after intravenous injection, total 44 per cent., which seemed to us a very good elimination considering all his conditions. The question of the cause of this complex situation led me to have another radioscopic examination performed as that done at the hospital in January was not conclusive, and also induced me to have at least two examinations of the urine for tubercle bacilli.

J.A.D. Uranalysis of Ureteral Catheterism March 1, 1912

	Left Kidney		Right Kidney.	
Quantity	16 ounces

"J. A. D. *x*-ray findings, March 16, 1912, Dr. Victor Cox Pedersen. Ribs, spine, transverse processes, spine of the ischium and coccyx show distinctly. Psoas muscle shows distinctly. The left kidney shows distinctly and is normal in size, shape, and position. The outline of the right kidney is not shown sufficiently distinctly to justify one in stating its size. There is one large and several small shadows in the region of the lower pole of the right kidney. There is a large, long, horn-like shadow in the region of the lower end of the ureter, and two clear-cut, well-defined shadows in the region of the bladder.

Diagnosis: From a study of these plates one is justified in stating that there is one large and several small calculi in the right kidney and a large calculus in the right ureter, and two moderate sized ones in the bladder." (Signed) Lewis Gregory Cole, M.D.

I am indebted to Dr. Lewis Gregory Cole for two investigations of this case March 8 and 16 at his *x*-ray research laboratory, with the resulting admirable photographs and final report.

Dr. Cole's examination of March 8 concurred in that of March 16, but as he was not fully satisfied

Fig. 2—Radiograph showing one large and three small shadows from calculi in the right kidney

himself he conscientiously and graciously repeated the entire procedure for me.

Examination of two 24-hour specimens of urine were done March 5 and 15, with the following results:

J.A.D. Uranalysis of 24 Hour Specimens March 5 and 15, 1912

24 hour spec.	Yes	Yes
Physical analysis: Quantity	1767 c. c.	1305 c.c.
Clearness	Turbid with heavy purulent sediment	Clear, small sediment
Color	Filtered No. 3 normal	No. 3
Reaction	Feebly acid	Acid
Spec. grav. at 150 C.	1018	1016
Biliary matter	None	None
Chemical Anaylsis: Peptones	None	None
Urea (normal 2 6-10 per cent.)	1.7 per cent.	1.2 per cent. (average 1.45)
Indican	Not noted, probably Normal	Normal
Diacetic acid	None	None
Acetone	None	None
Glucose	None	None
Diazo-reaction	Negative	Negative
Albuminuria (Purdy's method)	0.3 per cent. by weight	0.2 per cent. by weight
Microscop. analysis: Concretions	None	None
Pus	Heavy purulent sediment	Less sediment
Mucus	None	Mucopus
Red blood cells	None	None
Uric acid	None	None
Urates	None	None
Oxalates	None	None
Calc. phosphates	None	None
Bas. mag. phosph.	None	None
Gran. phosphates	None	None
General elements: Pus	Cells, innumerable, distorted	Cells innumerable
Epithelia	No characteristic cells seen	
Bacteria: Colon bacilli	Smears of sediment show frequent Gram negative bacilli which ferment lactone in presence of bile. This is of no value because of easy contamination of urine with bacteria from intestines	Innumerable colon bacilli
Tubercle bacilli	None	None

Having thus secured a definite diagnosis of

calculi in kidney, ureter, and bladder, and of passably efficient excretion of urine, intervention surgically was warranted. As the patient was conditioned, work was impossible. The desire of the man to get well and return to duty were also reasons for undertaking to help him. Members of his family and he himself specifically accepted the risk of operation, which was fully explained.

The patient was admitted to St. Mark's Hospital March 12, 1912, in good general condition. He was kept quiet in bed for three days in order to secure as much repose and reserve force as possible. A 24-hour specimen of urine totaled 500 c.c. and showed acidity, purulent cloudiness, 1010 specific gravity, 2½ grains of urea to the ounce, a trace of albumin, normal indican, absence of sugar and bile, trace of blood and large quantity of pus. His temperature prior to the operation was practically always nearly a hundred, but without wide variations.

The patient felt in the best of condition, and pleaded earnestly for one operation to relieve kidney, ureter, and bladder. In yielding to this solicitation, I believe, that I erred. It would have been much better if we had disregarded everything but the surgical considerations and had attacked the main focus of his trouble first, namely, the kidney. The three steps of the operation were done at one sitting on March 24, beginning at 3.20 and ending at 5.23 P.M., including the preliminary preparation of the various fields one by one. My consulting assistant was Dr. Benjamin T. Tilton, for whose interest, help, and service in the matter I desire hereby to tender grateful acknowledgments.

The ureteral calculus was attacked first through an oblique incision parallel with Poupart's ligament, placed a little higher than the herniotomy incision, and extended longer than it, inward to the sheath of the rectus, and deepened rapidly by sharp dissection to the extraperitoneal fat. This was rapidly and deeply separated from the wall of the bladder, previously distended with boric acid water, and consigned to wide retraction upward. Following the wall of the bladder carefully on the inside and the pelvic wall on the outside, the wound was deepened until the seminal vesicle was encountered, lying against the bladder and above the prostate. The ampulla of the vas deferens was next felt for and recognized. The ureter, much thickened, was then easily found lying highest and between the two structures last named, crossing more or less distinctly the space bounded by the pelvic wall, and seminal vesicle on the outside, the distended bladder and ampulla on the inside and the extraperitoneal fat above. The calculus was found practically at the surface of the bladder, which necessitated separation of the ureter carefully from the bladder, and the passing of a silk temporary ligature about it as a retractor, placed, of course, between the stone and the kidney. With blunt-pointed scissors the ureter was divided longitudinally down to the stone and evacuated of it. Digital exploration showed no other stone present, after the blunt spoon had removed one or two small fragments chipped off with the scissors. No instrument was passed into the bladder from this point, in virtue of the patency found during catheterizations of the patient's ureters, and of the need to save time. The wound was sewn up with free drainage to the ureter, which was not stitched, and a copious dressing applied.

The patient was now turned over into the kidney position and that field prepared for invasion. The unavoidable delays of adjusting the patient, the renewing of sterile towels, cleansing the fields, and rearranging and renewing the instruments, were unfortunate in prolonging the anesthesia, but could not be avoided.

Through a vertical incision from rib to crest of ilium, placed over the outer border of the rectus spinæ, the kidney was rapidly reached and partially exposed. It was found so densely adherent at the upper pole and so much enlarged that two inches of the twelfth rib had to be resected subperiosteally. Thereafter, the kidney was slowly, gently, and rather easily dissected free and delivered. To our surprise, no large calculus corresponding with the shadow of the radiograph was found. The kidney was divided from end to end with very little hemorrhage. The lower pole was

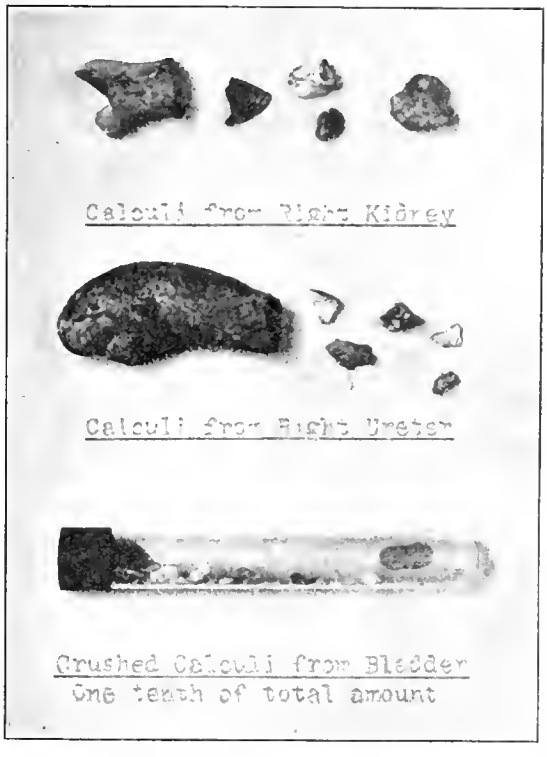

FIG. 3.—Photograph of card mounted with the calculi. Those from the bladder were approximately the same size of the largest two from the kidney in the top line. The bladder contents after the litholapaxy were passed through coarse gauze instead of through muslin by mistake of a nurse. Hence fully nine-tenths of these bladder specimens were lost.

shown to have an extensive, thick-walled abscess cavity corresponding with the radiographic shadow, and containing a small, friable stone. Slightly above this larger was a smaller abscess cavity with another stone of similar character. Fragments of these and other calculous foci were scooped up with the blunt spoon, and would have represented a perhaps gram in bulk. The fragments were lost, however, among the gauze and the towels through oversight. Although some of the irrigation fluid was passed through gauze, hardly any stone detritus was recovered in this manner. Various attempts were made to penetrate the ureter from above, but without avail. It was decided not to remove this kidney, on account of the variations in urea which the patient had showed, but to leave it in place freely drained, hoping that it might recover much of its function after the abscess walls had been trimmed away, drained, and healed. The

organ was replaced, freely drained, and the wound sutured.

As the patient seemed in reasonably good condition, it was decided to crush the stone in his bladder. This was done forthwith, with no trouble, and the bladder pumped clear with Chismore's evacuator. After irrigation of the bladder the patient was returned to bed, in very fair condition. During the early evening free stimulation was necessary, including an intravenous infusion of normal salt solution. After this and up to the expiration of the first twenty-four hours the patient was bright and cheerful, and gave promise of recovery. He passed a reasonable quantity of urine, had no definite hemorrhage from either wound, and seemed as comfortable as any patient could possibly be during the first twenty-four hours. Rather suddenly, and progressively, the patient's respiration began to go up and he complained of dyspnea. The writer was summoned, stimulation was augmented, and everything possible done for the patient. He died about thirty hours after the operation with symptoms of profound pulmonary embarrasment, but without hemoptysis. The house surgeon who saw him expire was of the opinion that pulmonary embolism was the immediate cause.

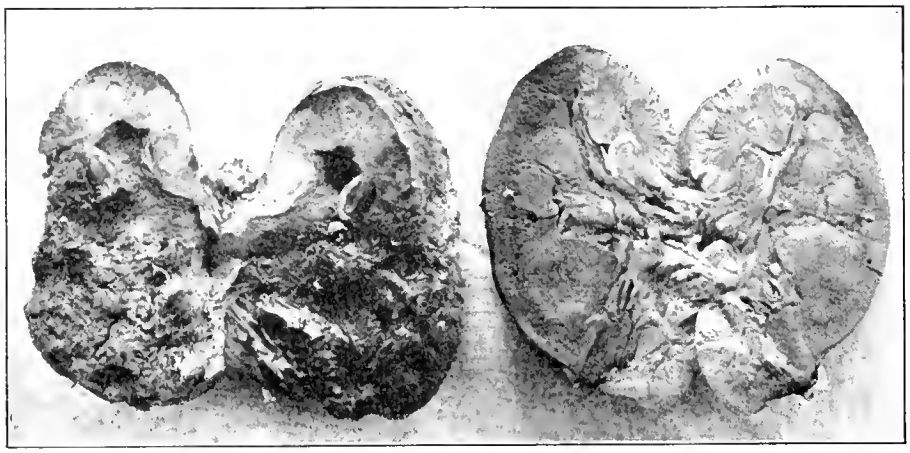

Fig. 4.—Right and left kidneys opened; front view. In the right kidney, the two major abscess cavities are distinctly seen, the larger involving much of the lower pole axially, laterally and anteroposteriorly, and the smaller abscess cavity situated above it. The radiographic shadows correspond more with the abscess walls than with the contained calculi. The pelvis of the kidney as a whole shows signs of chronic inflammation, the mucous membrane being rough and corrugated. The thickening of the pelvis wall is distinctly shown in the cut edge. The ureter appears to be patent. The left kidney is in passable condition and shows the usual changes in chronic diffuse nephritis.

It is unfortunate that this patient after so many examinations and operations should finally have perished. If one might draw any conclusions from the case, they would be as follows:

First, as a matter of record and of thoroughness of investigation in all urological cases, it is too bad that no radiography, no cystoscopy, and possibly ureteral catheterization was done when the patient was first seen with symptoms of stricture and prostatic enlargement. The character of the urine, however, at this time rather contraindicated such procedure. It is possible that he may have had the nuclei of renal calculi with only reflex symptoms and not standard subjective or objective signs.

Second, having reached a final diagnosis in the later periods of the man's disease, it would have been better had the operation been divided into at least two, possibly three, steps, in the order of their importance, kidney, ureter, and bladder, inasmuch as the kidney was the chief source of absorption and inasmuch as the ureteral calculus would very likely not have caused trouble after drainage of the kidney had been established be-

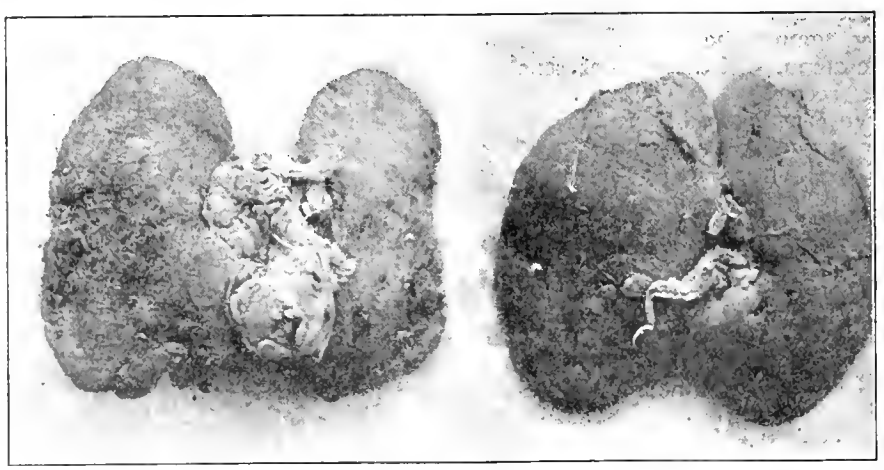

Fig. 5.—Right and left kidneys opened; rear view. The destruction of the kidney substance by the larger abscess is plainly seen over the lower pole. The enormous thickening of the inflammatory deposit around the pelvis and ureter is also clearly portrayed.

cause so deeply pocketed in the ureter behind the bladder. As to the origin of the man's later history and the course of his disease, might not the question be asked, is this not a case of ureteral deformity and obstruction secondary to the prostatectomy? It is known that in animals obstruc-

tion of the ureter invariably leads to infection and abscess of the kidney. Perhaps in this case the right ureter was sufficiently deformed to invite inflammation of the kidney, which in turn was followed by autoinfection with the *Bacillus coli* and calculus formation.

One of the regrets in this case is that we did not test the efficiency of his kidneys independently of instrumental invasion of his lower urinary tract. It would have been interesting to have given the man an injection of phenolsulphonepththalein, then to have observed the excretion in the mixed urines of the bladder. This total, when compared with the total excretion of the drug in the separated urines combined might have given a standard of judgment as to the degree of depression of kidney function secondary to instrumentation. It is at least reasonable to think that in some patients this variation may be wide and important, and act as a guide to the resistance of the urogenital tract to invasion or intervention. I am not aware that this practice is common, but it seems to me worthy of consideration.

FIG.—Microphotograph of kidney showing the lesions of a suppurative nephritis with connective-tissue proliferation

We already have in this case a comparison of the urea excretion during instrumental examination and independently of it. The charts show the differences. The low urea excretion was a good ground for refusing to do the operation in one sitting. Inasmuch as the patient died with pulmonary and not renal symptoms, this comment is of only passing interest, nevertheless the wishes of a patient to get through with it all quickly cannot possibly weigh against such a scientific indication, and I am sure that I will never again heed such solicitation from a patient.

On the other hand, however, the existence of chronic diffuse nephritis in the left kidney might indicate that both organs were ripe for infection without any definite exciting cause. This is known to be the fact not infrequently.

No matter what may be the ultimately correct viewpoint, which after all is only a matter of opinion, the case is sufficiently individualized perhaps to deserve publication.

Pathological report of the New York Hospital reads: Suppurative nephritis. Received August 16, 1912. Reported by Dr. Tytler, August 21, 1912. Dr. Michailovsky. Kidney everywhere shows yellowish white, cheesy areas of all sizes, alternating with, or in places surrounded by, areas of intense congestion. Microscopic sections show the appearance of a suppurative nephritis, with considerable diffuse connective tissue proliferation. Sections attained for tubercle bacilli negative.

Pathological report of St. Mark's Hospital reads: October 7, 1912. Section removed from left kidney. Diagnosis: Chronic diffuse nephritis. Glomeruli: Swollen, endothelium proliferated. Capsule somewhat thickened. Tubules: In some parts dilated with lining cells degenerated. In other parts, swelling of the tubular epithelium. Interstitial connective tissue is only slightly increased, except where there are patches marked increase. Vessels are congested. (Signed) F. Shostac.

45 WEST NINTH STREET. K

THE PRODUCTION OF MALIGNANT TUMORS FROM THE PARASITES OF THE EARTHWORM

BY H. D. WALKER, M.D.,

BUFFALO, N. Y.

THE search for the origin and cause of malignant disease has occupied the attention of the medical profession for many years and I believe it is the duty of every one to contribute anything he may discover which will help solve this problem. I have devoted all my time for the past eleven years to this subject and fully believe I have found the origin and cause of the disease, the manner of its production, and the methods by which it may be prevented. I have produced many tumors in animals by feeding or injecting them with the parasites from the earthworm. That these tumors were malignant there can be no doubt for they killed the animals, and some of these tumors were pronounced malignant by competent pathologists. In a paper read before the Buffalo Academy of Medicine, November 17, 1908, I gave the experiments in full and their results. This was afterwards published and distributed to the profession. Since that time I have succeeded in growing tumors from these parasites upon grass in sealed glass cells containing distilled water the parasites from *Lumbricus herculeus* and small pieces of grass. These tumors are composed entirely of the cells of the parasites and I believe them to be sarcoma, for when they are introduced into animals the tumors

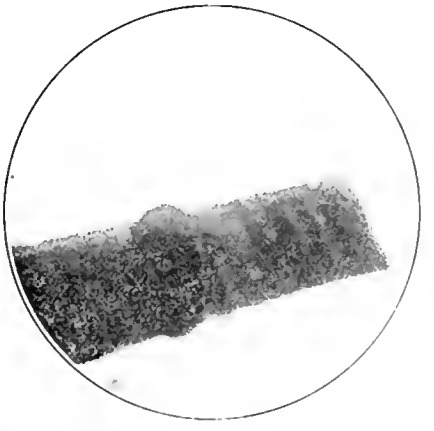

FIG. 1.—Tumor No. 1; Organisms from *Lumbricus Herculeus* enclosed in cell with distilled water and a small piece of grass; taken after being in cell six years. X25.

they produce in them have been pronounced sarcoma. Photographs are here given of two of these tumors in different slides. They are enlarged 25 diameters. The experiments for the production of tumors in animals are simple and easily repeated and I am sure they would be confirmed by others if taken up and then the methods of prevention I have pointed out for the destruction of earthworms could be adopted and many thousands of lives saved each year.

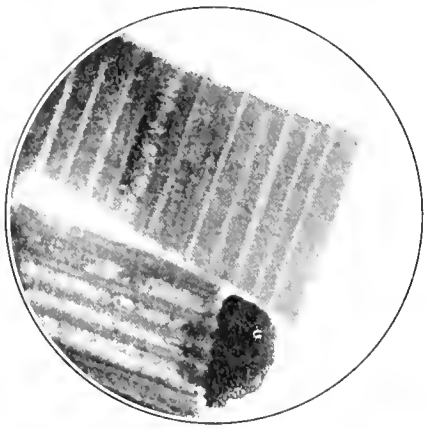

FIG. 2.—Tumor No. 2: Organisms from *Lumbricus Herculeus* enclosed in cell with distilled water and small pieces of grass; taken after being in cell six years. X25.

No earthworms, no cancer; plenty of earthworms plenty of cancer. In my pamphlet I have investigated this proposition and believe it to be true. If so, it is positive proof that my work is correct. The parasites from the earthworm are left upon cabbage, celery, lettuce, etc., by the earthworm when feeding upon them. They pass out through the orifices in their skin, and find their way into the leaves through the stomata. These parasites are shown in a cabbage leaf in one of the illustrations. Recent experiments by Dr. Peyton Rons on experimental sarcomatous tumors of a fowl have appeared in which, after the tumors were ground up with sand and centrifugalized, and then the supernatant fluid again centrifugalized and the upper part of the fluid injected, tumors were produced. When the liquid was passed through a coarse filter, Berkfeld No. 2, tumors were also produced, but none when it was passed through Berkfeld No. 5 medium. These filtrates were said by Rons to be cell-free.

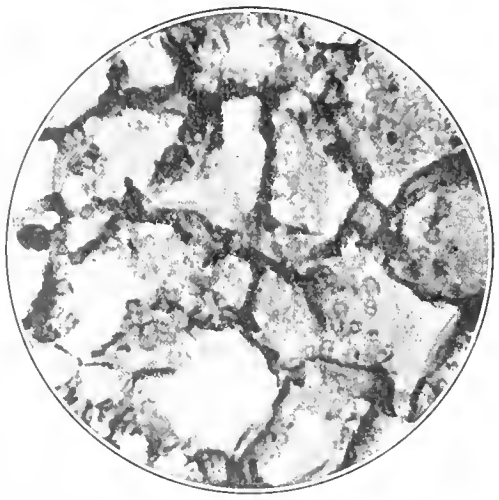

FIG. 3.—Cabbage leaf infected by *A. fœtida* fifty days. Sections from leaf stained with polychrome methylene blue and photograph taken showing parasites. X500.

In order to see if the cancer organisms from the earthworm would respond to any tests similar to the above I cut up an earthworm, *Allolobophora fœtida*, in a little water and placed the whole on firm filter paper in a funnel and on examining the filtrate under the microscope found an abundance of the cancer organisms in the ameboid form. Many of these were very small and on the surface of the filtrate. These organisms were exactly like those found in the blood of my experimental animals and in man and show that they correspond in this manner with the action of the organisms with what is acknowledged to be malignant tumors in animals. Now the ameba-like form I have described seems to have the faculty of passing through good filter paper, I presume on account of its not being a solid body its ameba form being of a liquid nature. I would again urge the cancer laboratories to repeat my experiments on animals as detailed in my pamphlet.

CERVICAL ADENITIS IN CHILDREN.

BY ROYALE HAMILTON FOWLER, M.D.,

BROOKLYN, NEW YORK.

CERVICAL adenitis in children is a common disease and is especially prevalent among the children of the poorer classes who live amid unhygienic surroundings. Pathological investigation of a form of adenopathy has revealed the fact that many of these hyperplasias are due to the tubercle bacillus. A large proportion of school children between the ages of four and ten years present cervical enlargement of the cervical lymphatic glands. It follows almost all the exanthems of childhood and may be due to a variety of lesions other than that due to tuberculosis. Lesions of the scalp (eczema and pediculosis), of the throat (tonsillitis), nasopharynx (adenoids), and of the teeth and the ear (otitis), are responsible for a large number of cases. It is frequently impossible, however, to trace the source of the infection. The difficulty of early clinical diagnosis is at once apparent in cases of glandular tuberculosis when we realize that the pathologist must frequently examine section after section under the microscope before he can satisfactorily determine the cause of the hyperplasia. Of the tuberculin tests the writer has found the von

Pirquet to be most delicate and reliable in children. There is no early diagnostic criterion for tuberculous adenitis. In the case of chronic adenitis without demonstrable cause tuberculosis should be suspected and appropriate treatment advised.

There are six important groups of glands in the neck: (1) Afferent vessels of the suboccipital group drain the occipital region. (2) The mastoid group drains the temporal region and the ear. (3) The parotid group drains the anterior scalp, the ear, the root of the nose, the nasal fossa and the pharynx. (4) The submaxillary group drains the upper and lower lips, the cheek, the nose, the side of the tongue, and the gums. (5) The submental group drains the lower lip, the tip of the tongue and the floor of the mouth. (6) The retropharyngeal group drains the nasopharynx. Each of these groups sends efferent vessels to the deep descending chain. The deep descending chain from the surgical standpoint may be considered as one group. These glands lie anterior and posterior to the internal jugular vein. In the upper part of the neck they lie almost entirely beneath the sternomastoid muscle, in the lower part at the posterior border of that muscle. This chain extends from the mastoid process to the junction of the internal jugular and subclavian veins. The deep chain also receives drainage directly from the scalp, tongue, palate, esophagus and thyroid gland. Efferent vessels from the deep chain form the jugular trunks. The right passes into the internal jugular vein or into the subclavian; the left into the thoracic duct. There is no direct connection between the cervical lymphatics and the lymphatic system of the thorax. Direct extension is therefore impossible. Infection affecting the cervical lymphatics is entirely local until it passes into the general circulation.

The tonsil is the most frequently accepted site of entrance of the tubercle bacillus. Tuberculosis of the tonsil, however, is rarely demonstrated to be associated with tuberculosis lesions of the cervical lymphatics. In a study of 1000 cases of tuberculous cervical adenitis, tuberculosis of the tonsil has been demonstrated in less than 2½ per cent. There is experimental evidence to show that cultures of the tubercle bacillus which have been swabbed over the tonsil leave no trace of the infection at the sight of innoculation, but invade the lymphatic glands of the neck which drain the tonsil. In a series of twenty-one experiments the cheesy material expressed from tonsils was injected into guinea pigs. Fourteen pigs developed tuberculosis.

As regards tuberculous adenitis in children there are certain well defined differences which occur. The disease is rare in children under two years of age. Dowd has collected 465 cases operated upon by himself and his associates at Roosevelt and St. Mary's Hospitals, of which about three and one-third per cent occurred in children under two years of age. This is in accord with Fischer's tabulation of 1484 cases reported by nineteen different observers in which he shows that three and nine-tenths per cent occurred in children under five years of age. When it does occur less resistance is shown toward the infection than in older children. Involvement is often extensive and the disease bilateral in about one-third of the cases. Incomplete operations are usually performed, which leave sinuses and ulcers which predispose to secondary infection. Complications frequently result. Bronchitis and bronchopneumonia are common and are often believed to be of tuberculous origin. Enlarged tonsils, retropharyngeal abscess and adenoids are not infrequently observed. Lupus, tuberculous meningitis and generalized tuberculosis have been frequently noted. This class presents a clinical picture which is fairly regular in its course. The upper nodes break down and discharge their caseous material through the ruptured capsule before the lower are extensively invaded. These children are brought for treatment on account of a lump in the neck. Forty-six per cent of Fischer's and eighty per cent of Dowd's have come to the surgeon between the ages of two and seventeen. The swelling is usually a cold abscess which points either in front or behind the sternomastoid muscle. The disease is more strictly localized in children and tends toward spontaneous limitation.

In regard to the treatment of non-tuberculous adenitis efforts should be made to cure or ameliorate the foci of infection which represent the causative lesions in the process. If the source cannot be demonstrated the case should be treated as one of tuberculosis. A large proportion of children will recover if placed in a suitable environment under medical care. This treatment should afford a maximum amount of sunshine and fresh air, a sufficient supply of good food. Of the tonics, the syrup of the iodide of iron and cod liver oil are the best. In suitable cases tuberculin is indicated. If the glands have broken down one can expect good results from this method of treatment. Three months of the treatment above outlined should prove the merits or demerits of medical attention. If in the course of this treatment the glands break down the abscess should be opened and drained. Care should be exercised in making the incision to avoid important structures. Dangers are hemorrhage and paralysis of muscles supplied by the spinal accessory and seventh nerves. Poulticing to encourage suppuration is to be condemned, the ice bag relieves pain and tends to discourage suppuration. The surgical treatment of choice for markedly enlarged glands occurring in children over five years of age in the absence of suppuration, which resist medical treatment for three months, is excision with removal of the gland bearing fascia. Breaking down of the glands to the extent of caseation is not necessarily a contraindication to excision. The radical operation in very young children is one which should be approached with caution, reverence and respect. It is not possible to remove all the glands in the neck nor is it necessary. Removal of those which are grossly diseased will place the patient in a condition to better combat the slight infection which may remain or which has not been attacked surgically upon the opposite side of the neck. The radical operation should be preceded by the removal of the tonsils and adenoids when these structures are enlarged. This diminishes the risk of adenectomy and removes the atrium of infection. The institution of general hygienic measures is as important after the operation as before this procedure. In selected cases tuberculin may be employed in the after care with good results.

Washington Court,
475 Washington Avenue.

Diuretic Action of Infusion of Convallaria.—G. Mouriguand and G. Dujal call attention to the marked superiority as a cardiac stimulant of the infusion of convallaria flowers over the watery extract which is generally employed. On account of the rapidity of the diuretic action of convallaria one may properly combine the administration of this drug with that of digitalis, whose action is slower but less ephemeral.—*Le Progrés Médical.*

ARTIFICIAL VAGINA BY INTESTINAL TRANSPLANTATION.

By J. F. BALDWIN, A.M., M.D.,

COLUMBUS, OHIO.

SURGEON TO GRANT HOSPITAL.

THE operation which I devised nearly ten years ago (*Annals of Surgery*, September, 1904) for the plastic formation of a vagina by transplanting a piece of intestine, has now been performed by a considerable number of surgeons scattered throughout the world. Though I have not kept an accurate account of the reports, I feel safe in saying that at least twenty-five or thirty of these operations have been made, and thus far, according to the reports, without mortality or serious morbidity, but with most satisfactory functional results. In my own work I have made six of these operations, but the last case was in some of its features so unusual as to merit publication.

Mrs. H., aged 27; referred to me by Dr. George W. Crile of Cleveland. Patient had been married twice. She lived with her first husband at intervals for four years, then after three years obtained a divorce and had remarried about two months before I saw her. This husband had left her after one month. At the age of 16 years she had been operated upon by Dr. Crile, who removed her ovaries for the relief of certain symptoms connected with the menstrual molimen. Later she was operated upon by a Toledo surgeon twice for the purpose of making an artificial vagina. At the first operation, as nearly as she could tell me, he had evidently separated the connective tissue between the bladder and the rectum and had trusted to packing to secure the canal. This operation failed and he had later reopened and then tried to pass in some strips of skin for lining. This operation was also a complete failure, and when she was referred to me there was no trace of a vagina whatever, but a few scars could be made out which were the remains doubtless of the attempts at flap formation.

Personal examination showed an unusually plump young woman, apparently in perfect health. The external genitals were normal, breasts well developed. A very satisfactory scar in the median line, but no trace of a vagina.

I operated September 6 in the presence of a number of visiting physicians. As the first step in the operation an opening was made after the usual manner between the bladder and rectum, this being made through a transverse incision in the perineum. The operation for the first two inches was exceedingly difficult, as the dissection had to be made in scar tissue. Above this point healthy tissue was reached, and further dissection was entirely simple. The peritoneum having been reached a large clamp was placed in the vagina and held there by packing in gauze around it.. The patient was then placed in the Trendelenburg position and the abdomen was opened through the old scar. I then encountered what I had not at all anticipated, namely, a pelvis filled with small bowel held by the firmest possible adhesions. Whether these adhesions had resulted from post-operative inflammation after her former operation, or had been the result of appendicitis, could not be determined. The appendix was present, embedded in very firm adhesions and badly diseased, though not presenting any recent infection. With the utmost difficulty the loops of bowels were separated, using gauze sponges and scissors. In this way the bowel was finally released and the appendix removed. A piece of the small bowel about fourteen inches long, a little above the lower end of the ileum, was brought up, cut across, and the ends inverted with purse-string suture. Care had been taken not to interfere with the mesentery of this piece of bowel. The continuity of the rest of the bowel was re-established by closing the ends with purse-string suture, and making a lateral anastomosis. An assistant then pushed the vaginal clamp upward, so that the peritoneum was readily incised as the jaws of the clamp were opened. The center of the detached loop of bowel was then caught with the clamp, and the bowel drawn down into the vaginal canal, leaving the two ends flush with the floor of the pelvis. The toilet of the pelvis was completed by bringing the peritoneum nicely together. The bowel had been drawn into place without undue tension on its mesentery. The abdomen was closed in layers as usual. The patient was then placed in the lithotomy position, as at first, the portion of the bowel which had been held by the clamp was opened and each side wiped out and then packed with iodoform gauze, so as to completely fill the vaginal space. The opening in the bowel was then attached by chromicised catgut to the margins of the perineal opening, which thus became the vulvar outlet. A little wisp of gauze had been introduced posteriorly to take care of any oozing which might take place from the vaginal space.

The patient made a very smooth convalescence. The gauze which had been packed in the two loops of bowel was withdrawn after a few days and replaced from time to time as necessary, and everything cared for as after an ordinary perineorrhaphy. After the lapse of three weeks a clamp was placed upon the septum between the two loops, and this was cut through by crushing, thus leaving but a single vaginal opening. The patient returned to her home in four weeks. Under date of October 8, 1912, Dr. Crile sent me the following communication: "I have just examined your patient and write to congratulate you on the beautiful work you have done. I really would have hardly believed that that particular plastic work could be so thoroughly accomplished."

While the operation outlined above was in this particular instance, owing to the thick abdominal walls, the scar tissue in the perineum, and the pelvic adhesions, unusually difficult, the procedure, when made under what might be called normal conditions, is one that is not difficult in the hands of surgeons accustomed to intestinal work. It is evident, however, that it is an operation, as I have always insisted, that should not be made by a tyro. I can hardly conceive, however, of a case in which the operation would be more difficult than in this instance. I know of no other method by which anything like as satisfactory a substitute can be secured in cases in which, from congenital defect or sloughing (as in my first case), there is entire absence of the vaginal canal.

Pneumococcus Peritonitis.—Lenormant and Pison report a case of primary pneumococcus septicemia, in which peritonitis was only an episode. The majority of cases of pneumococcus peritonitis are clinically primary, and most of those that are secondary result from a primary pleuropulmonary focus, the infection traveling directly through the diaphragm. There are, however, cases in which the peritonitis is an incident in a general pneumococcus septicemia.—*Le Progrès Medical.*

New York, December 28, 1912.

THE LIFE CYCLE OF THE TREPONEMA PALLIDUM?

THE recent triumphs of chemotherapy were in part the result of an intensive study of the pathogenic protozoa, and at the same time served to stimulate the investigation of this remarkable group of microorganisms. The success attained by Noguchi in cultivating the *Treponema pallidum* in a pure state, was shortly afterward followed by the announcement that Bass of New Orleans had accomplished the same result with the malarial plasmodium. A new era of discovery is dawning. Science is not content with the mere recognition of the morbid agent and of its association with the disease process, but would ferret out the offending germ in every stage of its development. Possibly the life history of the *Treponema pallidum*, the most notorious of the fell parasites of the human race, is now about to stand revealed.

A preliminary announcement of an observation of the life cycle of the organism of syphilis was made by J. E. R. McDonagh in the *Lancet*, October 12, 1912. In a paper read before the Pathological Society of London, December 3, 1912, the same observer described what he regarded as the complete life history of the *Treponema pallidum*. This he believed was a sporozoite, which developed in connective tissue cells, into immature male, female, and asexual bodies. The male gametocyte, after leaving a connective tissue cell, entered a large mononuclear lymphocyte, where it developed into three pear-shaped bodies, which then became transformed into a coil from which treponemata evolved. The female gametocyte remained extracellular and was a clear body containing a chromatic network at its upper pole, and one or two blepharoplasts at its lower pole. These disappeared when the cell reached the size of a red blood corpuscle. In the process of fertilization the female extruded two polar bodies, and was entered by one treponema which fused with the chromatin network of the female cell. This network became deeply stained, and the cell constituted a zygote. The deeply stained masses divided into sporoblasts which developed into a big spore-cyst or escaped with the formation of small spore-cysts. Upon the bursting of the spore-cysts the sporozoites were liberated. Female cells could also divide by parthenogenesis. The asexual body by a process of subdivision developed into a spore-cyst in the connective cell, and became extracellular only when the host-cell had degenerated.

The above observations of McDonagh are in part confirmed by E. H. Ross, who pursued his investigations along independent lines, and whose results are published in the *British Medical Journal*, December 14, 1912, under the caption, "An Intracellular Parasite Developing into Spirochetes." These and similar studies were rendered possible by the use of a new method of preparing the specimens obtained from syphilitic lesions. This, known as the "jelly method," was devised by H. C. Ross, and consists in the use of a solution of agar, with the addition of appropriate amounts of polychrome methylene blue, sodium citrate, sodium chloride, sodium bicarbonate, and atropine sulphate. The specimen to be examined is spread upon the surface of a drop of the jelly placed upon a slide. A drop of blood obtained from a chancre, and spread between the cover-glass and the jelly in a thin film, reveals under the microscope the characteristic parasites. These appear as copper-colored bodies, either free or included within the larger mononuclear cells. They resemble the peculiar cell inclusions known as Kurloff's bodies which are found in the mononuclear leucocytes of the blood of guinea-pigs. These cell inclusions have been proved to be parasites and have been given the name *Lymphocytozoon cobayæ*. By means of the jelly method it has been shown that the chromatin within the inclusion becomes formed into spirochete-like bodies, which upon the bursting of the inclusion swim freely in the blood. These parasites have been found in gumma-like tumors in the liver and spleen of the guinea-pig. Similar cell inclusions have been found in the fixed mononuclear cells of the seminal vesicles of earthworms.

The intracellular and extracellular parasites have been found by Ross in the various lesions in 143 cases of primary and secondary syphilis. The intracellular forms are found, multiple or single, embedded within the cytoplasm of the large mononuclear cells, and contain from one to as many as twelve chromatin masses. These are either round or pear-shaped and resemble the extracellular forms; indeed they are supposed to be the precursors of the latter. In some instances, the chromatin masses give rise to curled and twisted spirochete-like tails which are extruded upon the bursting of the inclusions.

Ross points out the homologies that have been observed between the parasites of human syphilis and the intracellular parasites of guinea-pigs and earthworms, and suggests that the spirochetes are really microgametes or male elements and that the round or pear-shaped bodies are macrogametes or female elements. He also advances the working hypothesis that the guinea-pig or rabbit parasites might produce in man a mild infection which would modify syphilis in the same manner as vaccination has modified smallpox.

In the same number of the *British Medical Journal* E. Jennings and S. R. Moolgavkar, working independently, report their observations in con-

firmation of those recorded by Ross. Jennings notes that the central part of the inclusions of the epithelial cells of chancres contains a bunch of treponemata which radiate from a central stained mass like the spokes of a wheel. This observer alludes to the simplicity of the jelly method, and advocates the examination for the so-called parasites as a routine means of diagnosis in syphilis. The parasites are found in the peripheral blood, but here they are not as abundant as in the various lesions of syphilis.

The investigations conducted by Noguchi, McDonagh, Ross, and others have resulted in substantial contributions to the knowledge of the pathogenic agent of syphilis. This knowledge is, however, as yet far from complete. The observations regarding the supposed life cycle of this organism must at any rate receive confirmation from trained protozoologists before they can be fully accepted by the scientific world.

THE QUESTION OF VENTILATION.

It is both curious and decidedly disturbing to the amour propre of the scientific man that many questions which were thought to be definitely settled have been brought once more into the arena of discussion. Up to a recent period authorities on ventilation seemed to be practically agreed that impure air was a potent factor in the causation of those ill effects which followed a prolonged stay in crowded rooms or buildings. An ill-ventilated room, for example, was regarded as a room in which the air was chemically impure, that is expired air which contained too much carbon dioxide and was deficient in oxygen. The theory was that in a crowded room the people therein consumed the oxygen and expired air containing carbon dioxide until in the course of time the atmosphere became surcharged with the latter and therefore chemically impure and hurtful to health. It is true that in a crowded room the air does become to some extent chemically impure, but the contention is now made that this has little or no injurious effect upon the health.

Mr. Leonard E. Hill of London has been the most prominent exponent of these somewhat iconoclastic views on ventilation, and it may be said that behind him he has the opinions formed as the result of the experiments of Flügge and others in Germany, of Haldane in England, and of a considerable number of investigators in this country. At the meeting of the British Association in 1911 Hill read a paper in which he propounded his views, or rather the views of this most modern school. In this paper he insisted that the dangers of ill-ventilated places arise from two causes, namely, (1) Infection by pathogenic bacteria, the mass influence of which is enormously increased in confined crowded places; (2) temperature, relative moisture, uniformity, and stillness—qualities of the air which profoundly influence the metabolism and health, and the immunity of the body, that is, the power of the body to resist the invasion of pathogenic bacteria. Hill maintains that so far as carbon dioxide and oxygen are concerned the chemical impurity of the air is a negligible quantity, even when there is a considerable variation in the percentage of these gases. According to physiological evidence, excess of carbon dioxide in the atmosphere cannot enter the body because the respiration is automatically regulated so as to keep the concentration of carbon dioxide in the lungs constant. The most ill-ventilated room never shows an analysis as much as 1 per cent. carbon dioxide, while in famous mountain health resorts there is a far greater deficiency of oxygen than ever occurs in the most ill-ventilated room.

Hill's conclusions are that the question of ventilation is primarily one of keeping the temperature, relative moisture, and movement of the air in a proper state so that the heat-regulating mechanism of the body works without strain, and the nervous system is stimulated by pleasant cutaneous conditions, and the circulation, respiration, and metabolism of the body are invigorated.

Dr. Simon Baruch, in a letter to the Medical Record, November 16, 1912, after referring to the views on the subject of Brannan, Yandell, Henderson, Hill, and Flügge with apparent approbation, goes on to point out that the condition of the skin exerts a potent influence upon the lungs, which may be in part a vasomotor reflex acting upon the pulmonary circulation.

Baruch concludes that the evidence available, although still far from complete, suggests that these pulmonary activities are indirectly, but powerfully, influenced through conditions affecting the skin, and that it is in this manner that ventilation influences both. As yet, however, all authorities do not agree with Hill and others that from the standpoint of health, chemical impurity of air counts for little or nothing, but argue that a vitiated air must contain certain substances which are harmful, even though not demonstrated by science. Naturally the point is of the first importance, for if Flügge and Hill are right the methods of ventilation employed during some years and now mainly in use are for the most part wrong. In fact, the most elaborate methods of ventilation have generally failed, and many if not most physicians of the present day advocate a return to the old-fashioned way of ventilating by means of the open window as the only effective one.

Chronic Infectious Polyarthritis.

This disease, commonly known as Still's disease, was described by Dr. G. F. Still of London in 1897. It is a rare disease and its etiology is obscure. In the *American Practitioner* for November Joseph Collins gives an account of an apparently typical case of this malady. By some writers the rôle played by the nervous system in its causation has been accorded an important place, but Collins thinks that this view is wholly unjustified. The most striking features of the case which he described were: (1) The stunted growth of the child's body; his entire length as he lay in bed seemed to be about 32 inches. (2) The fusiform enlargement of the joints, which appeared more enlarged and deformed than they really were because of the contrast with the profound wasting of the muscles. (3) The enormous enlargement of the liver and spleen. (4) The extreme dryness of the skin and diffuse alopecia. (5) The generalized adenoplasia. (6) The striking changes in the blood—marked

leucocytosis, eosinophilia, and evidence of conspicuous degeneration in the red cells. (7) The evidence in the urine of an amyloid degeneration of the kidneys. A consideration of the above condition leads Collins to the opinion that the case was one of some generalized form of infection. Such adenoplasia and such amyloid degeneration occur usually as the result of chronic infection, for instance, protracted tuberculosis. All features of the condition point to some long continued poisonous process, such as a low-grade septic infection. The acute stage of Still's disease as regards the joints resembles gonorrheal arthritis. Finally the unquestionable recoveries that have been recorded have fully convinced Collins that it is an infectious process, but whether specific or not yet remains to be determined.

Recent Views of Diphtheria Therapy.

A paper, read by Eckert on the present status of diphtheria therapy, an abstract of which has appeared in the Medical Record, called forth at the time an interesting discussion (*Deutsche medizinische Wochenschrift*, November 21). W. Braun, who sees numerous patients in the Frederickshain Hospital, many of whom are desperately ill when admitted, announced that increasing the dose of antitoxin beyond a certain point does not further lower the mortality, which, during the recent epidemic, was about 18 per cent. On the other hand, the results of immunization of those who had been or were to be exposed were brilliant. Of nearly 500 so immunized, but 5 developed the disease, and that in a very mild form. Of the small number in which immunization was refused 14 developed the disease with 3 deaths. Jochmann related his experience at the Rudolf Virchow Hospital, where he has treated 600 cases during the past year. Large doses of antitoxin he believes to exert a favorable influence over the toxic complications and sequelæ. He warmly recommends follow-up injections to prevent and cure postdiphtheritic paralyses. While some anaphylaxis is to be expected, he saw no serious results from the same. Curiously the only case in which severe shock was present occurred after a first injection. The source of the sensitization is not stated. He is certain that serum has no power over postdiphtheritic heart failure, nor are any drugs able to raise permanently the low blood tension.

News of the Week.

New Medical Society.—The American Society of Medical Economics was incorporated recently at Albany, N. Y., its aims being in brief as follows: To study all matters of medical economics. To maintain a high standard of medical education and of professional conduct. To consider and perform the duty of the profession to the public in making use of all proper means to expose all forms of quackery. To aid the constituted authorities in the enforcement of all medical laws. To secure legislation for the suspension or revocation of the license to practise medicine for causes such as insanity or professional misconduct. To cooperate with other societies with the object of establishing certified pharmacies where prescriptions may be filled with pure and standard drugs as ordered. To oppose all acts tending to encroach upon the practice of medicine, such as legislative enactments establishing pseudo-specialists in medicine, and the extension of the work of the Board of Health along the line of clinics and curative medicine. To organize and carry on a campaign against the abuse of medical charity. To aid all licensed physicians requiring postgraduate instruction to obtain it in the charity hospitals and dispensaries of the State. Dr. E. Eliot Harris of New York, chairman of the committee on legislation of the County Medical Society, has been elected president of the new society, and its five vice-presidents are Dr. Algernon T. Bristow, Dr. W. F. Campbell, Dr. Smith Ely Jelliffe, Dr. T. K. Tuthill, and Dr. T. F. Rally. The secretary is Dr. S. Dana Hubbard and the treasurer, Dr. Royal S. Copeland. The society will establish branches throughout the United States and in other American countries, and a board of seventeen directors has been named to advance the work in hand.

The Medical Profession and Lloyd George.—The British Medical Association on Saturday last refused to accept the modified terms offered by Lloyd George for medical attendance under the Insurance Act. The meeting of the delegates lasted all day and the final determination to reject the terms of the Chancellor was carried by a vote of 150 to 21. This action has raised a storm of abuse of the medical profession by the liberal papers, and the Government threatens to establish a state medical service.

The Children's Bureau.—An investigation into the causes of infant mortality will be the first subject to be taken up by the recently created Children's Bureau of the Department of Commerce and Labor, and will be begun by the first of the year. It will include a house-to-house inquiry as to the conditions surrounding the child, and will be based upon birth rather than death records. The Children's Bureau aims to reduce infant mortality in the United States by one-half.

Immunization against Typhoid.—Believing that immunization against typhoid fever has now passed beyond the experimental stage and become established as a prophylactic measure of proved efficiency, the Department of Health of New York City will be prepared after January 1, 1913, to make without charge preventive inoculations, under conditions similar to those governing the free administration of diphtheria antitoxin. On the request of the attending physician inoculations will be made at the homes of the applicants, or at the central office, or cultures will be furnished free to physicians for their own use. On the occurrence of a case of typhoid fever, free immunization will be offered to every member of the family of the patient and to those who have been in contact with him, and it is hoped that widespread immunization will materially reduce the incidence of the disease in the city. Requests for inoculation may be made either by telephone or by letter to the Division of Communicable Diseases of the Department of Health.

Porto Rico Plague-Free.—The United States Public Health Service reports that Porto Rico may now be considered as entirely free from plague. The last case of the disease in man was reported in San Juan on September 12 and the last plague-infected rat was found at Arecibo on October 30.

Study of Alcohol and Narcotics.—The Forty-second annual meeting of the American Society for the Study of Alcohol and Other Narcotics was held in Washington on December 10 and 11, 1912. Dr. Lewis D. Mason of Brooklyn, president of the so-

ciety, in his opening address reviewed the results of the study of alcohol in its relation to medicine, and this was followed by a long and interesting series of papers covering almost all phases of the sociological, pathological, and psychological effects of indulgence in alcohol and narcotic drugs upon the animal organism. The annual address was delivered by Dr. Henry O. Marcy of Boston, who took for his subject: "Dr. Benjamin Rush, the pioneer investigator of the effects of alcohol and tobacco on man." This society, organized in 1870, was the first association in the world to take up from a scientific viewpoint the study of alcohol and the diseases which follow its use.

Birth Statistics.—Health Commissioner Lederle of New York City has recently called attention to lapses in reporting births in the city. He states that during the year just ending the returns of births made by physicians and midwives have run considerably below the figures of the previous year, this decrease being due, in all probability, to a failure to comply with the law requiring the filing of birth certificates within ten days after the event. During the year 1911 fines for this offense were imposed on 312 physicians and midwives. The law confers upon the Commissioner the power to excuse such neglect of duty, and he has decided this year to excuse all derelictions in this respect on condition that all returns of births not already reported be sent to the Assistant Registrar before January 1, 1913. He further declares his intention of prosecuting on and after January 1 every violation of the regulations covering the reporting of births, and he hopes to secure the cooperation of all physicians and midwives in obtaining full returns for these important statistics.

Diphtheria in Brooklyn.—Reports from the Borough of Brooklyn, New York, show a marked increase in the number of cases of diphtheria, 350 having been reported between December 1 and 20, with 30 deaths.

Opening for Medical Missionary.—The Good Samaritan Hospital of Guanajuato, Mexico, a missionary hospital supported by the Methodist Episcopal Church, desires to obtain a physician to serve as interne in the hospital for two years. Communications on the subject may be addressed to the director, Dr. Levi B. Salmans, Good Samaritan Hospital, Guanajuato, Mexico.

Venereal Diseases.—The Commissioner of Health of New York City has issued a circular letter to all the physicians in the city requesting a prompt report of all cases of venereal diseases coming under their observation. Since May 1, 1912, the superintendents of all public institutions have been required by law to report such cases and it is desired to obtain the same information with regard to private patients, the name of the patient, of course, being withheld by the physician. The Department of Health is also prepared to assist in the diagnosis of these diseases by making Wassermann tests and bacteriological examinations of discharges free of charge.

Infant Deaths.—During the week ending December 14 there were in New York City only 175 deaths of infants under one year of age, a decrease of 85 as compared with the number for the same week of last year. This is the lowest mortality record for any week of 1912.

New Preparatory Course.—For the convenience of high school students finishing their work in January of any year, who desire to enter the University and Bellevue Hospital Medical College, the New York University announces a special one-year collegiate course, which will begin on February 3 and continue until September 19. Students completing the course will be prepared to meet the entrance requirements of the medical school which now include one year of college work. Fuller details as to the course may be obtained from the secretary, University and Bellevue Hospital Medical College, New York.

Smallpox on Liner.—The steamship *Eugenia* which arrived in New York recently from Trieste, was detained at quarantine because of a case of smallpox which was found among the steerage passengers.

Poisonous Matches to Go.—On January 1 the new law governing the sale of matches in New York goes into effect, and the Diamond Match Company has announced that on that date it will be prepared to comply with the regulations, and that prior to July 1, when the Federal non-poisonous match law becomes operative, it will stop the making of poisonous matches in its factories. The new laws are intended to prevent the use of white phosphorus, which has proved so injurious to the workers in the factories, as well as dangerous to the users of the matches.

Cartwright Lectures.—Announcement is made of the acceptance by Prof. Ludwig Aschoff of the University of Freiberg, Germany, of an invitation to deliver the Cartwright Lectures of the Association of the Alumni of the College of Physicians and Surgeons at some time between March 15 and 20, 1913, the exact date and the subject of the lectures to be announced later.

Smallpox in Immigrant.—Suffering from a severe case of smallpox, a young Austrian woman who had arrived in America ten days before, was removed to the Isolation Hospital at Passaic, N. J., on December 21. The patient was a steerage passenger on the Hamburg-American line, and, it is said, had never been vaccinated.

Genito-Urinary Section of the Academy.—The following officers were elected at the December meeting of this Section of the New York Academy of Medicine: *Chairman*, Walter Brooks Brouner; *Secretary*, Joseph Francis McCarthy.

Personals.—President Taft has decided, it is said, to send to the Senate the name of Brig.-General George H. Torney for reappointment as Surgeon-General of the United States Army.

Surgeon W. Page McIntosh of the United States Marine Hospital Service, who has been in charge of the Marine Hospital at Baltimore for the last four years, has been ordered to Louisville to take control of the hospital there.

Surgeon B. S. Warren of the United States Public Health Service has been sent to West Virginia to investigate the prevalence of smallpox there. He has been instructed to recommend means of preventing the spread of the disease.

Plague in Russia.—An outbreak of bubonic plague has been reported at Popovka in Southern Russia. It is stated that there have been many deaths from the disease and the town has been quarantined.

Obituary Notes.—Dr. Paul Oscar Meyer of Long Island City, N. Y., a graduate of the University of Berlin, Germany, in 1882, and a member of the New York State and Queens County Medical Societies, died at his home on December 17, aged 56 years.

Dr. George Clinton Crandall of St. Louis, Mo., a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1890, a member of the American Medical Association, and of the Missouri State and St. Louis City Medical Societies, professor of medicine in the St. Louis University, School of Medicine, president of the consulting staff of the St. Louis City Hospital, and medical director of the St. Louis Society for the Prevention of Tuberculosis, died at his home of Bright's disease, on December 5, aged 47 years.

Dr. Asbury J. Russell of Oakland, Cal., a graduate of the University of Wooster, Medical Department, Cleveland, O., in 1868, died suddenly at Grass Valley, Cal., on November 26, aged 67 years.

Richard H. Townley, superintendent of the Lincoln Hospital, New York, and formerly a lieutenant in the United States Navy, was accidentally killed while cleaning a gun in his rooms at the hospital on December 9.

Dr. Grenville A. Emory of Middleton, N. Y., a graduate of the Albany Medical College in 1867, died at his home on December 12, aged 74 years.

Dr. Eli Peck Miller of New York, a graduate of the Bellevue Hospital Medical College, New York, in 1864, died at his home of pneumonia on December 19, aged 84 years.

Dr. William Wallace Holliday of Cleveland, O., a graduate of the Western Reserve University, Medical Department, Cleveland, in 1876, a member of the American Medical Association and the Ohio State and Cuyahoga County Medical Societies, and president of the Western Reserve Medical School Alumni Association, died in the Lakeside Hospital, Cleveland, on December 7, aged 61 years.

Dr. James Alico Comstock of Greenfield, Ind., a graduate of the Medical College of Ohio, Cincinnati, in 1867, a veteran of the Civil War, and a member of the Hancock County Board of Pension Examiners, died in the Deaconess Hospital, Indianapolis, on December 8, aged 68 years.

Dr. Edward L. Casey of North Woodstock, N. H., a graduate of the University of Maryland, School of Medicine, Baltimore, in 1905, died in the Laconia Hospital from pneumonia, after a short illness, on December 9, aged 30 years.

Dr. David Alexander Kittle of Kansas City, Mo., a graduate of the Jefferson Medical College, Philadelphia, in 1838, and a holder of degrees also from the Rush Medical College, Chicago, 1846, the Medical Department of Washington University, St. Louis, 1853, and the Keokuk Medical College, Iowa, 1864, died at his home on December 1, aged 92 years.

Dr. Peter O. Bleiler of Allentown, Pa., a graduate of the Jefferson Medical College, Philadelphia, in 1876, and a member of the American Medical Association and the Pennsylvania State and Lehigh County Medical Societies, died at his home from arteriosclerosis, on December 10, aged 60 years.

Dr. William Samuel Love of Winchester, Va., a graduate of the University of Pennsylvania, Department of Medicine, in 1861, died at his home on December 12, after a short illness, aged 76 years.

Dr. William Hand Browne emeritus professor of English Literature at Johns Hopkins University, Baltimore, who died in that city on December 13, at the age of 34 years, was a graduate of the University of Maryland, School of Medicine, in 1850, although he had never entered upon the practice of medicine.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

INSURANCE STATEMENTS—EFFECT ON HOSPITALS—MEDICAL COUNCIL'S SESSION—PRIESTLEY LECTURE BY PROF. METCHNIKOFF—HISTORY OF MEDICINE SECTION INAUGURATED—OBITUARY.

London, December 6, 1912.

Last evening the Insurance Commissioners issued an account of the negotiations between the medical deputation and Mr. Lloyd George and added the steps to be taken to bring the Act into operation on January 15. They also issued the new regulations. The chief concessions made are representation on insurance committees increased to one-tenth, court of inquiry to consist of two medical men and one lawyer instead of the committee of complaints, some extra payment in mountainous districts, x-rays and bacteriology not to be expected in ordinary diagnosis nor major surgical proceedings in treatment. The British Medical Association also last night issued its statement. They have invited all members of the profession to decide whether to administer the medical part of the Act, have "not advised as to the nature of the answer to be given." A special representative meeting of the association has been called for December 21 in London.

A third document issued last night is from a number of practitioners who have decided to work under the Act, calling a meeting for December 13, to formally establish the "National Insurance Practitioners' Association," to promote and safeguard the interests of those who may accept service under the Act. They profess to see it to be their duty to themselves and the public to do so.

The practitioners at Henley have combined to form a public medical service and all private clubs will cease to exist there on the 15th prox., when wage-earners and their families whose income does not exceed £2 per week can enter the new combination and so secure attendance and medicine.

The effect of the Act on our hospitals is exciting grave apprehensions. At a meeting of the governors of the London Hospital on Wednesday, the House Committee reported that the cost of insuring the hospital employees would be about £850 a year. Worse still, a number of subscribers were withdrawing their support on account of the Insurance Act, and as the hospital's income is chiefly from voluntary contributions, the outlook is becoming serious. They would have to spend about £25,000 a year on patients who were insured under the Act. Surely, that is a good reason why they should be reimbursed to a considerable extent from the funds extracted from these people as insurance. Other hospitals will doubtless have to suffer in the same way, and the danger threatens to be a grave injury to the public.

The winter session of the General Medical Council has been held. It was opened on Tuesday, November 26, with an address by the president, Sir Donald MacAlister, who expressed regret at the death of Mr. Norton and referred to other changes in the personnel of the Council. He reported that, as they desired, he had communicated with the government the importance of their control of qualification and registration in Ireland being secured in case Home Rule should be carried. The government's reply was a request for a statement of the grounds on which this request was made. He ac-

cordingly furnished a memorandum which there was reason to suppose had been considered by the Cabinet, though he had not so far received any communication from the Lord President. Notices by private members proposing amendments had appeared on the order papers of the House, but under the present mode of procedure could not be considered. A hope was expressed that later an opportunity may be found, but it is difficult to see any justification of such a hope.

The Insurance Act could not be forgotten and the committee on this had reiterated the opinion of the Council that in the absence of provisions for institutional treatment of the insured, the existing facilities for the study of clinical medicine, surgery, and midwifery might be seriously endangered to the great injury of the public. The question is still being considered by the commissioners. A bill in the House of Lords suggested by the Council makes some alterations in the election of direct representatives. It is a small affair and might well have taken a wider sweep. The Council stands in need of no little reform, and if the Lord President could be induced to introduce a bill at all, surely he could have been persuaded to propose something more than a plan to reduce the expense of elections. It is clear the Council is as indifferent to its position as heretofore. Reports of several committees were received and ordered to be entered on the minutes. Much time was occupied by disciplinary proceedings. Several names were directed to be expunged from the register. Of these one was of a practitioner who was said to have died some time ago, but another person has been acting in his name. It is an unprecedented case in the history of the Council, and now it remains for the criminal authorities to take up the charge of personation.

We have had Prof. Metchnikoff in London last week, and on Friday afternoon he delivered the Priestley memorial lecture of the National Health Society, the R. S. M. lending its theater for the occasion. This lectureship was founded two years ago in memory of Lady Priestley, who was an original member of the National Health Society when it was founded some thirty years ago. The chairman, Sir J. Crichton-Browne, presided, and in introducing the lecturer conveyed to him an expression of regret from Princess Christian, president of the society, at being unable to be present, also of the French Ambassador, who wrote to say a previous engagement had unfortunately prevented him from attending. The chairman went on to say Pasteur's mantle had fallen on Prof. Metchnikoff, whose theory of immunity had revolutionized medical science and whose discovery of the function of the white corpuscles had modified treatment. He had taught them to help the beneficent organisms in their defense against invading microbes, showing them, so to say, "how in case of need to set a thief to catch a thief."

Prof. Metchnikoff, speaking in French, said tuberculosis was formerly looked upon as a disease of nutrition, though in some countries it was long held to be contagious. Villemin fifty years ago proved it could be inoculated into animals. Thirty years ago Robert Koch discovered the bacillus. Several species are distinguished, one in cold-blooded animals, another in birds, and another in mammals. The species peculiar to man was the chief cause of human tuberculosis, but precaution was necessary against infection by the bovine form. Cases of recovery had long been recognized in dissecting rooms and recent evidence of healed and past tuberculosis had accumulated so as to point to its being almost universal among the adults of town populations dying from other diseases; von Pirquet's test giving 90 per cent. as having been infected, though only 15 per cent. died of it, one-seventh of all deaths, so 85 per cent. had recovered and many of these never knew they had suffered from tubercle. Various methods of treatment were mentioned and Metchnikoff admitted that some of them had been useful, but no real remedy had been found. Unconscious inoculation by mild strains had led to immunity, and the present diminution of the death rate from tubercle in London and some other cities was probably due to this. The fall in the death rate in twelve years had been from 24 to 13 per 10,000 of the population per year. Such natural infection was a factor of great importance in the fight against any kind of infections disease. The disappearance of leprosy was probably so brought about. There are numerous opportunities for such immunizing strains of tubercle bacillus to gain access to human beings. What cause or causes had brought about the comparative mildness of these immunizing races on strains "had yet to be discovered, and the most active study of these strains and the precise conditions under which they occurred was needed to find out how they might be utilized for ensuring the protection of humanity instead of their beneficent invasions being left to chance. In that direction was their last hope, and the progress made up to the present in the war against tubercle justified the hope that in the not too distant future the *homo sapiens* would triumph over the *Bacillus tuberculosis*."

A vote of thanks proposed by Sir E. Ray Lankester and seconded by Sir James Goodhart was awarded to Prof. Metchnikoff by acclamation.

The new section of the R. S. M. has made an excellent beginning and vindicated the right of the "History of Medicine" to such a position. Sir F. Champreys, as president of the society, at a meeting on November 20, declared the section duly constituted. The officers of the section were then elected, Sir William Osler being president, and he, after some remarks on the objects to be kept in view, read a most interesting paper on "A Down Survey Manuscript of William Pett," who was born in 1623 and died 1687. He was for a short time professor of anatomy at Oxford University and vice-principal of Brasenose College, and if his other work overshadowed his professional he should be remembered for his share in the first "Bills of Mortality" of London (1661), the first work in English of the kind, and his "Observations on the Dublin Bills of Mortality" (1683). As a political economist he achieved a great reputation, and as Sir W. Osler said "his praise is in the schools." The Cambridge University Press reprinted his economic works in 1899, and Lord Edward Fitzmaurice issued his "Life" in 1895. In 1649 Petty had been named deputy to the Regius Professor of Medicine at Oxford and in 1651 succeeded to the chair of Anatomy. He became an active member of the society or club out of which originated the Royal Society. In 1692 he was appointed Physician General to the Forces in Ireland and immediately began to reorganize the medical service. He was an energetic man of great resources; energy he called the great requisite of life. The claims to the Irish lands could not be arranged—there was no survey and it was said none could be completed

for thirteen years. Petty said he would do it in thirteen months if he had a free hand. He agreed to "survey and measure and to map." He seems to have had a genius of organization and his work reads more like the Twentieth than the Seventeenth century. He completed his survey, which was known as the down survey as it was set down on the map. The manuscript shown by Sir W. Osler contains a copy of the contract he made to do it in Petty's own hand, dated Dublin, May 18, 1655.

Lieut. Col. Edward Alfred Birch, late of the Indian Medical Service, died on November 27. He qualified in Ireland in 1861 and soon after entered the navy, in which he served five years, having served at Kagosima and Simonoski, and was mentioned in dispatches. He took the F.R.C.S.I. in 1866; I.B.C.P., 1865; D.P.H., Cambridge, 1878; M.D., Brussels, 1879; was elected F.R.C.P. Lond. in 1892. He became Fellow and later Examiner in Medicine of the Calcutta University, Professor of Medicine and Principal of the Medical College and Physician to the College Hospital. He wrote "The Effects of Warm Climates on the Functions and Secretions"; "Epidemic Pleuropneumonia," and the "Management and Medical Treatment of Children in India."

Dr. Joshua Plaskitt, F.R.C.S., died suddenly on Sunday afternoon, falling dead on the pavement as he was walking home. He was 78 years of age.

Brigade-Surgeon Thomas Stick Veale, M.D., I.M.S., died on the 1st inst., aged 81. Dr. George W. Sparke, formerly of the Royal Artillery, died on November 22, in his 84th year. Surg. Col. H. M. Greenhow, F.R.C.S., late of the Bengal service, died on the 26th ult., in his 84th year.

NINTH ANNUAL MEETING OF THE PHILIPPINE ISLANDS MEDICAL ASSOCIATION.

(From Our Regular Correspondent.)

MANILA, November 5, 1912.

THE second session of the Ninth Annual Meeting of the Philippine Islands Medical Association began at 9 A.M. The first paper, entitled "Status Thymico-Lymphaticus in Filipinos" was read by Dr. B. C. Crowell. The author of this paper reported 19 cases of this disease, all of which he had observed in Filipinos. He stated that the experience here was similar to that had in Europe and the United States, namely, that the majority of the cases were discovered at autopsies which were made upon the usual run of cases that come to a city morgue. The number of cases observed, however, had been considerably augmented of late on account of the activity of the health officers in sending to the morgue for autopsy all bodies in which glandular enlargements were found. He stated that in making the diagnosis clinically in other countries, much stress was laid upon the square appearance of the pubic hair. This diagnostic sign was absent in Malays, particularly in Filipinos. The pathological findings in Malays, however, were otherwise practically the same as those found in other races. The principal points upon which Dr. Crowell based his diagnosis of this condition were, the enlargement of the lymph tissues at the base of the tongue and the fauces, the enlargement of the thymus gland, and hypertrophy of the lymph structures in the intestines associated with enlargement of the lymph glands.

The next paper was entitled "Sarcoma of Intestines, Pathological Anatomy, with Report of Cases," by Dr. R. W. Hammack. The author gave the history of three cases of primary sarcoma of the intestine. One of these was of the annular variety. He had seen a fourth case, but on account of the fact that it was not clear that the primary lesion was in the intestines, he did not include it with this series. He invited attention to the rarity of this affection and to the fact that in children the disease was nearly always confined to the large intestine.

The next paper was entitled "A Tumor of the Hypophysis Cerebri," by José Hilario. The author reported several cases of this disease which had been found at autopsy.

The next paper was entitled "The Rôle of the Individual Proteins in Nutrition," by R. B. Gibson, the Assistant Professor of Physiology in the College of Medicine and Surgery. The author called especial attention to the difference which existed between complete proteins and non-complete proteins. He stated that the proper nutrition of the organism depended largely upon a correct salt balance. He gave instances of feeding experiments made upon young rats, in which the requisite number of calories were supplied in the food, but in which a correct salt balance was not maintained, and he showed that practically no growth took place in such animals, but that an increase in weight immediately began when a correct salt balance was maintained. It was his opinion that this observation might be of great importance in throwing additional light upon the etiology of beriberi, especially in view of the fact that highly polished rice was a protein that lacked a proper salt balance. Rice polishings he considered to be complete proteins. The speaker said, however, that he had not had an opportunity to verify this supposition by analysis.

The next paper read was entitled "Polyneuritis Gallinarum—the Influence of Various Foodstuffs on Its Development," by Dr. Edward B. Vedder, of the Army Board for the Study of Tropical Diseases. Dr. Vedder reported on a series of feedings which had been made, in which chickens were fed polished rice and meat, polished rice and potatoes, polished rice and peas, polished rice and bananas, polished rice and condensed milk, and polished rice and white bread. The object of these experiments was to determine whether the neuritis preventing principle existed in the substance fed with the polished rice. The results of the experiment were, that polyneuritis gallinarum developed before the 23d day, in all of the fowls except in those in which peas were fed in addition to the rice. From these experiments, the author pointed out that peas possess the neuritis preventing principle, perhaps in practically as large proportions as it existed in mangoes or beans. He also called attention to the fact that it had been observed, on Norwegian ships, that after 1894 beriberi was frequently encountered among the sailors, whereas, prior to that date, it was practically unknown. An investigation of this matter showed that prior to 1894 the sailors used rye bread, and after that date, they used white bread, which was made of highly milled wheat. Upon bran being added to the ration, the beriberi promptly disappeared. He stated that similar experiences had also been had in Labrador, where beriberi is found to prevail very extensively. It was found that the staple article of diet among

the Labrador natives, at times, was bread made from highly milled wheat, and when this was used, beriberi almost invariably resulted. Here again, various experiments had shown that it was possible to eradicate beriberi when bran was added to the ration.

The next paper was entitled "Early Changes in the Peripheral Nerves in Polyneuritis Gallinarum," by Dr. Elbert Clark, Professor of Anatomy of the College of Medicine and Surgery. Dr. Clark made microscopical examinations of the sciatic nerves of fowls that were undergoing feeding experiments with polished rice, and invariably he found that marked degenerative changes took place in the nerve trunk between the axis cylinder and the medullary sheath, and transverse fibrils disappearing almost completely. The average time for paralysis to be observable clinically was generally found to be about the 23d day, after a feeding experiment was begun, although it had been observed as early as the 15th day. He then determined to make examinations of the nerve as soon as the experiments were begun. He found that distinct changes took place in almost every instance as early as the seventh day of the feeding experiment, and in such cases, no clinical manifestations of neuritis could be detected. He also pointed out that apparently, then, from the very beginning, certain of the nerve fibers were affected, and as the disease progressed, more and more became evolved until finally paralysis set in.

The next paper was entitled "Infant Mortality in Manila," by Dr. W. E. Musgrave. Dr. Musgrave stated that he was simply presenting the general considerations in connection with infant mortality, and that two other papers which were to have been read by his fellow members on the Committee appointed for the study of infant mortality in the Philippines, would not be read at this time as those members were not quite ready to report. The investigations, however, had gone far enough to show that the infant mortality in the Philippines was intimately associated with a lack of proper nutrition of the mothers, and that the pathetic part of the matter was that in most instances the mothers were not even aware of the fact that their simple diet of rice and fish was not sufficient to furnish an adequate amount of nutrition for themselves and a proper milk for their infants. He dealt at length with the difficulties in the way of providing a satisfactory raw milk in the Philippines, and pointed out that the solution of the problem lay in making available a good whole milk such as that which was now quite largely imported into the country in sterilized form.

In the discussion which followed upon the preceding four papers, Dr. Heiser stated that he was glad to note the additional light thrown upon the etiology of beriberi by the paper of Dr. Gibson, and that all that Drs. Vedder and Clark had done simply added more and more evidence to the vast quantity already accumulated, namely, that beriberi was intimately associated with nutrition, and that it was probably due to a faulty rice diet. Even though the etiology might not be accepted by all medical men, yet, from a practical standpoint, sufficient progress had now been made for the sanitarian to proceed without waiting for definite answers as to whether beriberi was a nutritional or an infectious disease. He stated that the matter had now reached the stage where it might be stated that an outbreak of beriberi could be stopped, or beriberi prevented, with the same certainty as it was possible for the sanitarian to stop an outbreak of cholera, or to prevent it occurrence. It was simply a question of selecting a diet which contained the neuritis preventing principle, such as was represented by unpolished rice. With regard to the paper by Dr. Musgrave, he agreed thoroughly regarding the difficulty in supplying a proper cow's milk to the residents of the Philippine Islands. The obstacles did seem almost insuperable, and for the present at least, an imported, canned, sterilized milk seemed to be the only practical substitute. He thought, however, that the difficulty might be met by introducing into every town and hamlet in the Philippine Islands, milk goats, and that through them, this very necessary food could be supplied to the masses of the people at a cost which was within their financial ability. That the Filipino people as a class were so poorly nourished had long since been recognized, and a campaign had been started over three years ago to teach them to utilize the food stuffs which contained adequate nourishment and which grew so abundantly in these islands on every hand.

Dr. Shaklee stated that perhaps the lack of salt balance, as pointed out by Dr. Gibson, might be further influenced by the presence or absence of certain salts; that unless magnesium was present in the proportion of practically ten times the amount in which calcium was present, a rapid drain of the body fluids took place, but that when the proper proportion was restored, this process immediately stopped.

Dr. Yeamans desired to ask Dr. Vedder whether experiments had been conducted in connection with his work on beriberi, which referred to the salt balance.

Dr. Clark wished to ask Dr. Gibson whether any histological examinations had been made of nerve fibers in cases in which feeding experiments had been carried on with the different salt mixtures.

Dr. Vedder stated, in reply to Dr. Yeamans, that he had conducted a large number of experiments, keeping in mind the salt balance, but that they had all proven negative. His conclusion that the salt balance is not concerned in the etiology of beriberi had received further confirmation by the fact that the neuritis preventing principle had not apparently been discovered.

Dr. Gibson, in reply to Dr. Clark, stated that so far as he knew, no histological examinations had been made in connection with stunted growth produced in rats by changing the salts in the diet.

The next paper was entitled "Experimental Acclimatization of the Philippine Monkey to a Tropical Sun," by Dr. A. O. Shaklee. This was a report upon an interesting series of experiments in which the author acclimated a number of monkeys by gradual exposures to the sun, and then exposed them, with other monkeys which had not been so acclimated. In practically every instance the monkeys which had not been acclimated died within a period of an hour, or less, and the acclimated monkeys resisted the effects of the sun's rays apparently without discomfort or elevation of temperature. The unacclimated died almost at the same rate as those monkeys reported upon in the experiments of Dr. Aron, which paper was read at the Seventh Annual Meeting of the Philippine Islands Medical Association.

The last paper on the program "Sunlight," was read by Harry D. Gibbs.

6. Congenital Pelvic Kidney. B. B. Cates.

1. The X-Ray Diagnosis of Gastrointestinal Conditions.—P. Brown states that the *x*-rays help to elucidate many problems in gastroenterology. The more simple diagnostic problems may relate to the determination of the size, the shape, and the position of the stomach and to that of the position and arrangement of the classical divisions of the intestines. Problems which may be considered as slightly less simple are those having to do with the determination of motility, or other evidence of peristaltic activity. Those more complex in nature are problems dealing with the diagnosis of some localized influences inhibitory to normal function; to wit, kinks, pressure-points, and other hindrances due to extrinsic causes such as adhesion bands and the like. Finally, there are very complex problems which are offered by the intrinsic lesions, of a nature either destructive or cicatrizing, which are often malignant and always seriously to be considered.

2. Prevention of Water-Borne Disease.—By A. J. McLaughlin. (See MEDICAL RECORD, November 9, 1912, page 861.)

3. Arteriosclerosis and the Involution Psychoses.—G. L. Walton studied with reference to the possible etiological rôle of arteriosclerosis, one hundred cases of that phase of manic-depressive insanity known as involutional, the patients presenting marked depression, often with agitation, with self-accusation, and with somatic delusions. An equal number of control cases were also examined. There was no more clinical evidence of arteriosclerosis in the psychosis than in the control cases.

4. Human Applications of the Mendelian Theory.—J. M. Connolly states that the inheritance of brachydactyly is clearly in accordance with Mendel's law. Brachydactyly behaves as a simple Mendelian dominant to the normal form, and the recessive normals cannot transmit the affected condition whatever their ancestry. Night-blindness has been traced through ten generations and nearly three centuries, in the 2,000 descendants of a native of southern France. The affection behaved as a Mendelian dominant. The principle "once free, always free," applied in these cases. The inheritance of retinitis pigmentosa and hereditary optic atrophy is also Mendelian. The inheritance of color-blindness illustrates a group of cases in which the incidence of disease is largely, if not absolutely, restricted to one sex. In color-blindness the burden is invariably borne by the male; but a color-blind man does not transmit color-blindness to his sons, but only to his daughters. The daughters, however, are themselves normal, providing the mother was, yet they transmit color-blindness to half their sons. A color-blind daughter could be produced, apparently, only by the marriage of a color-blind man with a woman who transmitted color-blindness, since the daughter to be color-blind must have received the character from both parents: whereas the color-blind son receives the character only from his mother; but a color-blind woman's sons will all be color-blind. It appears as though color-blindness were due to the presence of an extra Mendelian factor as compared with the normal, and that a single dose of it will suffice to produce color-blindness in the male, but a double dose is required to produce it in the presence of the factor for femaleness. In the peculiarly male disease, hemophilia, the pathological character is dominant in one sex, but recessive in the other. Other affections whose inheritance follows the law of Mendel are the following: polydactylism, split-foot, Huntington's chorea, deafmutism, feeblemindedness, twins, and ichthyosis. Davenport and Weeks have shown that epilepsy is inherited according to the Mendelian law, and advocate segregation of all epileptics during the reproductive period.

11. A Description of the Enteroptotic Woman. R. R. Smith.

1. The Prevention of Epilepsy.—L. P. Clark believes that the prevention of epilepsy is closely bound up with a more precise and intensive study of the family stock from which the disease is recruited. Birth injuries and accidents must be still further eliminated. The rearing of neuropathic individuals must be given more definite and painstaking attention. Finally, a proper metabolism in potentially epileptic individuals must be still more energetically safeguarded.

2. Overeating as a Cause of Appendicitis.—E. Novak advances the theory that a considerable number of cases of appendicitis are caused by overeating. As a result of overdistention of the stomach, the superior mesenteric vessels, lying immediately behind this viscus, may be subjected to compression, which produces a decided interference with the intestinal circulation. The first effect of such a circulatory disturbance is the excitation of more or less violent peristaltic activity in the intestine, thus explaining the pain usually felt in the epigastrium at the onset of an attack of appendicitis. Another effect, direct or indirect, of this disturbance of circulation is exerted upon the appendix, the resistance of which is diminished to such an extent that it often falls a prey to the action of the ever present colon bacillus and other intestinal organisms. A more or less severe attack of appendicular inflammation is thus precipitated.

6. Prognosis of Gallstone Disease.—E. MacD. Stanton notes that gallstones are found at autopsy in approximately ten per cent. of subjects past thirty years of age, but this figure is probably too high for the earlier decades of adult life and too low for the later decades. To be of practical value as indicating the real frequency of gallstones autopsy statistics should be collected in such a way as to show the frequency of gallstones in males and females during each decade of life. Notwithstanding the formidable pathological changes often found at operation during the period of acute exacerbation of gallstone disease there is overwhelming clinical evidence to the effect that the acute attack is only very rarely actually dangerous. Emergency operations are not as a rule life saving and are not justified if a safer operation can be performed during a quiescent period. A medical cure consists in a relatively symptomless quiescent period while by a surgical cure is meant a permanent relief from the symptoms and complications of the disease. Surgical end results are on the whole very satisfactory—almost ideally so in the early uncomplicated cases. If the surgeon can assure a low operative mortality gallstone cases should be operated upon at the first safe period after the diagnosis is made.

7. Albumin Determination.—G. W. Warren finds that the determination of the albumin content in its relation to the amount of pus in the urine is of the greatest aid in the diagnosis of kidney infections. The albumin content

in the most marked cases of cystitis does not exceed 0.15 per cent. Therefore, in pyuria of doubtful origin, where the urine is free from blood, an albumin content of more than 0.15 per cent. in the great majority of cases shows that the kidney is involved. With a small amount of pus and an albumin content of 0.15 per cent., it can safely be assumed that the kidney is infected.

1. Visceral Organisms.—A. Carrel details his technique by means of which entire systems of organs may be kept alive outside of the organism in an incubator at a temperature of 38° C. while the lungs are being ventilated. The method consists in removing aseptically *en masse* the heart, lungs, liver, stomach, pancreas, adrenals, kidneys, spleen, and part of the intestines of an animal, generally a cat. Artificial respiration is carried on by a continuous current of air interrupted ten times per minute. The results of these experiments were as follows: The viscera were functioning normally, the heart pulsating, the intestine contracting peristaltically, and the stomach digesting in the successful cases. After five or six hours intestinal hyperemia appeared and it seemed as though peritonitis developed progressively. While in some cases death occurred almost suddenly, in three or four hours, in most of the cases life continued even ten or thirteen hours. The death of the visceral organism was announced by a weakened heart action with later a sudden stoppage. In the last experiment organic death occurred thirteen hours and fifteen minutes after that of the cat from which the organs were taken.

2. Causes of Death in Cases of High Blood-Pressure.—By T. C. Janeway. (See MEDICAL RECORD, Vol. 81, page 1118.)

3. Duodenal Medication with Ipecac in Amebic Dysentery.—H. G. Beck, noting the general agreement that ipecac is the remedy for amebic dysentery, and the objectionable features of the methods in vogue, states that a simple, rational, and more practical method has suggested itself in the use of the Einhorn duodenal tube. For a complete description of this apparatus and the methods of its use the reader is referred to the original article by Max Einhorn in the MEDICAL RECORD, January 16, 1910. As a rule, patients have little difficulty in swallowing the tube and comparatively little discomfort afterwards. By aspirating a little of the fluid through the tube after it has entered the stomach and testing the fluid with congo paper one can tell whether the tube has entered the duodenum. In that case the aspiration is slower and more difficult and the fluid is alkaline and bile stained. The time required for the capsule to pass into the duodenum varies from one to five or more hours. Seven cases are reported in which this method was employed after other methods had been used without effect. It appears that the duodenal administration is distinctly more efficacious than other methods. Large duodenal doses of ipecac seem to have no bad effects. There are occasionally gastrointestinal symptoms such as nausea, vomiting, and, rarely, diarrhea lasting twenty to forty-eight hours. Slight general depression may appear with a lowered blood-pressure rarely amounting to more than 10 mm. even with doses as large as 2 grams.

4. Dairy Hygiene.—R. C. Newton points out the injustice of large companies charging a higher price for milk produced hygienically and allowing no share of the profits to the farmer. He describes the cooperative system adopted by a certain company with the result of securing a comparatively high and safe grade of milk produced at a price within the reach practically of all customers and at the same time a contented body of farmers producing the milk and getting a tangible reward for their improved methods. It is by education, by an appeal to the farmer's self-respect, and by an assurance that he will be a participant, that one can work out the desired changes in the milk-producing industry.

5. Action of Saliva on Tooth Enamel.—J. Head points out the fact that roughening of the surface of the enamel of the teeth as an indication of its softening is only the final rather than the complete process, and states that he can detect very minute degrees of softening by means of a microdynamometer for testing the hardness and softness. Enamel will soften and harden again within certain limits, and this hardening and softening is influenced by the saliva and foodstuffs. The same action can occur in dentine.

7. Safety Razor Blade Scalpel.—J. B. Murphy states that every surgeon has more or less frequently been annoyed by a dull scalpel when a sharp one was very much desired. Furthermore, after a few strokes of the scalpel, especially when made in a firm or resistant tissue, like an old scar, the cutting edge of the scalpel becomes dulled. Sharpening scalpels is a nuisance and at best very unsatisfactory. In order to overcome these objections, the author has devised certain handles to carry the two types of safety-razor blades most commonly used. After these blades are no longer serviceable for the purpose for which they were intended, they make excellent scalpels. They are cheap and easily obtainable.

9. Attitude and Trunk Development and Their Relation to Pain in Women.—R. L. Dickinson and W. Truslow present the results of their studies and measurements with reference to the relation between faulty attitude and painful manifestations in women. Three types of attitude are recognized and named as follows: (1) the "Kangaroo type," in which the line of gravity passes back of most of the pivotal points of the trunk and in front of most of those of the lower extremities; (2) the normal type, in which the line of gravity passes through the important pivotal points, and (3) the "Gorilla" type, in which it passes in front of most of the pivotal structures of the trunk and behind those of the lower limbs. These anteroposterior deviations from the normal type tend toward: (1) mechanical instability; (2) muscle and ligament strain, pain, and bony deformity; (3) abnormal relationships of the viscera and derangement of their functions. The congenital trunk deformities are the long-bodied type,

which invites further deformity by the easy crushing of ribs by tight corsets during adolescence, and the over-feminine type with a large development up to the waist line and a scant one above; this type usually presents a kangaroo carriage. The practice of looking for degrees of faulty carriage, which may account for pain and weakness, will result in many a cure otherwise impossible. The diagnosis once made, the remedy consists in the correction of vicious dress and the development of weak muscles. The most common pains due to false carriage are the sacral, lumbar, and dorsal. Many of these, particularly when connected with enteroptosis and neurasthenia, may be relieved by correcting the attitude, by strengthening the trunk muscles, and cultivating deep breathing. The average woman, as seen in the city, sags. The back is nearly upright, the shoulders tend only slightly to rounding, and the chin is drooping. The deformity which is practically constant is protrusion of the abdomen. The relaxed abdominal wall is one to two inches in advance of the normal in a large group of cases. As regards posture, one-third of the cases were found good; one-half were defective. The hour-glass type of corset was the average design. The gap of the corset when unhooked should not exceed two and one-half inches. The tight corset harms weak women badly; there is no substitute for Nature's corset—the well-set-up anterior abdominal wall. Too much emphasis cannot be laid on the normal wedge-shape of the lateral third of the abdominal cavity as seen in anteroposterior section and the importance of the uplift of muscular contraction cannot be overstated. Thoroughness of examination, inspection of the unclothed trunk, particularly in women with backache, enteroptosis, and neurasthenia, muscular training continued after puberty and systematically ordered after labor, together with the supervision of gymnastics and dress, are the measures advised.

10. After Results of Sanatorium Treatment.—By V. Y. Bowditch and W. A. Griffin. (See MEDICAL RECORD, October 26, page 784.)

11. Etiology of Beriberi.—C. Lovelace states that a fatal form of peripheral neuritis occurs among residents of the Madeira Valley and among the employees of the Madeira-Mamoré Railway. This neuritis must be classified as beriberi, or as a member of an as yet hypothetical beriberi group. This disease bears no intimate relation to the consumption of rice, polished or unpolished, as a staple article of diet, nor is the disease due to the absence of protein in the diet.

12. End Results of the Conserved Ovary.—J. O. Polak concludes that only healthy ovaries should be conserved. The right ovary when retained is less prone to subsequent inflammatory changes than the left. All retained ovaries or portions of ovaries should be placed in such a position in the pelvis that their circulation is not interfered with. Resection gives the best results when its application is limited to large monocysts, retention-cysts, fibroids, or dermoids. The multiple cystic ovary should be either left alone or ablated. Resection is not permissible. When a resection is made it should be extensive, excising the entire diseased area. The suture should only approximate the wound edges, not constrict them. The retained portion should be tacked up in the pelvis to maintain an equal circulation, and the suture line should be always covered with a reflexion of the peritoneum.

1. The Biology of Tumors.—G. Mansell Moullin states that whatever form is assumed by the tumors that originate from the somatic elements or the structures derived from them, the underlying principle of their growth is the same. The power that would compel the higher differentiation of the cells that compose them ceases to act. The cells that form the tumor-bud cease to develop further, and never do any work. They cease to bear any relation to the rest of the body, except that they draw their food-supply from it and give up their waste products to it. They do not influence other tissues in any way, nor are they influenced by them. They continue to grow and multiply, perhaps with all the greater energy, because the force that would have been consumed in raising the cells to a higher plane of differentiation is available now for growth. How is it that the tissues at one small spot in the body are suddenly able to assert themselves in this way? How is it that almost from one minute to another they can shake off all allegiance to the other tissues, and except that they are dependent upon the rest of the body for their food, grow upon it, entirely independently of its growth, and thrive while it may starve? How is it that from normal tissues, doing their normal work, they can suddenly develop into structures like parasites that drain the body of its sustenance and do nothing for it in return? There is only one answer to questions such as these. The progressive development of the organs and tissues of the individual, as of the race, is the outcome of the mutual relations that have been built up in the course of ages between the infinite variety of cells of which the body is composed, transmitted from generation to generation. Environment and the actual working of the organs and tissues in the individual are but forces of the moment. The real controlling power is the hereditary transmission of the relations which the different parts of the body have exerted upon each other through immeasurable time, and which have been handed down in ever increasing numbers from countless ages. It is this that directs development and differentiation and keeps growth in check. If it fails from any cause, or if it is overpowered by the forces of the moment, whether they form part of the environment or originate in the body itself, development and differentiation come to an end; organs fail to attain their normal perfection, and tissues remain at that level of specialization at which they happen to be at the moment, incapable of work because of their imperfect development, but with their power of growth not only intact, but released from all restraining influence, and, it may be, even increased in vigor.

2. Cases of Pyrexia.—R. V. Solly reports a number of cases illustrating many different conditions causing pyrexia. Pyrexia may be due to typhoid and to paratyphoid fever, to the pneumococcus, and to syphilis; to pyemia and septicemia, including malignant endocarditis; to subdiaphragmatic abscess, to portal pyemia, and to nematoid worms; to urinary conditions, and to rat bite fever.

3. The Suppression of the Convulsion in Eclampsia.—A. J. Wallace notes that in December, 1910, L. Murray made the suggestion that as intrathecal injections of solutions of magnesium sulphate had proved useful in tetanus they might also be of service in eclampsia. This valuable suggestion has not received the recognition it merited, for the results in the treatment of tetanus have been at least encouraging. Crandon states that of 206 cases of post-operative tetanus collected by various writers the large majority were fatal. Fox's collection of fifteen acute cases of tetanus treated by intrathecal injections of mag-

nesium sulphate showed a recovery rate of 50 per cent. The usual 25 per cent. solution of magnesium sulphate was employed after sterilization in the treatment of the convulsions of puerperal eclampsia. The drug was injected into the subarachnoid space of the spinal cord. The dose was regulated by the body-weight of the individual patient, 1 c.c. being allowed for every 25 pounds of body-weight. The results were satisfactory.

5. Gasworks Tar and Epithelial Proliferation.—N. Bayon has been able to demonstrate on rabbits the deleterious influence of gasworks tar in the production of proliferation in epithelial tissue, and believes that this phenomenon explains to a certain point the influence of gasworks tar in producing and preparing a receptive situation for a cancerous growth. These growths differ from true cancer in one very important feature, namely, although the epithelium is seen to proliferate actively, it does not invade the lymphatics and causes no metastatic nodules.

3. The Functional Nature of the Cecum and Appendix. A. Keith.
4. Recent Progress in Connection with Syphilis. D'A. Power.
5. A Sequel to Novocaine Injection. S. Gooding and F. L. Etheridge.

1. The Treatment of Fractures.—R. Jones comments upon the recent report of the committee on fractures appointed by the council of the British Medical Association. He states that the value of a correct alignment in conjunction with complete obliteration of shortening should be appreciated. A reduction quite incomplete during the primary anesthesia may easily be made complete during the following forty-eight hours. This correction is brought about by continued fixed extension, aided by appropriately placed pads; in other instances by approximating the lower to the upper fragment by posture of the limb. One should study the causes of non-union from the clinical side, and in the application of splints should avoid rigid circular compression. Splints should always be wider than the limb they protect. Delayed union in a certain proportion of cases is inevitable. Care must be taken not to carelessly relegate such cases to the more serious class of ununited fractures. The academic period of consolidation authoritatively asserted is not accurate, and that bones which appear firm to the hand will yield after many weeks to the incidence of body weight. Extensive callus exudation with pain on pressure most probably represents incomplete union. After having corrected by pulling and manipulation delayed and ununited fractures, the mere change in position and accurate retention will often rapidly bring about firm union. To still further ensure success the bone may be percussed and elastic tubing may be applied above and below the fracture to produce congestion. It should be taught that a malunited fracture interferes with the function of the limb by deflecting the body weight from accurate incidence upon the joints above and below. Treatment should therefore be preventive. Fractures above the elbow-joint should be fixed in supination and hyperflexion. Passive movements should not be commenced too early, and should be practised in the gentlest manner. The radial deformity of a Colles' fracture should be completely rectified; the ulnar prominence is of little consequence. For Pott's fracture the displacement of the ankle should be especially overcome and the inversion of the ankle should be secured. Steps should be taken when walking is begun to maintain the inversion. The indications for operation clearly differ from the individual standpoint of the surgeon, and no rules can be laid down.

3. The Functional Nature of the Cecum and Appendix.—A. Keith notes that when one thinks of how the diet of highly civilized races has changed—in quality, quantity, and character—in comparatively recent times, one must marvel that our organization, which was evolved to deal with a more primitive and more precarious supply of food, has accommodated itself to modern conditions so well as it has. We know that beyond the neolithic period, when cereals began to be cultivated, some six thousand years ago, there lies a vast hinterland of rude human existence, when man must have lived on the natural products of the country. With the discovery of fire and of the artificial preparation of food (we know that man had discovered the use of fire before the end of the Pleistocene period) the task of the alimentary system must have been greatly altered. The greatest changes, however, are those of more recent centuries—the concentrated nature of food, its plentiful supply, its highly artificial character. When one comes to realize how slowly evolutionary processes have affected man's body in past times, one can hardly expect the internal digestive system to adapt itself to the rapid pace demanded by the ever-accumulating resources of civilization. The modern changes at work in the teeth and jaws have set in since neolithic times; we have every reason to suppose these are allied to, and contemporaneous with, changes affecting the whole alimentary system. Thus an impartial survey of the evidence at the disposal of the anatomists indicates very plainly that one cannot hope to prevent or cure the ailments to which the great bowel is liable so long as we regard it as a hopelessly injurious or useless structure. On the other hand, if we regard it as having all the anatomical appearances of a useful structure, our outlook becomes hopeful if we can only discover what its uses are. If one only knew how to keep it suitably and profitably employed by altering our diet to meet its requirements, it would serve the present and future generations just as well as it answered the digestive needs of primitive and successful races in the past.

Sinus Stimulation in Resuscitation of the Heart.—J. Erlanger states that four series of experiments which he has performed indicate that tetanic stimulation of the sinus region of the auricles is of material assistance to massage in the resuscitation of the heart. It causes the auricles to generate impulses, either rhythmical or irregular, to which the ventricles, when susceptible, respond. When massage administered for brief periods has failed to resuscitate the heart, the same period of massage combined with tetanic stimulation of the sinus has usually brought the circulation back to normal. In some instances massage alone when continued over long periods has been without effect, and to all appearances would have continued to be without effect, whereas at such a time massage combined with stimulation of the sinus has effected recovery. Whether the stimulus causes the auricles to beat normally or to fibrillate seems to make no essential difference in the end result. Not infrequently conductivity and irritability are lowered to such an extent by the cessation of the circulation, that impulses generated in an auricle started by stimulation can at first manifest no effect upon the ventricles. Under such circumstances massage alone or, more frequently, massage plus stimulation may cause the ventricles to beat with their inherent slow rate. Often then the force of the ventricular contractions is insufficient for the maintenance of an effective circulation. In such cases, however, with the gradual improvement in the condition of the heart, the auricular impulses, as a rule, soon begin to reach the ventricles, with the result that the latter immediately begin to beat more rapidly and effectively. The beneficial results of stimulation of the auricles, therefore, manifest themselves relatively late, but none the less effectively. It has been found that even after the heart has begun to beat, stimulation of the sinus region may still be of some assistance, though in another direction. It not infrequently happens that after resuscitation of the heart the blood pressure fails to rise above a certain low and insufficient level. In such cases repeated tetanic stimulation of the sinus may accelerate the rise of blood pressure and so hasten recovery. No attempt has been made to determine the mechanism of this effect.—*Journal of Experimental Medicine.*

Insurance Medicine.

The Rural Death Rate of the State of New York.—Frederick L. Hoffman, LL.D., statistician of The Prudential Insurance Company of America, on Friday morning, December 6, at the twelfth annual conference of the Sanitary Officers of the State of New York, held in Syracuse, New York, presented the results of an original and comprehensive inquiry into the important subject of "The Rural Death Rate of the State of New York." The speaker said at the outset that the problem had not heretofore received as much attention as would be desirable, largely, no doubt, on account of the preponderating numerical importance of the city population, constituting 78.8% of the whole. But, he said, it required no extended argument to prove that there was indeed a very close relation between urban and rural mortality, and that, as a matter of general public policy, much more should be done in the field of hygiene for the adequate protection of the population of the State as a whole. The speaker pointed out that the rural death rate of the State of New York was at present about the same as the city death rate, although in former years the latter had been considerably in excess. For illustration, he said, in 1900 the city death rate had been 19.5 per 1,000, against 15.5 for the rural districts, but in 1909 the respective rates were 15.9 per 1,000 for the cities and 15.1 for rural territory. It would, therefore, seem quite conclusively established that there had not been the measurable progress in rural health which had apparently taken place in the cities of New York State, considered as a group.

Among the causes of death more common in the rural districts of the State of New York, the speaker referred to typhoid fever, malarial fever, influenza, and cancer. After discussing in considerable detail the prevailing death rates from all of the principal causes, the speaker presented in brief outline the essential statistical facts regarding the comparative mortality of the fifty-seven counties, disclosing marked variations in the geographical incidence of particular diseases and a wide range in fluctuations in the death rates during the last decade. Conceding the inadequacy of the available information for precise conclusions in the matter of any one of the subjects discussed, the speaker concluded his remarks with a number of recommendations, suggesting among others, (1) a complete sanitary survey under the direction of the State Board of Health; (2) a study of the geographical distribution of disease throughout the rural portion of the State; (3) a study of the mortality of farmers, farmers' wives, agricultural laborers, and others employed in agricultural industries; (4) a study of occupational accidents in agriculture; (5) a study of the relation of canals and railways to the health of the rural population; (6) the question of rural isolation hospitals and dispensaries; (7) a study of the geographical distribution of cancer; and (8) the establishment of a division of rural hygiene in the State Board of Health for the purpose of providing a more effective sanitary supervision of rural districts and making the necessary scientific investigations preliminary to a substantial reduction in the rural death rate from preventable or postponable causes.

Anthrax as a Disease of Occupation.—Krauss relates the following: a tanner's widow made application for the life insurance of her husband upon the ground that he had lost his life as a result of a professional mishap. It was deposed that the deceased, employed in a leather factory, fell ill on December 11, 1909, the day following some work in freeing hides from arsenical dust. The symptoms were chilliness, malaise, prostration, anorexia, nausea. Swelling of the fingers was noted by the second day. The diagnosis was influenza. The patient did not improve and on December 27 another physician was summoned, the original medical attendant having apparently lost his interest in the case. There were found pain and tenderness in the abdomen, constipation, anorexia, weak and rapid pulse, cardiac murmurs, moderate fever of an almost intermittent type. Under observation the patient became weaker, the legs swelled and gangrenous areas appeared on the left foot early in February, 1910. This phenomenon was immediately followed by somnolence and other manifestations due doubtless to edema of the brain. Death resulted on February 12, and was accounted for by the supposition of an ulcerative endocarditis, due in turn to some blood poison absorbed through an unknown primary focus. The cryptogenetic character of the infection, together with the extreme poverty of the widow, was responsible for the omission of an autopsy. The claim was then referred to another magistrate, and at the hearing the deceased's employer testified that no arsenic had been used in the work; and that while now and then raw hides were handled, the patient had not been exposed to them at that period. The physician, who had first attended the patient, deposed that the occupation of the latter was not in his opinion in any way responsible for the death. Another physician summoned as an expert concurred in this view. The diagnosis of influenza was upheld by exclusion. Intestinal anthrax was naturally suggested at the outset, but the edema of the fingers was merely transitory, and diarrhea was not in evidence until late in the disease. Pustules were moreover absent. Cryptogenous sepsis was also to be thought of as the cause of the supposed ulcerative endocarditis, but there were no other evidences of its presence and this lesion could complicate any acute infectious disease, influenza as well as any other. He, therefore, exculpated the occupation of the patient as having caused death. Another medical man, testifying as an expert for the plaintiff, made a long deposition, which was intended to show that the weight of evidence spoke for an anthrax infection from the hides. The magistrate took this view and decided for the plaintiff, but the case was at once appealed. The omission of an autopsy naturally rendered the case a very unusual one, and the failure of the employer to demand and pay for one may have been construed against him. In its absence a formidable body of facts was adduced in relation to the nature of latent anthrax, the suspicious nature of the class of hides handled, and much worse, the weight of evidence in favor of anthrax as compared with such vague affections as influenza and cryptogenetic sepsis, led to a final verdict, after more than two years of litigation, for the plaintiff. It was decided that even momentary contact with infected hides was sufficient for a fatal infection. A "deadly parallel" was utilized in which the victim's symptoms were compared item for item with similar cases known to have been due to anthrax infection (intestinal anthrax), and the correspondence proved absolutely the identity of the morbid conditions.—*Zeitschrift für Versicherungsmedizin*, 1912, V, Nos. 9 and 10.

Book Reviews.

MANUAL OF CHEMISTRY. A Guide to Lectures and Laboratory Work for Beginners in Chemistry. A Textbook specially adapted for Students of Medicine, Pharmacy and Dentistry. By W. SIMON, PhD., M.D., Professor of Chemistry in the College of Physicians and Surgeons of Baltimore and in the Baltimore College of Dental Surgery, Emeritus Professor in the Maryland College of Pharmacy, Department of the University of Maryland, and DANIEL BASE, Ph.D., Professor of Chemistry in the Maryland College of Pharmacy, Department of the University of Maryland, and of Analytical Chemistry in the Department of Medicine, University of Maryland, Baltimore. Tenth Edition, thoroughly revised, with eighty-two illustrations, one colored spectra plate, and eight colored plates representing sixty-four chemical reactions. Price $3. Philadelphia and New York: Lea & Febiger, 1912.

VERY few medical books reach a tenth edition; that a work on chemistry should have achieved this distinction is sufficient proof that it has supplied a want and justified its existence. This new edition of Simon's Chemistry has been thoroughly revised and brought up to date; at the same time it retains its former appearance and characteristics. The section on physiological chemistry has been rewritten; there is also a new chapter on the theory of electrolytic dissociation or ionization, in which are considered the origin of the theory, ionic equilibrium, ionization of acids, bases, and salts, reactions on the ionic basis, activity of acids and bases, hydrolysis of salts, neutralization, electrolysis, and Faraday's laws. For the practitioner who has been out of school for some years, and who wishes to bring his knowledge up to date, this is probably the most useful work on chemistry in the market.

PRACTICAL ANATOMY. An Exposition of the Facts of Gross Anatomy from the Topographical Standpoint, and a Guide to the Dissection of the Human Body. By JOHN C. HEISLER, M.D., Professor of Anatomy in the Medico-Chirurgical College of Philadelphia. With 306 illustrations, of which 225 are in color, by E. F. FABER. Price $4.50. Philadelphia and London: J. B. Lippincott Company.

THIS, the latest addition to works on anatomy, is a handsome volume of 900 pages, well printed and plentifully illustrated. It follows the general plan of similar works, and only a thorough use of the volume in the dissecting room will demonstrate its special merits and its faults. The book is in some respects a companion and supplement to Piersol's Anatomy, and those using this latter work as their text-book will most likely turn to the present volume as their guide in dissecting. In addition to the material ordinarily supplied in a dissecting manual, this work contains a certain amount of surface anatomy and also of surgical anatomy. The Basle Anatomical Nomenclature has not been slavishly followed; in many cases the B.N.A. terms have been used directly, and where not employed they have been added in parentheses. The volume does not readily lie open at any given place as a book intended for use in the dissection room or laboratory should do. For a first edition of a work containing so many names the pages are surprisingly free from misprints. Teachers and students will do well to examine this work with care.

PHARMACOLOGY. Action and Uses of Drugs. By MAURICE VÉJUX TYRODE, M.D., ex-Instructor of Pharmacology in the Medical School of Harvard University. Second Edition. Philadelphia: P. Blakiston's Sons & Co., 1912.

THERE is a great deal to commend in this book, which, although of small size, nevertheless covers the entire field of pharmacology. The systematic plan in which the subject is presented enables the author to condense a great many topics into a small compass. Part I deals with the drugs, such as morphine, whose constitutional action is in greater prominence; Part II deals with the ferments, secretions, and extracts of animal organs; Part III discusses the drugs whose local action is most in evidence; and Part IV deals with the drugs of inorganic origin. The plan of the author may be indicated by referring to the description of the drugs forming the ether and chloral group. The general characteristics of this group are first described. Then follows a separate description of the action of the various drugs composing the group. The therapeutic application of these drugs is then described. Then follows a summary of the materia medica of the drugs already described. The same plan is applied to all the other groups. The omission of unnecessary details and the inclusion of only what is definitely known have enabled the author to present a volume that is of eminent value to the student and even to the practitioner who would refresh his knowledge of the action of drugs.

ELEMENTS OF PRACTICAL MEDICINE. By ALFRED H. CARTER, M.D., M.Sc., Fellow of the Royal College of Physicians, London; Professor of Medicine, University of Birmingham; Emeritus Professor of Physiology, Queen's College, Birmingham; Consulting Physician to the Queen's Hospital, Birmingham, to the Corbett Hospital, Stourbridge, the Bromsgrove Hospital, the Smallwood Hospital, Redditch, and Guest Hospital, Dudley, etc. Tenth Edition. Price 9/ net. London: H. K. Lewis, 1912.

AN existence of thirty-two years is certainly a long one for a text-book which like the present has in its ten editions passed through many eras of change in medical science. American medical readers will probably be interested in the English methods of treatment. Yet it is hardly likely that the entire British profession reflects the conservative and old-time methods that are presented in this volume. Thus, no mention is made of the serum treatment of cerebrospinal meningitis, nor of the use of salvarsan in syphilis. The book contains many useful suggestions as to treatment. It is noted that in the paroxysmal stage of whooping-cough the best medicine is carbolic acid in doses of one-half to one minim given in a little mucilage, glycerine, and aromatic water every two or three hours. One admirable feature of this work is the therapeutic formulary at the end of the volume. The book is well written and will probably continue to maintain a wide popularity.

MATERIA MEDICA AND THERAPEUTICS, INCLUDING PHARMACY AND PHARMACOLOGY. By REGINALD WEBB WILCOX, M.A., M.D., LL.D., Professor of Medicine (retired) at the New York Post-Graduate Medical School and Hospital, Consulting Physician to St. Mark's and to the Nassau Hospitals, President of the Medical Association of the Greater City of New York, President of the Society of Medical Jurisprudence, ex-President of the American Therapeutic Society and of the Harvard Medical Society, Fellow of the American Academy of Medicine, Honorary Member of the Connecticut State Medical Society, formerly Vice-chairman of the Revision Committee of the United States Pharmacopeia, etc. Eighth Edition, revised; with Index of Symptoms and Diseases. Price $3. Philadelphia: P. Blakiston's Sons & Co., 1912.

THIS well known text-book appears once more in a single volume. The two previous editions had been expanded so that they occupied two volumes, thus making the work more bulky and more expensive without any appreciable increase in its value. The work in one volume had achieved a position of its own, and a very enviable position it was. For the medical student this has long been a popular text-book, and it is now brought up to date most thoroughly. The book has a very complete index, so that it is quite easy to find the numberless items which the volume contains. A prominent feature of this index is the inclusion of the diseases and disease symptoms, and this will be much appreciated by the practising physician. The chief change in the contents of this edition is that only pharmacopeial drugs and preparations are included. This is quite sufficient for the medical student, and the better he becomes acquainted with these, the less use will he have, later on as a practitioner, for the numberless nonpharmacopeial preparations which are flooding the drug stores and physicians' offices and whose therapeutic efficiency is often in inverse ratio to their commercial value. This new edition will easily maintain the popularity of its predecessors.

PATHOLOGY OF THE EYE. By P. H. ADAMS, M.A., M.B., D.O. Oxon., F.R., C.S., Surgeon to the Oxford Eye Hospital; Consulting Ophthalmic Surgeon to the Radcliffe Infirmary. Price $1.50. London: Henry Froude, Oxford University Press, Hodder & Stoughton, 1912.

ADAM'S work comprises a small volume of 194 pages. It is well printed and illustrated by 43 figures in the text. The first chapter, which is devoted to describing methods for preserving and staining tissues, is followed by chapters on the various anatomical divisions of the tissues of the eye. A brief description of the anatomy and normal histology is followed by a short discussion of the pathology of each part. A chapter on glaucoma, general diseases affecting the eye and the bacteriology of the eye conclude the work. The statements are brief and to the point. There is no bibliography. This concise consideration of the pathology of the eye will be of value to students who are beginning the study of ophthalmology.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON OBSTETRICS AND GYNECOLOGY.

Stated Meeting, Held October 24, 1912.

DR. FRANK A. DORMAN IN THE CHAIR.

Renal Hematuria; Decapsulation, Nephrectomy.—Dr. HENRY DAWSON FURNISS reported this case. The patient was a woman, 50 years of age, who was seen in December, 1911, at which time she reported that the urine had been as dark as port wine for three months from the admixture of blood. There was no pain or frequency of urination. The radiographic examination for stone was negative. The blood pressure was 125 mm. The daily amount of urine was 450 c.c. The examination of the bladder was negative, except that just inside of the normal ureteral opening there was a slight depression that looked like the orifice of another ureter. This could not be catheterized, nor was colored urine seen coming from it after the injection of indigo-carmine. After the injection of indigo-carmine into the gluteal muscles elimination began from both sides in fourteen minutes, a bright red fluid coming from the right ureter at each spurt, while that from the left was clear. The urine from the left side showed a slight amount of albumin. An injection of adrenalin into the renal pelvis had no effect on the hematuria. There were a few hyaline and finely granular casts. On February 10 the right kidney was cut down upon. The capsule of this kidney was about four times as thick as that of a normal kidney and very adherent; the kidney itself was of normal size. There was no cessation of the hematuria after the operation. The patient was treated with human blood serum for two weeks and then with calcium lactate without any effect on the hematuria. On March 12 indigo-carmine R. was administered and colored urine came from the left ureter in twelve minutes. As the hemorrhage did not cease at the end of six weeks a nephrectomy was done when it was found that there were two ureters and a double renal pelvis. Examination of the kidney showed some edema and round-celled infiltration of the cortex which was probably due to the former decapsulation. There was free blood in the straight and convoluted tubules which showed that the hemorrhage was from the kidney substance. The patient made an uninterrupted recovery. The daily amount of urine increased to 1200 c.c. two weeks after the operation and was free from albumin and casts.

Renal Hematuria; Cessation after Ureteral Catheterization.—Dr. HENRY DAWSON FURNISS reported this case. The patient was a woman, 50 years of age, whose previous history was negative except that three years before she had had a hematuria which lasted for several days. There had been no return until March of this year, since which time the urine had been continuously port wine colored. There was some dull aching pain in both lumbar regions, but no loss of weight or strength. Examination showed a normal bladder. Bloody urine was obtained from the left ureter, while the urine from the right ureter was negative both microscopically and chemically. Two days after the cystoscopy the urine was free from blood and had remained so ever since. Hagner of Washington, who had reported a case of cessation of hematuria after ureteral catheterization, suggested that possibly a small ureteral polyp had accounted for the hemorrhage and that it had been scraped away in passing the catheter. It hardly seemed that such was the case in this instance, as the ureteral catheter continued to drain bloody urine; had it scraped off and passed the attachment of a polyp, clear urine should have been obtained. It was possible that a polyp just at the point to which the cystoscope was passed had been scraped away.

Renal Hematuria; Cessation after Decapsulation.—Dr. HENRY DAWSON FURNISS reported this case. This patient was also a woman 50 years of age. She was seen for the first time on September 1, 1911. Her previous history was negative. Her present trouble began two months before when the urine became bloody. She suffered from no pain or frequency of urination. The bladder was normal with urine red in color coming from the right ureter; that from the left ureter showed a trace of albumin and an occasional hyaline or finely granular cast. On September 14 the right kidney was cut down upon and found to be perfectly normal in appearance. Decapsulation was performed and two days later the urine was free from blood. On October 4 an estimation of the renal function with phenolsulphonephthalein was made which showed 50 per cent. in the first hour and 23 per cent. in the second.

Fulguration Cauterization.—Dr. HENRY DAWSON FURNISS reported this case which had been referred to him by Dr. E. W. Peterson. The patient, a woman 49 years of age, gave a history of an attack of pain eleven years before which lasted three days and was followed by the passage of gravel and hematuria. Three months ago she had had pain in the right lumbar region which lasted for an hour and since that time she had had hematuria almost constantly. She suffered from urgent and frequent urination. Examination showed the urine turbid and dark pink in color. Cystoscopy revealed what looked like a broad base papilloma just over the area of the right ureter and anterior to it. There was some edema. Believing it to be a papilloma, it was fulgurated twice, the interval between treatments being four days. Three days after the second fulguration examination revealed a dark stone just showing through the tumor-like mass. An attempt was made to liberate this with the patient in the knee-chest position using a Kelly tube and a small curette. The patient was unable to keep still and so the attempt had to be abandoned. Four days later the patient was again examined and the stone was almost born; it was as large as the tip of an adult male ring finger. She was advised to come into the hospital for the removal of this through the bladder. They had planned to dislocate the stone, passing a wire snare around it, and remove it through the cystoscope. If it had been too large for this it would have been crushed with a lithotribe and washed with an evacuator. The patient was very stout and the radiograph failed to show the presence of the stone. Dr. Furniss believed that any growth or tumefaction at the vesical orifice of the ureter, especially if there was an edematous condition, should make one suspicious of stone. These patients should be radiographed before any attempt was made to fulgurate a supposed papilloma. In the fulguration they had a bloodless method of releasing impacted stone as the fulgurated tissue would in a few days slough away.

When Is the High Forceps Operation Justifiable?—Dr. JAMES A. HARRAR read this paper. He said that the extending of the indications for cesarean section had placed the high forceps operation on the defensive, many of our best obstetricians going so far as to deny it a place among the recognized methods of treating dystocia. When the forceps was used, as it so often was, to do what amounted practically to a cranioclasty, it was utterly to be condemned. The term high forceps was understood to indicate application of the instrument to the fetal head when its largest diameters were still above the plane of the pelvic inlet. The writer took exception to the statement, "Never apply forceps to the head above the brim." This might be a safe working rule to hand the general practitioner for his proper guidance, but in the hands of the experienced operator there were not a few cases where a baby's life might be spared or a mother's morbidity avoided by the judicious use of the high application. It was a major operation, not to be undertaken except by one well versed in pelvic obstetrical work. The bad results were usually due to faulty judgment in the selection of procedure. The operator then perverted his forceps delivery into a procedure destructive alike to mother and child. There should be ideally no such thing as a "hard high forceps" in the sense of brute force. These admonitions had been made before, but they would bear repetition. High forceps was never an elective operation. A common problem was the decision between version and forceps in deformed pelves of moderate degree. The fetal mortalities distinctly favored high forceps in the ratio of 17 to 25 per cent. at the best. The idea that it was easier to snap a head through a contracted pelvic brim with a version than with a forceps too often proved disastrous to the unfortunate head. It is valuable to divide contracted pelves of moderate degree into two classes, depending upon whether the head could be made to engage in the brim by suprapubic pressure, properly directed under anasthesia, or not. If it would so engage it was a "workable contraction" either for spontaneous delivery or forceps. If it would not so engage it was a "dangerous contraction" and might demand pubiotomy, craniotomy, or even the performance of cesarean section. It was not the indications, which were few, so much as the situations which arose, in which it was advisable to apply forceps to the head above the brim, that were of interest. They saw so many cases when it was already too late to do the proper operation which should have been done had they been earlier in charge of the labor. There was nothing left to do but a possible forceps or a craniotomy. A used and abused uterus was inelastic and would rupture readily

with a late version. Great aid was rendered in the simple flat pelvis by putting the patient in the Walcher position. Inertia uteri, in multipara, delayed dry labor in normal pelves, dystocia resulting from rigidity of the cervix, neglected presentations of the brow at the brim, were situations, illustrated by case reports, in which the high application of forceps was justifiable. Before applying forceps to the floating head, first be assured by suprapubic pressure that the head could be made to bite into the brim. If it should not so engage it was almost certain that it could not be safely delivered with forceps, except with the aid of pubiotomy. One should always desist from further attempts with forceps if after one or two moderate tractions on the instrument the head failed to enter the pelvis.

Dr. William S. Stone believed that Dr. Harrar had given a very fair presentation of this subject. He wished to emphasize one or two points. He recalled his first case in which this operation was attempted and the forceps were applied three times. One should have an exact idea as to the relation of the head to the pelvis in order to determine whether or not the forceps should be used. In many of these cases, if a keener diagnosis had been made, craniotomy would have been resorted to. After hearing the paper one was struck by the difficulty of doing the high forceps operation; this operation was more difficult than was ordinarily believed and should be carried out only by men who were specially qualified to do the work. Dr. Stone said he had received a very important point from the late Dr. Emmett and that was to apply the forceps, whether the head was high, medium, or low, when there was flowing; in other words, no matter where the head was when it became stationary (not receding between pains) the forceps should be applied and that without waiting.

Dr. Simon Marx asked what was meant by high forceps operations. The text-books were misleading. When the head was above the brim of the pelvis a high forceps operation was not always required. In many of the cases if they waited a while the head would engage. If the head did not engage there were two reasons: either there was too little water or the head was too small or too large, causing a malposition of the presenting part. In many of these cases there was malposition which could be corrected if recognized early enough. With advancing experience the use of the high forceps operation would not be so much in demand. In many of these cases craniotomy would be preferable for the reason that with these women who had increased pulse rate, high temperature, and all the accompanying disturbances of labor it seemed a crime to attempt the use of high forceps or even to perform version. High forceps operations were usually late operations and frequently the child was already dead, and in these cases it was better to resort to craniotomy.

Dr. Sidney D. Jacobson said that Dr. Harrar was to be congratulated upon his skill in debating this question. Much had been made by various authors of the value of the Walcher position in slight pelvic contraction. He could not agree with Dr. Harrar upon this point and believed that the Walcher position was not of much practical importance. Walcher himself claimed only an increase of about one-half centimeter in the length of the conjugate by hyperextension of the thighs; usually only a few millimeters were added to its length and that could not be of much practical use. Dr. Jacobson further disagreed with Dr. Harrar that pubiotomy could not be regarded as a method of delivery in contracted pelves, but that it was rather an aid to the forceps in delivering the patient. He believed that pubiotomy was well able to accomplish delivery in a contracted pelvis, even without the aid of forceps, but forceps would fail to accomplish delivery without pubiotomy. Hence the argument did not apply.

Dr. Frank A. Dorman said that his interpretation of the high forceps operation was that it lasted a shorter length of time than had been suggested by Dr. Marx. Where there was a larger circumference and with the head above the pelvic brim and not engaging the high forceps operation was indicated. There were positive indications for doing this operation, but the work should be in the hands of a competent operator. Dr. Tucker had obtained results that few could get to-day. At the Sloane Maternity all failed to place the solid blade; it would slip. In regard to version as compared with high forceps operations, statistics would show, as Dr. Harrar had stated, that when carefully done the high forceps operation was better than version. If there was a flattened pelvis better results were obtained by turning the after-coming head if the child was in the transverse diameter. If there was an ample pelvis the child should be delivered early.

Dr. Harrar, in closing the discussion, said he was surprised at what could be learned when they compared the high forceps operation with version. What interested them most was the fetal mortality. The general practitioner seemed to become addicted to the use of version because he was so often without the proper instruments for the high forceps operation. The fetal mortality in these cases was greater than was generally supposed. Craniotomy in many of these cases was justifiable but only when the child was in bad shape with a heart beat above 160. If the high forceps operation could not be done without danger to the mother craniotomy should be considered, especially when it was too late to do a cesarean section.

Immediate Treatment of Depressed Fracture of the Skull in the Newborn.—Dr. George W. Kosmak presented a brief communication in which the advisability of elevation of depressed fractures soon after birth was advocated, reports of three recent cases successfully done were presented and likewise a simple contrivance for this purpose. The speaker said that in his experience all depressions of the skull in the newborn resulting from pressure of projecting parts of the maternal pelvis or from instruments were probably true fractures, and that the simplicity of the operation recommended it as a prophylactic measure in view of the supposed influence of cranial injuries in later life.

Dr. Ralph Munson Beach reported the case of a primipara, 21 years of age, who went into labor at full term October 12 at 5 o'clock P. M. Strong pains began at 8 P. M. and from midnight they occurred at two minute intervals. There was spontaneous rupture of the membranes at 4.30 A. M. and at 5.30 the attending physician made one application of the forceps. After five or six tractions he decided that the head would not come through and Dr. Beach was called in. The vaginal examination showed a flat pelvis with a very sharp protruding promontory. The fetal head was pressed tightly against the inlet in the left occipito-transverse position, both fontanelles being at the same time level; the disproportion was evident. One application of the forceps was made in order to satisfy the friends of the patient and then she was removed to the hospital where he did a cesarean section. The operation was uneventful but the baby was born asphyxiated; he was resuscitated in about fifteen minutes by means of the Schultz method and oxygen. He did not cry vigorously and showed a depression of the skull over the left frontal region extending from the top of the forehead to the coronal suture and from the median line to the temporal region. About six hours after delivery a jerking of the left hand and forearm and then of both forearms was noticed. Later nystagmus appeared in both eyes together with some bulging of the face and an inability to take milk from the bottle. These symptoms continued until after the fourth day, when the baby began to take its milk better. On the tenth day it was decided to raise the depression and this was done by means of the little elevator loaned the speaker by Dr. Kosmak. For twenty-four hours after the elevation of the depression the baby showed some increase of the twitchings and nystagmus, but from that time there had been no symptoms. The baby now appeared normal in every particular.

Dr. Simon Marx said that he had seen many cases of the kind reported and it seemed to him that they got along without any trouble whatever. The method invented by Dr. Kosmak seemed very ingenious but was useful only from a theoretical standpoint.

Dr. Frank A. Dorman said it had been his privilege to see Dr. Kosmak treat depressed fracture of the skull in the newborn by this method and he was very much impressed by the simplicity of the operation. No anesthesia was required, there was no shock following the operation, and there was apparently no chance for sepsis to occur. No cerebral irritation followed. The instrument was cleverly conceived and worthy of trial.

Dr. S. Jacobson congratulated Dr. Kosmak upon the results that he had obtained by the use of this instrument and reported a case in which operation was done under spinal anesthesia; in this instance the baby was born with paralysis of one side of the face while there was an extensive lesion on the opposite side of the brain caused by a depressed fracture. He had had good results with spinal anesthesia during labor. In an article by Harvey Cushing in Keen's surgery the statement was made that 40 per cent. of the cases of intracranial hemorrhage in the newborn recovered.

Dr. Frank A. Dorman said that he had seen one or two cases of depressed fracture of the skull in the newborn in which the depression was relieved by a little massage.

However, the device offered by Dr. Kosmak was very ingenious and practical. If there was a deep furrow the employment of the instrument was all right. Harvey Cushing's statistics had reference to hemorrhage and not to depressed fracture of the skull in the newborn.

Dr. KOSMAK called attention to the advisability of treating these fractures as soon as they occurred. He said that only that day he had seen a boy six years of age with a marked depression of the right frontal bone and no attempt had been made to correct it. The child was not particularly bright but was not epileptic. He always thought these injuries were depressions and not fractures.

PATHOLOGICAL SOCIETY OF PHILADELPHIA.

A STATED meeting was held at the Medico-Chirurgical College on November 7. Dr. GEORGE W. OUTERBRIDGE presented a specimen of "Struma Ovarii," a new growth with respect to which there are many differences of opinion. As a rule benign, in some instances it gives rise to secondary growths, with characters of malignancy. The new tissue is indistinguishable from thyroid structure.

Dr. RUSSELL RICHARDSON exhibited a specimen of "Diffuse Papilloma of the Foot and Leg," developing in a patient to whose lower extremity a bandage was applied firmly for a considerable period of time.

Dr. M. HOWARD FUSSELL exhibited a specimen of "Purulent Pericarditis. The patient presented symptoms of appendicitis, for which an operation was performed, but on the following day symptoms of pneumonia appeared. In the further progress of the case purulent pericarditis developed for which puncture and aspiration were practised, with great relief to the symptoms. On reaccumulation of the fluid in the pericardium a rib was resected, the pus evacuated, and drainage provided for, but the patient failed to recover. After death the pus was found to contain pneumococci in pure culture.

Drs. J. STUART RODMAN and E. A. CASE presented a specimen of "Sarcoma of the Kidney, with Extensive Metastasis, in an Infant." The patient was a child, 17 months old, who presented numerous masses in the abdomen. Operation was undertaken, but the condition was found inoperable and the wound was closed. After the death of the child the right kidney was found the seat of an enormous hypernephroma, and metastases were presented in the mesentery and other structures.

Drs. R. M. PEARCE and H. T. KARSNER presented a communication entitled "Charts Exhibiting Increased Resistance of Red-Blood Corpuscles (Dof) After Splenectomy." The conclusions reached as a result of this investigation are that the increased resistance to hemolysis exhibited by the red blood-corpuscles after removal of the spleen is due to the associated anemia and is observed also when this exists independently of splenectomy.

Dr. JOHN A. KOLMER presented a communication entitled "A Study of Diphtheria Bacilli," in the course of which the behavior of microorganisms from undoubted and suspicious cases of diphtheria of the nose and throat and also of the so-called pseudo-diphtheria was compared.

AT the Conversational Meeting held November 21, Dr Ross G. HARRISON of New Haven, Conn., delivered by invitation, the first lecture of the course founded by the Society as the Samuel D. Gross Annual Lecture, and he spoke of "The Life of Animal Tissues Outside the Organism." He pointed out that it was difficult to say precisely when the first attempts were made to maintain the life of animal tissues outside the organism, but it is certain that efforts to accomplish this end were made by a number of investigators during the second half of the nineteenth century. Dr. Harrison's interest in the subject was aroused from a desire to determine if possible whether nerve-fibers developed gradual extension from a process of a ganglion-cell or are laid down primarily and gradually evolved into a mature and full-formed structure. His original observations were made on embryonic tissues of the frog whose development was studied in hanging drop preparations suspended in fluid obtained from the lymph-sac of that animal. It was found that the nerve originated from the ganglion-cell process and gradually extended to the periphery by gradual growth, the direction of growth being perhaps determined by certain as yet undetermined chemotactic influences. Later studies were made with the aid of blood-serum of various animals. Growth of tissue seemed to be favored by the presence of some supporting structure, such as is constituted by the network of fibrin which forms in coagulated lymph and plasma.

PHILADELPHIA NEUROLOGICAL SOCIETY.

AT a stated meeting held November 22 Dr. TOM A. WILLIAMS reported (1) "A Case of Diffuse Spinal Sclerosis, Non-syphilitic, with Glossitis," and (2) "A Case of Tabes Dorsalis without Lymphocytosis."

Dr. ALFRED GORDON presented "A Case Simulating the Tremor of Multiple Sclerosis." The patient was a man, about 22 years old, who, following the sudden application of cold water to the nape of the neck in the course of treatment for a mild attack of heat-stroke, developed an oscillatory movement of the head, with marked intention-tremor of the hands, the more pronounced on the left side. The disturbance was so severe that the patient was unable to feed himself and to help himself in other ways. There were no sensory changes, no disorder of the reflexes, no nystagmus, no disturbance of speech. The affection was considered functional.

Dr. GORDON presented also "A Case of Palsy of Only the Upper Branch of the Facial Nerve." The patient was a woman, about 37 years old, who was unable to close perfectly the right eye and to move the right half of the forehead, although the mouth could be moved equally to either side.

Dr. E. B. KRUMBHAAR exhibited "A Patient Yielding a Babinski Reflex from the External Half of the Foot, with a Normal Plantar Reflex from the Internal Half." The patient presented a right hemiplegia. When the inner half of the sole of the foot was irritated normal plantar flexion of the great toe took place, while when the outer half of the sole was irritated dorsal extension occurred. Careless examination in a case like this might fail to demonstrate the presence of the Babinski reflex, a phenomenon that has been observed by Babinski himself and by others.

Dr. FRANCIS X. DERCUM, presented "A Case of Somnolence." The patient was a man, about 24 years old, who at the age of fifteen increased considerably in size, and subsequently developed intense somnolence. There were no motor or sensory disorders, no trophic phenomena, no changes in eyegrounds or in reflexes. Sexual desire was diminished. It was thought the condition might be due to some derangement of internal secretion, perhaps of the hypophysis.

Dr. GEORGE E. PRICE presented a communication entitled "Spinal Gliosis Occurring in the Members of the Same Family, Suggesting a Familial Type," and he demonstrated the patients. The children affected were 24, 22, and 13 years old respectively, while two younger children were healthy. In each instance painless whitlows developed on one or other extremity, resulting in loss of parts. There was reduction in pain and temperature sense, but no sensory dissociation. The reflexes were diminished or lost. The cases were considered as examples of the Morvan type of spinal gliosis. Leprosy was excluded.

Drs. T. H. WEISENBURG and L. BEECHE reported "A Case of Lesion of One Superior Cerebellar Peduncle," and they demonstrated the patient. The case occurred in a man almost seventy years old who was seized with left hemiplegia and diplopia, gradually clearing up and followed by ataxia upon the right side of the body.

Dr. CHARLES K. MILLS presented "A Case of Occlusion of the Posterior Inferior Cerebellar Artery."

Drs. ALFRED REGINAL ALLEN and J. EDWIN SWEET presented a communication entitled "The Effect of Removal of the Hypophysis Cerebri in the Dog." Animals from which the gland was removed lived for varying periods of time after the operation, death resulting from various causes. In those that lived for considerable periods after the operation, the most conspicuous phenomena were atrophy of the organs of generation and an increased deposition of adipose tissue, as manifested by increase in weight.

Action of Epinephrin Upon the Coronary Artery.—E. H. Park has found that excised rings of the coronary artery of the ox properly weighted react to epinephrin by dilatation. This reaction of the ox coronary is not an active dilatation, but is in the nature of a sudden lowering from a high to a relatively low degree of tonus. The tonus is not, however, entirely abolished by epinephrin. The degree of relaxation produced by epinephrin is not constant. It depends on several factors other than the concentration of epinephrin used. It is possible to increase the sensitiveness of the coronary artery to epinephrin. There is no evidence of any primary constrictor effect on the ox coronary from epinephrin in most dilute solutions, nor can the existence in this artery of any constrictor mechanism of sympathetic origin be determined by the excised ring method.—*Journal of Experimental Medicine.*

Medicolegal Notes.

Impeachment of Medical Experts' Testimony.—The testimony of a medical expert cannot be impeached by instances of special cases in which he may have been mistaken in his diagnosis. That would bring in issue the question as to whether or not in each particular case the diagnosis was correct or incorrect. Testimony as to the witness's general reputation, and not as to his success or failure in special cases, is admissible for the purpose of impeachment.

In support of a medical expert's qualification, testimony was held properly admitted showing that the expert had held many positions in different sanatoriums and hospitals, where he had had extensive experience in medicine and surgery, such evidence tending to show expert opportunities and experience.—Southern Ry. Co. v. Parham, Georgia Court of Appeals, 73 S. E., 763.

Opinion Based on Third Person's Statements Inadmissible.—In an action for injuries a physician testified for the plaintiff that he saw her two months after the accident; that she exhibited to him a scar about two inches long across the top of her head, which she said she had received from being thrown out of a carriage; that she complained that since the accident she had suffered from various nervous manifestations, dizziness, headache, and the like. He further testified that a physician could not prove whether a woman was sleepless or dizzy, and that he had to rely upon her statements for that. It was held that the physician's opinion, based upon the plaintiff's statements, was inadmissible.—John J. Radel Co. v. Borches, Kentucky Court of Appeals, 145 S. W. 155.

Expert's Right to Guaranty of Fees.—In a criminal case a physician was called to the witness stand by counsel for the defendant and asked to examine a rock and say, by a mere inspection and without a microscopical examination or other scientific analysis of certain spots on the rock, whether there were blood stains thereon. The doctor refused to testify as an expert unless he was guaranteed the usual fee for such services, and counsel for the defendant requested the court to make an order for the payment of such fee out of the county treasury, declaring that his client was without the means to defray the expense. This the court refused to do. The doctor, having been sworn as a witness, could have been required to answer such pertinent questions as might have been put to him, notwithstanding that they might call for expert testimony and though the doctor was not recompensed or guaranteed compensation for his services as an expert, but the court would not have been authorized to compel him to go to the trouble and probable expense of scientifically investigating the cause of the marks on the rock for the purpose of qualifying himself to give expert testimony on the subject.—People v. Conte (Cal.), 122 Pac. 450.

Claims Against County—Authority to Employ Physician.—In an action by a physician against a board of county commissioners in the State of Kansas for compensation for services one of the causes of action stated that the health officer of the county was called on by another doctor to diagnose a case, and they disagreed. The other doctor called in the plaintiff for a consultation which the health officer, though notified, did not attend. The plaintiff, like the other doctor, pronounced the case to be diphtheria, from which four children in one family were suffering. He quarantined the family at their home, administered antitoxin, and gave general instructions for the treatment and isolation of the cases and of the family, and for the protection of the public against the spread of the disease. The county had a poor farm, but one with no facilities or conveniences for isolating or quarantining persons suffering from contagious or infectious diseases. He presented a bill for $15, alleged to be a reasonable compensation, to the county board, who refused to pay. It was held that the plaintiff, not being a volunteer, but answering the call of the attending physician, acted promptly and properly, and, in so far at least as his services tended to such protection, a moral obligation existed for his reasonable compensation. As, however, the pleading showed that his services were performed upon the request of one who had no authority to bind the county, and did not allege that the family were unable or unwilling to pay for the services, it was held that a cause of action was not stated.

Other items were for services rendered, on the order of the mayor of the city of the third class within the county, to non-residents suffering respectively from catalepsy, appendicitis, and broken collar bone. It was held that the plaintiff was entitled to the reasonable value of his services and treatment afforded such persons.—Dykes v. Board of Com., Kansas Supreme Court, 121 Pac. 1112.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

THE SHIP CAPTAIN'S MEDICAL GUIDE. Edited by CHARLES BURLAND, M.D., F.R.G.S. 214 pages; illustrated; cloth; price 2s. Board of Trade, Publishers, London, England.

BACTERIA. By Dr. MAX SCHOTTELIUS. Second Edition. 324 pages; illustrated; cloth; price $2.50. Oxford University Press, Publishers, New York.

SECOND ANNUAL REPORT OF THE STATE CHARITIES COMMISSION TO THE HONORABLE CHARLES S. DENEEN, GOVERNOR OF ILLINOIS. 532 pages; cloth.

A SYNOPSIS OF MEDICAL TREATMENT. By GEORGE CHEEVER SHATTUCK, M.D. 60 pages; illustrated; cloth. W. M. Leonard, Publisher, Boston.

DIE KLINISCHE STELLUNG DER SOGENANNTEN GENUINEN EPILEPSIE. By Prof. Dr. E. REDLICH and Prof. Dr. O. BINSWANGER. 146 pages; paper; price 6 M. S. KARGER, Publisher, Berlin.

THE TRANSACTIONS OF THE EDINBURGH OBSTETRICAL SOCIETY. Vol. XXXVII. Session 1911-1912. 320 pages; illustrated; cloth. Oliver & Boyd, Publishers, Edinburgh.

PENAL PHILOSOPHY. By GABRIEL TARDE. 581 pages; cloth; price $5.00 net. Little, Brown & Co., Publishers, Boston.

FORENSIC MEDICINE AND TOXICOLOGY. By G. O. HAWTHORNE, M.D. Third Edition. 344 pages; cloth; price $1.70 net. Longmans, Green & Company, Publishers, New York.

THE PROTEIN ELEMENT IN NUTRITION. By Major D. MCCAY. 216 pages; illustrated; cloth; price $3.00 net. Longmans, Green & Company, Publishers, New York.

UEBER DIE SERODIAGNOSE DER SYPHILIS. By Dr. A. BRAUER. 40 pages; paper; price 1.20 M. Carl Marhold, Publisher, Halle.

THE CARRIER PROBLEM IN INFECTIOUS DISEASES. By J. C. LEDINGHAM, M.B., D.Sc. and J. A. ARKWRIGHT, M.D. 310 pages; cloth; price $3.50 net. Longmans, Green & Company, Publishers, New York.

AIDS TO TROPICAL HYGIENE. By Major R. J. BLACKHAM. 187 pages; cloth; price $1.25 net. William Wood & Company, Publishers, New York.

THE CLINICAL PATHOLOGY OF SYPHILIS AND PARASYPHILIS. By HUGH WANSEY BAYLY, M.A., M.R.C.S., L.R.C.P. 191 pages; illustrated; cloth; price $2.25 net. William Wood & Company, Publishers, New York.

PHYSICAL DIAGNOSIS. By RICHARD C. CABOT, M.D. Fifth Edition. 510 pages; illustrated with five plates and 268 figures in the text; cloth; price $3.00 net. William Wood & Company, Publishers, New York.

THE TREATMENT OF INFANTILE PARALYSIS. By OSKAR VULPIUS M.D. 318 pages; illustrated; cloth; price $4.00 net. William Wood & Company, Publishers, New York.

LEHRBUCH UND ATLAS DER KONSERVIERENDEN ZAHNHEILKUNDE. By Dr. GUSTAV PREISWERK. 404 pages; illustrated; cloth; price 14 M. J. F. Lehmann, Publisher, Munchen.

Miscellany.

Alcoholism in the Eighteenth Century.—Charles Mercier presents the following interesting description of the convivial customs of former days: "In the latter part of the eighteenth century, people sat down to dinner at 4 or 5 o'clock in the afternoon. Dinner was a stately and solemn ceremony, as needs must be when host and hostess carved for their guests, and were allowed after each course a quarter of an hour's law, to eat their own when the others had finished. After two or three hours, the cloth was removed, and the decanters went round in coasters on the polished mahogany. After a decent interval, the stories began to broaden, and the ladies retired, while the gentlemen settled down to the business of the evening. From that time until midnight, drinking went on; not rapid or furious drinking, but slow and steady absorption, as the decanters went round. From time to time the process was accelerated by the host calling upon one of his guests for a toast, or a sentiment, and then all were obliged to fill and empty their glasses. Nowadays, no one notices whether a health is actually drunk or not, but in those days the rule against heel-taps was rigorously enforced, and he who left any remainder in his glass was held to be wanting in respect and loyalty to the toast, and might very well have to answer for his negligence next morning in a duel. The fashion of the toast is still with us, but in a mitigated and attenuated form. We do not now toast the reigning beauty, and the rule against heel-taps is no longer enforced; and we are spared altogether the horrors of the sentiment. We are not now called upon after dinner to drink to 'the reflection of the moon on the calm bosom of the lake,' or to 'the man who would place king and country before life and wealth.' We should as soon think of toasting the man who broke the bank at Monte Carlo.

"In the days I speak of, our forefathers did not dine by the light of the electric filament, or of incandescent mantles, for in the reign of George III. these conveniences had not yet been invented. They dined by candle light, and from time to time the servants came in to snuff the candles, and took the opportunity to loosen the cravats of those guests who had subsided under the table. At length the orgies came to an end, and the half-drunken servants staggered in to carry their wholly drunken masters to bed.

"In those days, the doctor was often half seas over when he attended his drunken patient; the parson was often drunk in the pulpit; judge, counsel, and attorneys pursued their avocations in court in a prevailing atmosphere of hot coppers. The Prime Minister went drunk to the House of Commons, where he was attacked by the leader of the Opposition, also drunk, while order was kept by a Speaker who was half seas over. There was no excise on spirits, and the coarser kinds of distilled liquors were ridiculously cheap. As you passed along the bye streets of London, and perhaps of other great cities, you might read the legend hung out over the drink cellars, 'Here you may get drunk for a penny: dead drunk and clean straw for twopence.'"—*The Lancet*, November 30, 1912.

Woman's Place in Medicine.—H. Drinkwater takes exception to the statement frequently made that women have not contributed very materially to the advancement of practical medicine, for there are at least two therapeutic measures for which they can claim credit. Madame Mouffer possessed a secret nostrum for the treatment of *Tenia solium*, and in 1775 Louis XVI. purchased it from her for 18,000 francs. It proved to be the rhizome of male fern. This was its introduction into France. It fell into disuse until again recommended by C. Peschiers in a work published in 1826. The discovery of radium was due chiefly to Madame Curie. Though it cannot be claimed for women that up to the present they have contributed largely to the theoretical or practical side of medicine, surgery, or gynecology, there is one closely related subject in which they have certainly taken the initiative and leading part, and which they have brought to a high state of perfection as a science and an art—namely, nursing. Women were closely identified with the early history of obstetrics. One thing which helped to place the greater part of the practice of midwifery in the hands of women—in England as well as on the Continent—was the fact that most of the physicians and many of the leading surgeons were members of the priesthood; and we read that Guy of Chauliac thought it did not become a priest to have anything to do with obstetrics or gynecology. What the future will bring no one can tell. At present, medical women occupy so many posts as lecturers, hospital physicians, surgeons, and accouchenses, medical officers of health, school medical officers, besides those in general practice—their number is so rapidly increasing, and their work is done in such a satisfactory manner—that the chief difference between medical men and medical women will be a numerical one if the latter will give their attention to original research and pursue it with the same enthusiasm that they manifest in other departments.—*Liverpool Medico-Chirurgical Journal*, January, 1912.

Diagnostic Cloaks for Carelessness.—H. Macnaughton Jones once pointed out that the words, "neurosis," "neurasthenia," and "hysteria" are given as convenient excuses when patience and trouble are alike demanded in a reasonable search after the true cause of a woman's complaint. There are no more dangerous terms in the gynecological vocabulary than these. They are apt to lead the young and unwary practitioner into a diagnostic cul-de-sac, missing, in his stumble therein, the track to some serious pathological condition.—*Clinical Journal.*

The Present Discontent.—No one has explained the cause of the discontent and the unsatisfactory position of the doctor more happily than Bacon, whose summary of the position will bear quotation:—"Almost all other arts and sciences are judged by their power and operation and not by their successe and worke. . . . Therefore, it often falls out that the imposter bears away the prize, virtue the censure. Nay, the weaknesse and credulity of men is such, as they often preferre a montebank, or witch, before a learn'd physitian. . . . And what I pray yee followes? Even this, that physitians say to themselves, as Salomon expresseth it upon a higher occasion, *If it befalls to me as it befalls to the foole, why should I labor to be more wise?* Therefore, I cannot much blame physitians, if they use commonly to intend some other art which they fancy more than their own profession; for you shall have of them, poets, antiquaries, politicians, critics, divines, and in these arts better seen than in their own profession."—*The Universal Medical Record*, November, 1912.
